## Introduction

Each year, an estimated 300,000 infants are born with either of the two most common hemoglobinopathies: sickle hemoglobinopathies or thalassemia.<sup>1</sup> Sickle cell disease (SCD) makes up 85% of these infants, and thalassemias the remaining 15%.<sup>1,2</sup> These inherited diseases are the most prevalent monogenetic disorders worldwide. It is increasingly apparent that SCD and thalassemia have become a major health challenge in emerging countries as more infants with hemoglobinopathies survive beyond infancy and into adulthood. Sickle hemoglobin (HbS) is a structural variant causing severe disease in the homozygous state and when in combination with other hemoglobin variants. The  $\alpha$ - and  $\beta$ -thalassemias are genetically diverse with more than 200 mutations accounting for decreased production of  $\alpha$ - or  $\beta$ -globin chains, respectively, in those affected. The thalassemia phenotype varies from mild to severe states of anemia. Either chronic or episodic red blood cell (RBC) transfusions are indicated for both hemoglobinopathies. In SCD, transfusions prevent and/or treat complications and ameliorate anemia by decreasing HbS concentration. In the thalassemias, transfusion prevents the anemia associated with decreased or absent hemoglobin production.

The prevalence of significant hemoglobin traits (HbS, HbC, HbE, HbD, etc., and  $\beta$ -thalassemia and  $\alpha^0$ -thalassemia) varies from about 1% in all of Europe to as high as 18% in all of Africa; the prevalence in the American population is 3%. The presence of disease is 10.8/1000 in Africans, 0.6/1000 in Americans, and 0.2/1000 in all of Europe. Half of the people in the world with SCD live in three countries: Nigeria, Democratic Republic of Congo, and India. In West Africa, about 1000 infants a day are born with SCD.<sup>2</sup>

In the world's population, 1.5% are  $\beta$ -thalassemia mutation carriers.<sup>3</sup> Hemoglobin E-beta<sup>0</sup> thalassemia (Hb E/ $\beta^0$ -thalassemia) is the genotype responsible for approximately one-half of all severe  $\beta$ -thalassemia worldwide.<sup>4</sup> The distributions of the phenotype and genotype of North American thalassemia patients today—as well as their transfusion management—are dramatically different from those in the past decades. The majority of patients, previously of Mediterranean descent, are now largely of Asian, Indian, and Middle Eastern origin.<sup>3</sup> In Thailand, almost 4000 affected children are born annually, with estimates of about 55,000 living patients

with transfusion-dependent thalassemia.<sup>5</sup> In southern China, the gene frequencies for  $\beta$ -thalassemia and for HbE are over 4%, resulting in thousands of annual births of  $\beta$ -thalassemia major and hemoglobin Hb E/ $\beta^0$ -thalassemia.<sup>6</sup>

In addition to the hemoglobinopathies, other hereditary hemolytic anemias resulting from erythrocyte membrane abnormalities (e.g., hereditary spherocytosis, elliptocytosis, pyropoikilocytosis, stomatocytosis, and ovalocytosis) or enzyme defects (i.e., glucose-6-phosphate dehydrogenase [G6PD] deficiency, and pyruvate kinase deficiency) contribute to global hematological disease burden. However, the need for transfusions, and especially chronic transfusion therapy, is often less frequent in these disorders due to the decreased prevalence of phenotypes associated with severe hemolytic anemia.

## Malaria, hematologic diseases, and blood groups

Malaria is a devastating parasitic disease in humans in which the clinically symptomatic stage involves sequential rounds of parasite invasion, multiplication, maturation within RBCs, and erythrocyte rupture upon release. Malaria infection results in particularly high mortality rates among children and pregnant women, and has been the largest cause of childhood mortality globally for much of the last 5000 years.<sup>7</sup> Due to the high infection and mortality rates, malaria is an extremely strong force for natural selection. It is estimated that there are 228 million cases of malaria worldwide, with over 90% of cases in Africa, followed by 5% in Southeast Asia, and 2% in the Eastern Mediterranean region. Although global mortality rates have improved over the last two decades, the World Health Organization still records over 400,000 malaria deaths per year worldwide, with 90% of deaths occurring in sub-Saharan Africa.<sup>8</sup> Numerous polymorphisms resulting in changes to the red cell membrane, blood group antigens, and hemoglobin have evolved and have been selected for in regions where malaria is most predominant because of survival advantages in individuals with these variants.<sup>9</sup> Subsequently, due to past and ongoing global migration, many of these polymorphisms including those that result in SCD, thalassemia, congenital red cell disorders, and

expression of certain blood group antigens can now be found in high prevalence in areas that are free of malaria. As such, an understanding of malaria and the mutations it has caused lays a foundation for understanding SCD, thalassemia, various other congenital red cell disorders, as well as transfusion therapy.

Currently, there are five species of malaria parasites infecting humans: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and most recently *Plasmodium knowlesi*. *P. falciparum* causes the largest disease burden, followed by *P. vivax*. *P. falciparum* predominates in sub-Saharan Africa, New Guinea, and Hispaniola (Haiti and the Dominican Republic), and is responsible for two-thirds of cases on the Indian subcontinent, eastern Asia, and Oceania.<sup>10</sup> *P. vivax* is much more common in the Americas and the western Pacific, although a significant number also occurs in Africa and South America.<sup>11</sup> *P. falciparum* accounts for the vast majority of severe disease and deaths.<sup>12</sup> Because of this fact, the selective pressure for evolutionary adaptations in the human population is most obvious with *P. falciparum* infection.<sup>12,13</sup>

The association between hematological disease and malaria was first noted in the 1940s in the Mediterranean by Haldane and in Africa by Beet.<sup>14,15</sup> Since then, it has been established that malaria parasites have exerted selective pressure on several genes. This evolutionary process has produced alleles that confer resistance to infection, but unfortunately concomitantly produce novel diseases due to altered forms of hemoglobin ( $\alpha$ - and  $\beta$ -thalassemia, hemoglobin S, and hemoglobin C), RBC enzymes (glucose-6-phosphate dehydrogenase deficiency), and RBC membrane proteins (Southeast Asian Ovalocytosis). Malarial resistance has also selected for a series of benign blood group antigen polymorphisms within the Duffy, Gerbich, MNS, Knops, ABO, and Lewis blood groups.<sup>7</sup>

## Structural hemoglobin mutations

### Hemoglobin S

Hemoglobin S ( $\beta$  Glu6Val, GAG>GTG) in the heterozygous form is a benign carrier condition, usually with none of the symptoms of SCD. Sickle cell trait (HbAS) is extremely common in much of sub-Saharan Africa where malaria is endemic. Hemoglobin S has become the dominant mutation due to superior protection against *P. falciparum* in the heterozygote. Sickle cell trait (HbAS) is the strongest protection against infection, demonstrating 90% efficacy in preventing severe and/or complicated malaria (cerebral malaria and severe anemia) in multiple studies.<sup>7,13,16</sup> In addition, a birth cohort study of 1022 Kenyan children demonstrated that HbAS confers 60% protection against mortality in children between ages 2 and 16 months when compared with HbAA, whereas HbSS showed no survival advantage.<sup>17</sup>

Most of the research on protective mechanisms against severe malaria has been carried out in areas where *P. falciparum* is prevalent. Although not entirely understood, there are several proposed mechanisms of HbAS protection against *P. falciparum*:

- **Increased sickling of infected erythrocytes:** Increased sickling of infected HbAS erythrocytes leads to increased RBC clearance within the spleen, promoting removal of infected cells from the circulation.<sup>18,19</sup>
- **Impaired intraerythrocyte parasite growth:** HbAS red cells infected with *P. falciparum* show increased polymerization of hemoglobin and have an intracellular environment that decreases parasite growth due to the enhanced polymerization as well as high levels of potassium and osmotic loss of water.<sup>20-22</sup> Additionally, dysregulated microRNA composition has been

shown to contribute to resistance against *P. falciparum*. Two microRNAs (miR-451 and let-7i) are highly enriched in HbAS and HbSS erythrocytes, which upon translocating into the parasite result in translational inhibition.<sup>21</sup>

- **Impaired intraerythrocyte actin cytoskeleton network:** It has been shown that HbS and HbC alter actin polymerization and disrupt the intracellular trafficking system required to direct parasite proteins to the surface of infected erythrocytes. This impairment results in less Pf-EMP-1 (*P. falciparum* erythrocyte membrane protein-1) on the red cell plasma membrane,<sup>23</sup> which in turn reduces cytoadherence of parasitized RBCs to the vascular endothelium as well as binding of parasitized RBCs to uninfected RBCs to form rosettes.<sup>24-26</sup>
- **Enhanced acquired immune response to malaria:** Immune-mediated protective mechanisms have also been associated with HbAS (as well as thalassemia and G6PD deficiency). Enhanced phagocytosis by monocytes of ring-parasitized erythrocytes from sickle trait (and  $\beta$ -thalassemia trait) individuals has been demonstrated in vitro, possibly due to increased production of reactive oxygen species intrinsic to these variant RBCs.<sup>7,27</sup> Others have shown increased lymphoproliferative responses to malaria antigens in children with HbAS compared to HbAA.<sup>28</sup>

Although these effects lead to plausible explanations for protection from severe malaria in HbAS individuals, it remains unclear which mechanisms are significant in vivo. Many of these protective mechanisms against severe malaria have also been observed in other hemoglobinopathies, RBC enzymopathies, and RBC membrane disorders.

### Hemoglobin C

Hemoglobin C (HbC) results from a mutation where lysine is substituted for glutamate in the sixth position of the  $\beta$ -globin chain. The variant HbC is less soluble than HbA, forming hexagonal crystals (in contrast to the long polymers seen in SCD), and induces red cell dehydration.<sup>29</sup> Individuals with hemoglobin C trait (HbAC) are phenotypically normal and do not show any symptoms, while persons with hemoglobin C disease (HbCC) may have a mild degree of hemolysis with splenomegaly and mild to moderate anemia. Whereas individuals with HbCC do not experience sickling events, individuals coinherit HbC and HbS (HbSC) may have serious sickle-related consequences. Hemoglobin C occurs almost exclusively in West Africa, having a frequency of 50% in the Ivory Coast. Unlike HbS, where there is a disadvantage for the homozygote, there appears to be no selective disadvantage in individuals with HbCC with respect to malaria.

HbC is not as effective in the prevention of severe malaria as HbS, which may explain why it is not more prevalent in sub-Saharan Africa. For example, HbC does not appear to protect against uncomplicated malaria, although it has been shown to safeguard against the more severe forms of the disease. One case-control study performed in Burkina Faso involving 4348 subjects demonstrated a reduction of 29% in risk of clinical malaria in individuals with HbAC and 93% in those with HbCC.<sup>30</sup> These findings were corroborated by a case-control study of 2397 children in Ghana, where a 47% reduction in risk of severe malaria was observed for children with HbAC compared to a 90% risk reduction in children with HbAS. The sample size was unfortunately insufficient for a meaningful statistical analysis of HbCC and HbSC.<sup>31</sup> The presence of HbC in the erythrocyte also appears to alter the red cell membrane as well as hinder the development of *P. falciparum* within the cell.<sup>32</sup> Similarly to HbS, protection from severe malaria conferred by HbC is largely due to

changes in the plasma membrane expression of PfEMP1 in HbCC and HbAC erythrocytes. This reduction in erythrocyte surface PfEMP1 leads to decreased cytoadherence, impaired rosetting, and possibly an increase in acquired immunity against *P. falciparum* variant surface antigens on the membrane of infected erythrocytes.<sup>33</sup> However, the enhanced immune response theory has been questioned in a report demonstrating no increase in antibody response to a diverse array of *P. falciparum* antigens in children with HbAS and HbAC infected with malaria.<sup>34</sup>

## Thalassemia

Thalassemia refers to a group of hereditary hemolytic diseases characterized by reduced or absent production of one of the globin chains which disrupts the balance between the alpha and beta or gamma globin chains. The two most common forms, alpha thalassemia and beta thalassemia, have also been associated with malarial resistance.

### Alpha thalassemia

Alpha thalassemia is the most common single-gene disease in the world and results from impaired or absent production of alpha globin chains. This results in fewer normal tetrameric hemoglobin molecules due to a relative excess of gamma globin chains in the fetus and newborn, and beta globin chains in children and adults.

Alpha thalassemia has been found to be protective against severe malaria in multiple case-control studies in Africa<sup>35–38</sup> and the southwest Pacific.<sup>39</sup> This protective effect is stronger in homozygous α<sup>+</sup>-thalassemia (α-/α-) compared to heterozygous α<sup>+</sup>-thalassemia (α-/αα).<sup>38,39</sup> An interesting phenomenon of negative epistasis has been observed where the antimalarial protective effects seen with sickle cell trait and alpha thalassemia individually are lost when α-thalassemia and sickle cell anemia are coinherited.<sup>35</sup> Although the mechanism is unclear, this phenomenon is likely the reason why the incidence of homozygous α<sup>+</sup>-thalassemia is significantly higher in parts of India and Asia (up to 80%) compared to sub-Saharan Africa (≤50%) where the beta<sup>s</sup> globin allele is more prevalent despite endemic severe malaria.<sup>35</sup> It may also explain why the beta<sup>s</sup> globin allele is infrequent in the Mediterranean where thalassemia is common.<sup>40</sup>

Proposed mechanisms for the protective effects of thalassemia include the inhibition of *P. falciparum* growth within infected red cells particularly in individuals missing three α-chain genes (i.e., HbH);<sup>41,42</sup> increased phagocytosis in *P. falciparum* infected α-thalassemia RBCs;<sup>43</sup> reduced surface expression of Pf-EMP1 resulting in less microvascular endothelial cell adherence and impaired rosetting;<sup>44</sup> and reduced α-thalassemia erythrocyte expression of complement receptor 1 (CR1), which is responsible for RBC rosetting and *P. vivax* invasion.<sup>45</sup> Additionally, thalassemic erythrocytes may demonstrate increased susceptibility to non-lethal *P. vivax* infection, particularly in young children with α-thalassemia, resulting in limited cross-species protection against severe *P. falciparum* infection.<sup>46,47</sup> Lastly, it has been postulated that increased erythrocyte count and microcytosis in children with homozygous α<sup>+</sup>-thalassemia may contribute to their resistance to severe malarial anemia.<sup>48</sup> (See further discussion on α-thalassemia in the “Thalassemia” section.)

### Beta thalassemia

β-Thalassemia results from mutations in the beta globin locus which lead to absent (β<sup>0</sup>) or decreased (β<sup>+</sup>) production of beta globin chains, and an excess of alpha globin chains. Although β-thalassemia is prevalent in malarial areas, the evidence

for β-thalassemia’s protective effect against malaria is less convincing than for other hemoglobin mutations, primarily due to the fact that the areas around the Mediterranean where β-thalassemia has been prevalent are now free of the malaria parasite. In Africa there are only a few studies investigating β-thalassemia protective effects against malaria, none of which are case-control studies on the scale of those completed in HbAS or α-thalassemia.<sup>49</sup> In a population survey in northern Liberia conducted in 1983, prevalence rates of *P. falciparum* were similar in normal children and those with β-thalassemia trait; however, the β-thalassemia trait group had lower parasite densities.<sup>50</sup> Consistent with reduced malaria burden, in vitro studies have shown protective effects. Coculture experiments have demonstrated impairment of *P. falciparum* growth in β-thalassemic erythrocytes; however, impairment was less prominent in β-thalassemia than in α-thalassemia RBC populations.<sup>42,51</sup> Further studies have shown that *P. falciparum*-infected β-thalassemic erythrocytes have marked reductions in the cytoadherence and rosette formation in the trophozoite/schizont (but not young ring) stage;<sup>52</sup> and ring-parasitized β-thalassemia trait erythrocytes undergo increased phagocytosis by human monocytes (likely due to increased membrane-bound hemichromes, IgG and C3c fragments, and aggregated band 3).<sup>27</sup> Transgenic β-thalassemic mice models have demonstrated lower and delayed peak parasitemia after infection with *P. chabaudi adami* (which causes a non-lethal infection mainly in mature red cells).<sup>53</sup> (See further discussion on β-thalassemia in the “Thalassemia” section.)

## Hemoglobin E

Hemoglobin E (HbE) is the most common hemoglobin structural mutation in Southeast Asia. HbE results from a point mutation at codon 26 of the β-globin gene (Glu>Lys). This mutation results in marginally reduced expression of β-globin chains and a mild β-thalassemia phenotype.<sup>54</sup> Although this thalassemia is common in malarial areas, there has not been direct evidence for a protective effect in large case-control population studies in Southeast Asia. The only epidemiological data come from an analysis showing higher prevalence of antimalarial titers (indicative of previous malarial exposure) in Southeast Asian refugees with HbAE or HbEE compared to refugees with HbAA.<sup>55</sup> In vitro studies have demonstrated decreased growth of *P. falciparum* in HbE-containing erythrocytes with a more pronounced effect as the concentration of HbE increases within the RBCs.<sup>55</sup>

## RBC enzymopathies

### Glucose-6-phosphate dehydrogenase (G6PD) deficiency

The gene for glucose-6-phosphate dehydrogenase (G6PD) is located on the X chromosome (band X q28). G6PD is expressed in all cells but is particularly important in erythrocytes because it is the sole source of NADPH which is necessary for the regeneration of reduced glutathione, a key metabolite in the control of oxidative damage. The global prevalence of G6PD deficiency has been estimated at 4.9% (both males and females included) with prevalence reaching 20% in some regions in Africa and Asia.<sup>56,57</sup> The mutant allele (A-), encoding 10–50% of normal G6PD enzyme activity, is the most frequent variant in western and central Africa.<sup>58</sup> The Mediterranean variant is found in the Mediterranean, India, and Indonesia, and results in only approximately 3% G6PD activity; hemolysis in people with this variant can be severe. Haplotype

analysis of both the A– and Mediterranean variants indicates increased frequency in areas where malaria is prevalent.<sup>58</sup> Case-control studies in Kenyan and Gambian children have demonstrated that G6PD deficiency (G6PD A–) is associated with a significant reduction in risk of severe malaria in male hemizygotes and conflicting evidence of risk reduction in heterozygous females.<sup>59,60</sup> These results have been questioned because of the finding that the DNA methodology used for G6PD typing likely misclassified a large proportion of the samples from the Gambia cohort.<sup>61</sup> The processes responsible for resistance remain unresolved; however, proposed mechanisms include inhibition of parasite growth<sup>62</sup> and increased phagocytosis of infected G6PD-deficient red cells due to parasite-induced oxidative modifications to RBC membranes.<sup>63</sup> (See further discussion on G6PD deficiency in the “Red cell enzymopathies” section.)

### RBC membrane mutations

The most common erythrocyte membrane disorders include hereditary spherocytosis (HS), hereditary elliptocytosis (HE), and hereditary pyropoikilocytosis (HPP), which result from mutations leading to abnormal expression of alpha spectrin, beta spectrin, ankyrin, protein 4.1, band 3, or glycophorin C. Southeast Asian ovalocytosis, dehydrated hereditary stomatocytosis (also referred to as hereditary xerocytosis), and overhydrated hereditary stomatocytosis are less common RBC membrane disorders, and result from mutations leading to abnormal expression of band 3, PIEZO1 (mechanosensitive cation channel), and Rhesus-associated glycoprotein (RhAG), respectively.<sup>64</sup> Southeast Asian ovalocytosis (SAO), hereditary elliptocytosis, and possibly hereditary spherocytosis and hereditary xerocytosis may confer protection against malaria. SAO may confer protection against cerebral malaria in patients infected with *P. falciparum*,<sup>65</sup> and may also provide resistance to high levels of parasitemia with *P. falciparum*, *P. vivax*, and *P. malariae*.<sup>66,67</sup> Evidence for protection against malaria by HE largely comes from epidemiological data that HE is found in high prevalence in regions of Africa where malaria is endemic.<sup>68</sup> In vitro data have demonstrated diminished invasion and impaired parasite growth of infected HE erythrocytes possibly due to abnormal protein 4.1/glycophorin C/p55 complexes in HE.<sup>69,70</sup> There is no published epidemiological evidence for a protective role against malaria conferred by HS. In vitro data and ankyrin/spectrin deficient mouse model experiments have demonstrated impaired parasite invasion and/or growth in HS erythrocytes largely attributed to α-spectrin deficiency.<sup>71,72</sup> It has recently been demonstrated that a novel gain-of-function PIEZO1 polymorphism (E756del) with an allele frequency of 18% in the African population is associated with xerocytosis-like RBC dehydration and protection from *P. falciparum* in vitro.<sup>73</sup>

### Blood groups

Some human blood group antigens serve as either receptors for the malaria parasite or are involved in the rosetting of infected erythrocytes, which is responsible for red cell sequestration in the microvasculature and severe malaria. The antigens which have been shown to have an effect on malaria infection include the Duffy blood group as well as those on glycophorins (i.e., MNS, Gerbich), the Knops blood group, and the ABO blood group system.

### Duffy blood group

The Duffy glycoprotein, also known as the Duffy antigen receptor for chemokines (DARC), is a receptor that binds C-X-C and C-C class chemokines as well as expresses six separate blood group antigens on the RBC surface. The Fy<sup>a</sup> and Fy<sup>b</sup> antigens are encoded by codominant *FY\*A* (*FY\*01*) and *FY\*B* (*FY\*02*) alleles. Fy<sup>a</sup> and Fy<sup>b</sup> differ by one amino acid at position 42 (Fy<sup>a</sup>: glycine; Fy<sup>b</sup>: aspartic acid), which defines the three predominant phenotypes: Fy(a+b–), Fy(a–b+), and Fy(a+b+).<sup>74</sup> A fourth common Duffy phenotype, Fy(a–b–), is the result of a mutation (–67T>C) in the erythroid-specific promoter of the GATA-1 transcription factor region; this mutation blocks the expression of the Duffy antigen specifically on red cells. The mutation is in the *FYB* allele, designated erythroid silent: *FYB<sup>ES</sup>* (ISBT allele: *FY\*02N.01*). The erythroid silent mutations does not affect Duffy antigen expression on other somatic cells. As a result, patients carrying *FYB<sup>ES</sup>* are not at risk for anti-Fy<sup>b</sup> and do not require Fy<sup>b</sup> negative RBCs for transfusion. The Fy(a–b–) phenotype is rare in Caucasians but has a prevalence of 67% in African Americans and reaches 100% in much of sub-Saharan Africa<sup>75</sup> (see Table 30.1). The Duffy antigen is the receptor for *P. vivax* (also known as the *P. vivax* Duffy binding protein [PvDBP]) and *P. knowlesi* allowing entry of the parasite into the red blood cells. As such, Fy(a–b–) individuals have been shown to be resistant to infection.<sup>76–78</sup> Recently, it has been appreciated that *P. vivax* is able to induce clinical malaria in Duffy-negative people, although the underlying mechanisms are still not understood.<sup>79</sup>

### Glycophorin C and D (Gerbich blood group)

The Gerbich (Ge) blood group includes 11 antigens and is expressed on glycophorin C and glycophorin D. Both glycophorins are encoded by the *GYPC* gene that is located on chromosome 2, 2q14>2q21. There is no homology with the glycophorins of the MNS system. There are two initiation codons: initiation at the first codon results in glycophorin C, while initiation at the second codon results in glycophorin D. Deletion of exon 3 in the *GYPC* gene results in Ge negativity. This phenotype has reached almost 50% prevalence in coastal areas of Papua New Guinea where malaria is endemic, likely due to the fact that glycophorin C is one of the receptors of *P. falciparum* (EBA-140).<sup>80</sup> Glycophorin C also interacts with the 4.1R protein, stabilizing the red cell membrane. A reduction of these antigens leads to hereditary elliptocytosis, which has also been associated with protection against malaria (see above). Furthermore, decreased intraerythrocyte parasite growth and adhesion of malaria-infected red cells to the vascular endothelium may be compromised in Ge negative individuals due to destabilization of the protein 4.1/glycophorin C/p55 complex.<sup>69,70</sup>

**Table 30.1** Prevalence of Duffy Antigens

Red Cell Phenotype	Prevalence %		
	Caucasians	African Americans	Allele
Fy (a+b–)	20**	10**	<i>FY*A/FY*A</i> (or <i>FY*01/FY*01</i> )
Fy (a–b+)	32	20	<i>FY*B/FY*B</i> (or <i>FY*02/FY*02</i> )
Fy (a+b+)	48	3	<i>FY*A/FY*B</i> (or <i>FY*01/FY*02</i> )
Fy (a–b–)	Rare	67%	<i>FY*02N.01/FY*02N.01</i>

\*\* 70–90% of Asians have this phenotype; *FY\*02N.01* is the notation for the erythroid silent GATA mutation *FYB<sup>ES</sup>* primarily seen in individuals of African descent.

## Glycophorin A and B (MNS blood group system)

The MNS blood group system includes three red cell antigens on two glycophorins. M and N antigens are found on glycophorin A, and S/s and U antigens are on glycophorin B. These two glycophorins carry two receptors for *P. falciparum*: EBA-175 on glycophorin A and EBA-1 on glycophorin B (see Table 30.2). The MNS system is second in complexity only to the Rh system, with unequal crossovers, deletions, gene conversions, and point mutations leading to 46 different antigens. The S-s-U-phenotype is found in up to 5% of Africans. Glycophorin B-deficient S-s-U- erythrocytes have been shown to be relatively resistant to *P. falciparum* invasion,<sup>81</sup> strongly suggesting malaria may have provided a selective force driving the expansion of this polymorphism. A novel malaria resistance gene in the glycophorin gene cluster has been described, which results in the loss of GYPB and gain of two GYPB-A hybrid genes encoding the Dantu blood group antigen. This antigen results from a glycophorin protein that contains the extracellular domain of glycophorin B and the transmembrane and intracellular domains of glycophorin A.<sup>82</sup> Dantu antigen homozygosity confers a strongly protective effect against severe malaria from *P. falciparum* due to inhibition of parasite invasion mediated by increased red cell membrane tension rather than receptor-ligand interactions.<sup>7</sup> Interestingly, the Dantu polymorphism is found at highest frequencies in East Africa, but is rare or absent in other malaria endemic regions within Africa, suggesting that the glycophorin gene may be subject to a number of opposing evolutionary driving forces.<sup>7,16</sup>

## Knops blood group

The Knops blood group is found on the complement receptor 1 (CR1), a glycoprotein present on the erythrocyte as well as other circulating blood cells. CR1 is one of a group of membrane proteins termed the *regulators of complement activation*. Other members of this group include decay accelerating factor (DAF/CD55), membrane cofactor protein (CD46), and membrane inhibitor of reactive lysis (MIRL/CD59). CR1 also binds C4b/C3b immune complexes for transfer to the liver or spleen where the immune complexes are ingested by macrophages, returning the red cells to the circulation. CR1 has a binding site for *P. falciparum* (through the PfRh4 parasite protein), allowing malaria entry into the host cell through a glycophorin-independent pathway.<sup>83</sup> CR1 is also involved in red cell rosetting of uninfected red cells to *P. falciparum*-infected cells via interactions with PfEMP1.<sup>84</sup> McCoy (McC) and Swain-Langley (SL) are two antigens within the Knops system which have been associated with mutations of CR1 and show marked frequency differences between Caucasians and Africans.<sup>85</sup> The McCb and the SL2 antigens are present almost exclusively in individuals of African ethnicity and may provide protection from *P. falciparum*.<sup>86,87</sup>

## ABO, Lewis blood groups

There is strong evidence that *P. falciparum* has influenced the distribution of the ABO blood groups to favor group O in regions where malaria is endemic. Blood group O is more common in equatorial

endemic malarial regions, whereas group A is more common in northern, nonendemic latitudes.<sup>88</sup> Multiple case-control studies in Africa<sup>16,89-93</sup> and a recent meta-analysis<sup>94</sup> have conclusively shown that blood group O confers protection from severe malaria from *P. falciparum*; in contrast, group A has been associated with the highest risk for severe disease.<sup>95</sup> This effect is due to the fact that A and B blood group antigens serve as coreceptors for PfEMP-1 on infected erythrocytes. PfEMP-1 binding to group A (or to a lesser extent, group B) contributes to rosetting of parasitized and uninfected red cells, and vascular cytoadherence. In vitro data have demonstrated higher *P. falciparum*-induced rosette number, size, and stability in blood groups A, B, and AB compared to blood group O red cells.<sup>96,97</sup> Inhibition of this effect can be demonstrated in vitro using soluble A and B antigen, blocking the PfEMP-1 receptor.<sup>96</sup> Inhibition may also occur in vivo due to the effect of the Lewis and Secretor gene transferase phenotype in non-O blood type individuals.<sup>88</sup> These transferases directly influence the quantity of soluble A and B antigens found in the plasma of group A and B individuals. The highest levels of soluble A and B antigens, a phenotype that may confer protection from *P. falciparum*, are seen among those expressing the combination of Le(a-b-) and Secretor-positive (Se) genes. This may account for the threefold higher prevalence of Le (a-b-) phenotype observed in individuals with African ancestry.<sup>88,98</sup>

## Sickle cell disease

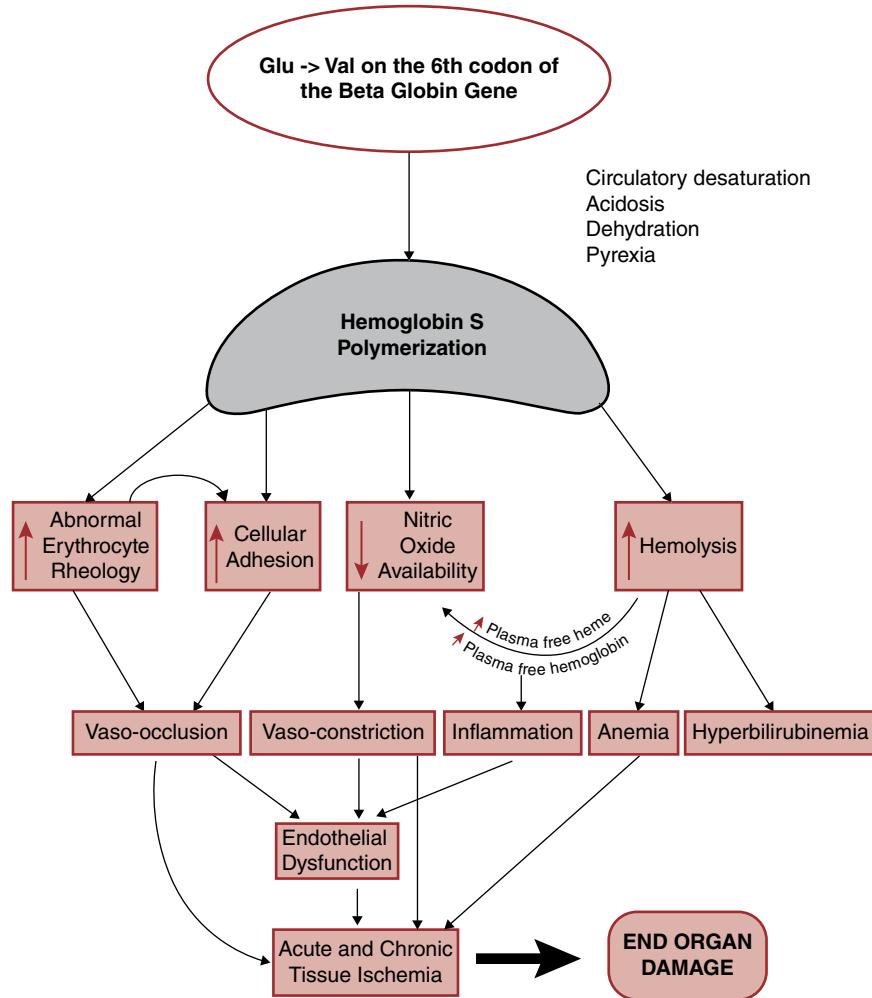

### Pathophysiology

Homozygous HbS results in hemoglobin polymerization at low oxygen tension, low pH, and with temperature elevation. HbS polymerization disrupts normal red cell membrane structure, leaving phosphatidylserine exposed on the surface of the red cell which promotes erythrocyte adherence to the vascular endothelium.<sup>99,100</sup> The distorted red cell is also rigid, predisposing to hemolysis. When sickle erythrocytes lyse, they release arginase, free hemoglobin, and heme (hemin) into the plasma, depleting nitric oxide.<sup>101</sup> As endogenous nitric oxide plays an important role in maintaining vessel wall patency, and nitric oxide depletion leads to vascular dysfunction in people with SCD.<sup>102</sup> The hemin released during hemolysis also activates toll like receptor 4 (TLR-4) and other signaling molecules, leading to proinflammatory responses.<sup>103</sup> Altered interactions between the vascular endothelium, neutrophils, platelets, and sickled erythrocytes have been identified as direct promoters of sickle-related vaso-occlusions and inducers of a chronic inflammatory state in people with SCD.<sup>104</sup> These changes in the red cell membrane, the activation of cellular elements, and changes in the vascular endothelium account for many of the clinical findings in SCD (see Figure 30.1).

HbS can also polymerize in the presence of other hemoglobin variants. These combinations are collectively referred to as SCD if they cause or have the potential to cause clinical symptoms. The most common forms of SCD are HbSS, HbSC, HbS $\beta^0$ -thalassemia, and HbS $\beta^+$ -thalassemia. SCD severity varies among these genotypes, with HbSS and HbS $\beta^0$ -thalassemia (sickle cell anemia [SCA]) classically having more serious complications compared to patients with HbSC or HbS $\beta^+$ -thalassemia. There are at least 14  $\beta^+$ -mutations commonly occurring in African Americans, which can produce a wide range of hemoglobin A concentrations in the red cell and influence the clinical disease phenotype.<sup>105</sup>

<i>P. falciparum</i>	PfEMP-1	ABO (A, B, AB)

**Figure 30.1** Pathophysiology of sickle cell disease. The pathophysiology of sickle cell disease is complex and stems from the polymerization of HbS that occurs during periods of hypoxemia, dehydration, acidosis, and pyrexia. Polymers of sickle hemoglobin cause the characteristic shape change of the erythrocyte and lead to hemolysis, abnormal rheology, cellular adhesion, and decreased nitric oxide availability. These changes result in vaso-occlusion, vaso-constriction, anemia, and chronic inflammation that contribute to SCD-associated end organ damage.

Furthermore, clinical complications can vary dramatically even among patients with the same genotype,<sup>106</sup> which has led to a decades-long ongoing search for global SCD severity predictors. Modifiers of SCD include  $\alpha$ -thalassemia, fetal hemoglobin (HbF), nutritional, and environmental factors.<sup>107-109</sup> In a recent systematic review of SCD severity predictors,  $\alpha$ -globin gene number was the most commonly studied severity predictor, followed by HbF and reticulocyte count. Coinheritance of  $\alpha$ -thalassemia trait was protective against overt stroke and abnormal transcranial Doppler (TCD) in all but one study, but not frequency of painful crisis or silent cerebral infarct. Fetal hemoglobin (HbF) is the only hemoglobin that is known to inhibit HbS polymerization, and thus its expression can reduce disease severity.<sup>110</sup> Two-thirds of the HbF studies reported beneficial effects with increasing HbF levels; however, increased HbF levels were not associated with lower hospitalization or stroke rates in other reports. The ability to predict SCA complications was mixed for all variables, except TCD and absolute reticulocyte count,<sup>107</sup> and TCD is the only currently available validated predictor of severe outcomes in SCA.<sup>111</sup> TCD, however, only identifies children with SCA who are at the highest risk of stroke; thus far predic-

tors for recurrent painful episodes or acute chest syndrome are not available. An elevated absolute reticulocyte count (ARC) between two and six months of age was associated with cerebral vasculopathy (including stroke), early hospitalization for VOE, and splenic sequestration.<sup>112-114</sup> Genome-wide association studies have looked for single nucleotide polymorphisms associated with severity, but most of these polymorphisms do not appear clinically relevant.<sup>107</sup>

## **Indications for transfusion**

Red cell transfusion is an effective therapy for SCD, but there is a paucity of randomized clinical trials to guide practice. The transfusion complications outlined later in this chapter highlight the need for evidence based indications for transfusion in SCD. Three sets of guidelines have been released in the past seven years from the National Heart Lung and Blood Institute (NHLBI),<sup>115</sup> the British Committee for Standards in Hematology (BCSH),<sup>116</sup> and the American Society of Hematology (ASH)<sup>117,118</sup> to guide transfusion decisions in individuals with SCD. Table 30.3 provides a summary of these consensus guidelines for acute and chronic transfusions.

**Table 30.3** SCD Transfusion Indications

Indication	Transfusion Method	Guideline
<b>Generally Accepted Indications for Transfusion</b>		
• Acute ischemic stroke	Exchange transfusion	BCSH, ASH <sup>N</sup> , NHLBI
• Primary stroke prevention	Chronic simple or exchange transfusion	NHLBI, ASH <sup>N</sup> , ASH <sup>T</sup> , BCSH
• Secondary stroke prevention	Chronic simple or exchange transfusion	BCSH, ASH <sup>N</sup> , ASH <sup>T</sup> , NHLBI
• Acute chest syndrome (acute)	Simple or exchange transfusion <sup>a</sup>	BCSH, ASH <sup>T</sup> , NHLBI
• Acute splenic sequestration	Simple transfusion	BCSH, NHLBI
• Acute splenic sequestration, recurrence	Chronic simple transfusion, prior to splenectomy <sup>b</sup>	NHLBI
• Preoperative	Simple transfusion	BCSH, ASH <sup>T</sup> , NHLBI
• Transient aplastic crisis	Simple transfusion	BCSH, NHLBI
• Acute multiorgan failure syndrome	Simple or exchange transfusion <sup>a</sup>	BCSH, NHLBI
• Acute hepatic sequestration	Simple transfusion	BCSH, NHLBI
• Acute intrahepatic cholestasis	Simple or exchange transfusion <sup>a</sup>	BCSH, NHLBI
• Acute sickle/obstetrical complications during pregnancy	Simple or exchange transfusion <sup>a</sup>	BCSH, ASH <sup>T</sup>
<b>Possible Indications for Transfusion</b>		
• Recurrent Acute Chest Syndrome	Chronic simple or exchange transfusion <sup>c</sup>	BCSH
• Recurrent painful vaso-occlusive episodes	Chronic simple or exchange transfusion <sup>c</sup>	BCSH
• Pulmonary hypertension	Chronic simple or exchange transfusion <sup>c</sup>	BCSH, ATS
• Uncomplicated pregnancy	Chronic simple or exchange transfusion <sup>c</sup>	BCSH, ASH <sup>T</sup>
• Central retinal artery occlusion	Simple or exchange transfusion for arterial infarct	None <sup>d</sup>
<b>Transfusion Generally Not Indicated</b>		
• Acute, uncomplicated painful vaso-occlusive episode	NA	BCSH, NHLBI
• Priapism	NA	BCSH, NHLBI
• Leg ulcers	NA	None <sup>d</sup>
• Nonsurgical avascular necrosis	NA	None <sup>d</sup>

<sup>a</sup> Exchange transfusion should be performed in rapidly deteriorating patients or when there are concerns for post-transfusion hyperviscosity due to high pretransfusion hemoglobin of  $\geq 9$  g/dL.

<sup>b</sup> Chronic transfusion may be utilized to delay splenectomy in children less than two years of age who are at high risk of invasive pneumococcal disease.

<sup>c</sup> Exchange transfusion preferred in patients with iron overload.

<sup>d</sup> There is insufficient evidence for benefit to make recommendations about using transfusion therapy to manage complication. National Heart, Lung, and Blood (NHLBI);<sup>115</sup> British Committee for Standards in Hematology (BCSH);<sup>116</sup> American Society of Hematology ASH<sup>N</sup><sup>118</sup> and ASH<sup>T</sup><sup>117</sup> American Thoracic Society (ATS);<sup>158</sup> NA: not applicable.

## Cerebrovascular disease

**Acute stroke treatment:** Stroke risk for children with SCA is 200 times that of the general pediatric population (see Table 30.4).<sup>119,120</sup> Prior to annual TCD screening, 10% of children suffered from an overt stroke before the age of 20 years.<sup>121</sup> Stroke risk continues at older ages, with hemorrhagic stroke more common between the ages of 20 and 30 years.<sup>122</sup> It is recommended that children and adults with SCD and an acute ischemic stroke should receive an emergent red cell exchange (RCE), preferably by erythrocytapheresis, with a postexchange target HbS <20%; total Hb should not exceed 11 g/dL to avoid hyperviscosity.<sup>118</sup> A simple transfusion may be considered for immediate treatment if there are delays expected in establishing central venous access, procuring and crossmatching multiple RBC units, and mobilizing the apheresis team for erythrocytapheresis. There is a lack of formal studies to guide management of hemorrhagic strokes in individuals with SCD. However, in most cases, RCE is employed as ancillary treatment to standard therapy for acute intracranial hemorrhage for the general population; in this setting, RCE is guided by similar postexchange targets as described for ischemic strokes.<sup>123</sup>

## Primary stroke prevention

Overt strokes have become less common in children and young adults since the institution of TCD screening. TCD measures the flow velocity through the cerebral arterial circulation. Increased flow velocity in the internal carotid or middle cerebral arteries ( $\geq 200$  cm/second) is strongly associated with increased risk of stroke.<sup>124</sup> In the Stroke Prevention Trial in Sickle Cell Anemia (STOP trial), chronic blood transfusions aimed at maintaining HbS concentration to 30% or less decreased the stroke rate from 10% to less than 1% in children who had two consecutive abnormal

**Table 30.4** Stroke Risk in Children with SCA

Condition	Annual Stroke Risk (%)
Healthy children (without SCA or congenital heart disease) <sup>120</sup>	0.003
Children with SCA (HbSS) <sup>121</sup>	0.5–1
Children with SCA and SCI on MRI <sup>130</sup>	2–3

TCD results.<sup>111</sup> Prior to the publication of the TCD With Transfusions Changing to Hydroxyurea (TWiTCH) study results in 2016, chronic transfusions and chelation therapy were continued indefinitely because the STOP 2 (Optimizing Primary Stroke Prevention in Sickle Cell Anemia) trial demonstrated that discontinuation of chronic transfusions caused reversion to abnormal TCD values and, in some cases, overt stroke.<sup>125</sup> The TWiTCH trial randomized children with abnormal TCDs who had received at least one year of chronic transfusions and who did not have severe cerebral vasculopathy<sup>126</sup> to either continue transfusion therapy and

iron chelation or change to hydroxyurea (HU) and phlebotomy. In the alternate HU + phlebotomy study arm, transfusions were weaned over 4–9 months as HU dose was escalated to maximum tolerated dose (MTD). Phlebotomy commenced once transfusions had stopped, and patients were monitored by TCD every three months to ensure that TCD velocities did not revert to abnormal. The study was terminated by the NHLBI when the first interim analysis showed noninferiority of HU and phlebotomy. This study established HU as an acceptable substitute for primary stroke prevention in children with abnormal TCD without severe vasculopathy after at least one year of chronic transfusion therapy.<sup>127</sup>

Thirty percent of children with SCA will have evidence of silent cerebral infarcts (SCIs; silent strokes) on MRI,<sup>128</sup> with prevalence increasing to as high as 50% in adults.<sup>129</sup> Although individuals with SCIs appear normal on physical examination and by history, they are at increased risk of poor academic achievement, lower IQ, as well as future overt stroke and new SCIs.<sup>130,131</sup> The Silent Cerebral Infarct Multi-Center Clinical Trial (SIT) trial randomized children with SCA who had at least one SCI ( $\geq 3$  mm in two planes on T2-weighted MRI images) to either chronic transfusion therapy or observation (standard of care at the time of the study). Study accrual occurred from 2004 to 2010, when early institution of HU was not the standard of care for children with SCA. The incidence of recurrent cerebral infarcts was reduced in those who received chronic transfusions.<sup>132</sup> However, given a host of factors including a relatively high number needed to treat to prevent recurrent infarcts, the unknown optimum age and frequency for MRI screening, and the widespread prescription of HU in children with SCA with SCI since the initiation of SIT, the role of chronic transfusion therapy for children with SCI remains ill-defined.

### Secondary stroke prevention

In comparison to primary stroke prevention, chronic transfusion therapy is less effective in preventing future strokes and progressive cerebral vasculopathy in patients with a history of overt strokes<sup>133,134</sup> (see Table 30.4). In a retrospective cohort study of 137 children with SCD and history of overt stroke, 22% of patients had a second stroke at a mean follow-up of 10 years.<sup>135</sup> However, this is a significant reduction from a 60% to 90% historical recurrence rate in patients without therapeutic intervention.<sup>136</sup> Although no prospective randomized clinical trial has been completed, a large retrospective observational study demonstrated a significant reduction in the rate of recurrent stroke in patients treated with chronic transfusions to maintain pretransfusion HbS level <30%.<sup>134</sup> As a result, it is recommended that children and adults who have a history of overt stroke should be placed on chronic transfusion therapy.<sup>118,137</sup>

The randomized phase 3 trial, Stroke with Transfusion Changing to Hydroxyurea (SWiTCH), attempted to address whether transition to HU was a safe alternative to chronic transfusions for patients with a history of stroke and iron overload. SWiTCH compared HU + phlebotomy (alternative therapy) to transfusion therapy + chelation (standard therapy) in children with SCD and history of overt stroke. The trial was closed early because of statistical futility on the composite endpoint of iron overload improvement and stroke prevention. At the time of study closure, equivalent liver iron concentrations were seen in both treatment groups, but an increase in recurrent strokes was observed in the HU/phlebotomy arm (7; 10%) compared to the transfusion/chelation arm (0%).<sup>138</sup> Taken together, chronic transfusion with chelation remains the mainstay of secondary stroke prevention in children with SCA.<sup>138</sup> It should be noted that RCE can also eliminate or decrease iron burden in

patients with overt stroke on chronic transfusion<sup>139,140</sup> (see the Erythrocytapheresis section).

When using chronic transfusions for stroke prevention, it is recommended to administer transfusions (simple or exchange) every 3–4 weeks to maintain a pretransfusion HbS level <30% and Hb level >9.0 g/dL.<sup>118</sup> The post-transfusion Hb level target should not exceed 12 g/dL to avoid the potential for increased morbidity due to hyperviscosity.

### Acute chest syndrome

Acute chest syndrome (ACS) is defined as a new infiltrate on chest X-ray in a febrile person with SCD who has at least one respiratory symptom (most commonly cough, chest pain, and shortness of breath).<sup>141</sup> ACS is the second most common cause of hospitalization and the leading cause of death in individuals with SCD.<sup>142</sup> The clinical severity of ACS can range from an incidental finding on chest X-ray, identified after an individual presents with fever and cough, to a rapidly progressive respiratory failure that requires intubation and RCE. The rapidly progressive subtype of ACS has recently been described as a distinct phenotype of the illness that is frequently preceded by thrombocytopenia and often progresses to multisystem organ failure. This rapidly progressive phenotype is more commonly seen in adults compared to children and requires aggressive transfusion support given its high mortality (6.3%).<sup>143</sup>

The management of ACS is primarily supportive and includes respiratory therapy, antibiotics, and often RBC transfusion. Much of the data used to guide transfusion decisions for ACS treatment come from retrospective reports including a large ACS epidemiologic study showing that red cell transfusions improve oxygenation in SCD patients with ACS.<sup>144</sup> There have been no randomized controlled trials comparing either simple transfusion or RCE transfusion versus no transfusion for ACS, nor whether simple transfusion versus RCE results in improved patient outcomes. In clinical practice, patients with milder degrees of hypoxia and/or low Hb often receive simple transfusions, whereas RCE is commonly reserved for more severe cases. Guidelines from the NHLBI, ASH, and BCSH generally recommend simple transfusion for patients with ACS with hypoxia or an Hb concentration significantly below their baseline. RCE is recommended for patients with more severe presentations and/or rapid progression of ACS manifested as increasing respiratory distress or progressive pulmonary infiltrates requiring invasive respiratory support, and/or declining hemoglobin concentration despite simple transfusions.<sup>115,117,141</sup> Patients with milder ACS but an Hb >9 g/dL (i.e., HbSC patients) may require RCE as the initial therapy.

### Aplastic crisis and symptomatic anemia

Parvovirus B-19 can cause transient red cell aplasia (also called aplastic crisis) and symptomatic anemia in individuals with SCD. Reticulocytopenia accompanying a drop in hemoglobin is the hallmark for this complication. Simple red cell transfusion may be necessary depending on the severity of the anemia, the clinical status of the patient, and the degree of reticulocytopenia.<sup>145</sup> Because the anemia is often subacute, patients are typically euvolemic and physiologically compensated. In these cases, RBC transfusion should be administered slowly with serial small aliquots to prevent circulatory overload. Aplastic crisis due to Parvovirus typically does not recur because of sustained protective immune response even in patients on HU.<sup>146</sup>

Patients with severe symptomatic anemia (usually a hemoglobin of 5 g/dL or less, depending on the patient's baseline hemoglobin)

should be transfused to improve oxygen delivery and prevent complications of anemia. The transfusion goal for symptomatic anemia should be the patient's baseline hemoglobin (provided that patient has an adequate reticulocyte count).<sup>147</sup> Transfusion is not indicated in anemic patients who are asymptomatic with a brisk reticulocytosis. Etiologies for the severe anemia should be sought, and the patient should be closely monitored.

### Acute splenic sequestration crisis

Acute splenic sequestration crisis (ASSC) refers to an acute condition of intrasplenic sickling and pooling of large amounts of blood that most commonly occurs in children between ages five months and two years. During ASSC, the blood-filled spleen may enlarge to the point of filling the entire abdomen and the hemoglobin may drop acutely. This requires prompt treatment with volume expanders and simple blood transfusion to remobilize the blood sequestered in the spleen. Care must be taken to avoid overtransfusion that can lead to hyperviscosity-related morbidity when treating sequestration. Overtransfusion can occur when blood is released from the congested organ, increasing the hematocrit (Hct) to dangerously high levels. Recurrent episodes of ASSC occur in 50–75% of patients with the risk highest when the first episode occurs before two years of age.<sup>148</sup> The utility of temporary chronic transfusions in patients with recurrent ASSC is debatable. The NHLBI 2014 Evidence Based Management Guidelines do not recommend initiating chronic transfusions in children with recurrent ASSC, albeit recognizing the low quality of evidence available to guide this recommendation.<sup>115</sup> However, chronic transfusion therapy is often used to delay definitive treatment of splenectomy in very young children with recurrent ASSC until at least two years of age when the pneumococcal polysaccharide vaccine (PPSV23) can be administered.

### Sickle hepatopathy

Hepatobiliary complications are common in individuals with SCD. They can range from asymptomatic cholelithiasis; to acute hepatic sequestration manifesting as painful hepatomegaly, worsening anemia, reticulocytosis, thrombocytopenia, direct hyperbilirubinemia, and mild transaminitis; to sickle cell intrahepatic cholestasis (SCIC), a life-threatening manifestation associated with hepatomegaly, severe direct hyperbilirubinemia, significantly elevated transaminases, coagulopathy, renal insufficiency, and acute liver failure in severe cases.<sup>149,150</sup> Hepatic sequestration is often treated with simple transfusions to resolve the hepatopathy and correct the anemia. Similarly to ASSC, transfusions should be performed carefully to avoid overtransfusion and hyperviscosity.<sup>116</sup> Although SCIC outcome data are limited, transfusions, particularly RCE, appear to provide a benefit for severe cases<sup>151</sup> and are recommended in the management of acute SCIC.<sup>115,116</sup> Correction of coagulopathies with plasma, cryoprecipitate, and platelet transfusions may also be necessary. Chronic RCE has been proposed for patients with recurrent episodes of acute SCIC or chronic progressive hepatopathy.<sup>152</sup>

### Preoperative

When SCD patients undergo procedures, a myriad of perioperative scenarios exist that can increase erythrocyte sickling and place these patients at increased risk for morbidity. These include suboptimal hydration, poor oxygenation, and acidemia. The Transfusion Alternatives Preoperatively in SCD (TAPS) trial compared outcomes of preoperative transfusion to no transfusion

in patients with HbSS/HbS $\beta^0$  undergoing low- or medium-risk surgery and demonstrated that preoperative transfusion was associated with decreased perioperative complications. Specifically, 13 of 33 (39%) individuals who did not receive preoperative transfusion experienced postoperative complications compared to 5 of 34 (15%) patients who received preoperative transfusion. Ten of eleven serious adverse events were ACS: nine in the no-transfusion group and one in the transfusion group. The trial did not include individuals with HbSC or S $\beta^+$ -thalassemia, and low-risk procedures were too low in number to clarify optimal management for this surgical category.<sup>153</sup>

In a previous randomized control trial, preoperative simple transfusion with a post-transfusion Hb target of 10 g/dL was found to be equally effective in preventing postoperative complications compared to RCE which targeted a postexchange HbS  $\leq 30\%$ .<sup>154</sup> Based on this study, it is recommended that individuals with SCD with Hb less than 9 g/dL, and who are undergoing any surgical procedures determined to be medium- or high-risk, or with an anesthesia time of one hour or more, should receive preoperative transfusion. Post-transfusion Hb should not exceed 11 g/dL to avoid hyperviscosity. RCE should be considered in patients undergoing high-risk surgeries (i.e., neurosurgery or cardiac surgery, or general anesthesia time expected to be greater than four hours) or in HbSS/HbS $\beta^0$  patients undergoing medium-to-high risk surgery whose baseline Hb is  $\geq 10$  g/dL.<sup>116,117,147</sup> The utility of preoperative transfusion in patients undergoing low-risk surgeries (i.e., tympanostomy tubes when anesthesia time <1 hour), patients with milder genotypes (HbSC and HbS $\beta^+$ ), or those with a higher hemoglobin ( $\geq 10$  g/dL) or HbF level due to HU treatment remains unclear. Therefore, preoperative transfusion management decisions should be individualized in these circumstances.<sup>147</sup>

### Indeterminate indications for transfusion

#### Pregnancy

Pregnancy carries a high risk for women with SCD and their fetuses. Pregnant women with SCD should receive red cell transfusions for acute SCD complications where transfusions are usually indicated. Further, if the woman was receiving chronic transfusions prior to conception, they should be continued. There is no clear evidence that prophylactic transfusions improve fetal outcome, but they may reduce pain crises and other SCD complications for the mother.<sup>147</sup> There is currently insufficient evidence to recommend universal prophylactic chronic transfusions for pregnancies in patients with SCD. However, transfusions should be considered for women with previous severe SCD-related complications (including during previous pregnancies), women on HU prior to conception due to severe disease, or additional features of high-risk pregnancy (i.e., additional comorbidities or twin pregnancy).<sup>116,117,147</sup> A multicenter feasibility trial comparing standard of care to RCE every 6–10 weeks starting before 18 weeks gestation is ongoing and intends to assess willingness of pregnant women with SCD to participate in a chronic RCE regimen and to evaluate maternal and fetal outcomes.<sup>155</sup>

#### Pulmonary hypertension

Pulmonary arterial hypertension (PAH) is common in adults with SCD; right heart catheterization is the gold standard for diagnosing PAH. However, an elevated tricuspid regurgitant jet velocity (TRV) of 2.5 m/second or higher has been associated with a higher risk of death in adults with SCD.<sup>156</sup> N-terminal-pro B-type natriuretic peptide (NT-proBNP) levels have also been correlated to pulmonary artery pressures. Two large registries identified that adults with

SCD with elevated TRV and NT-proBNP levels had over 10-time increased mortality rates compared to adults with normal values for both markers.<sup>157</sup> Transfusions may prevent chronic regional hypoxia, improve nitric oxide depletion, and improve endothelial dysfunction in the pulmonary vascular bed, all of which would theoretically improve pulmonary arterial pressures.<sup>123</sup> No randomized controlled trials of HU or chronic transfusion therapy for treatment of PAH in adults with SCD have been published. Despite this, based on the benefits of HU in reducing mortality in SCD and the potential of chronic transfusions to mitigate deleterious pulmonary endothelial effects, the American Thoracic Society (ATS) has promoted the use of HU for patients with SCA who have a TRV of 3.0 m/second or greater or a TRV of >2.5 m/second with either an elevated NT-pro-BNP level or RHC-confirmed PAH. The ATS also proposed that chronic transfusions be administered to patients who are not responsive to, or not candidates for, HU.<sup>158</sup> A Phase 3, multicenter, randomized controlled trial of chronic RCE versus standard of care in adults with SCD at high-risk of mortality (based on PAH risk factors or the presence of renal disease) is ongoing.<sup>159</sup> While awaiting the results of this trial, chronic transfusions for adults with PAH may be considered after weighing the risks and benefits of this therapy.

### Ophthalmologic complications

Two common ophthalmological complications of SCD include proliferative sickle retinopathy and acute retinal artery occlusion. Over the age of 30 years, 43% of HbSC patients and 13% of HbSS patients will develop retinopathy, which can lead to significant visual loss from vitreous hemorrhage, and retinal ischemia and detachment.<sup>160</sup> Central retinal artery occlusion (CRAO) is a rare cause of acute blindness almost exclusively in children and young adults with SCD and presents as a sudden, painless loss of vision.<sup>161,162</sup> Because the vision loss is often permanent if macular infarction occurs, individuals with SCD who present with these signs and symptoms often are treated with exchange transfusion despite the lack of randomized controlled trials determining if long-term vision loss is prevented with RCE. Since the central retinal artery is a branch of the ophthalmic artery that originates from the internal carotid artery, some consider CRAO a variation of an acute ischemic stroke and support chronic transfusion therapy in patients with a history of CRAO despite the lack of published evidence. Similarly, chronic transfusions are sometimes considered for patients with severe proliferative sickle retinopathy with vision loss despite a lack of published evidence.

### Contraindications for transfusion

Since SCD is a hematologic disorder, any complication could theoretically be improved by transfusion. However, the benefits of transfusion therapy must be balanced with the risks, which are numerous for individuals with SCD and are highlighted later in this chapter. Transfusions for acute and/or chronic SCD manifestations where there is either insufficient evidence of benefit, or possibly increased risks, are generally not recommended and should be based on a case-by-case assessment after full risk–benefit analysis. Examples where there is little-to-no evidence of benefit of transfusions include treating patients with asymptomatic anemia, uncomplicated painful vaso-occlusive episodes, acute or recurrent priapism, recurrent splenic sequestration (in children >2 years of age), acute kidney injury (in the absence of multisystem organ failure), avascular necrosis (except when preoperative transfusion is needed for surgical intervention), and leg ulcers.<sup>115,116</sup>

### Thalassemia

Thalassemia is the most common monogenetic diseases worldwide.<sup>163</sup> These syndromes are classified according to whether the mutation causing the defect affects the  $\alpha$ -globin gene cluster or the  $\beta$ -globin gene cluster. Duplicated  $\alpha$ -gene clusters occur on chromosome 16 ( $\alpha\alpha/\alpha\alpha$ ). There is one  $\beta$ -globin gene cluster on each chromosome 11 ( $\beta/\beta$ ). Mutations in the globin genes reduce or eliminate the synthesis of the respective globin molecule. The majority of  $\alpha$ -gene mutations are deletional, although structural mutations occur. There are over 120  $\alpha$ -gene mutations reported.  $\beta$ -Globin mutations are primarily point mutations leading to absent  $\beta$ -globin synthesis ( $\beta^0$ -mutations) or decreased  $\beta$ -globin synthesis ( $\beta^+$ -mutations). There are well over 350  $\beta$ -globin gene mutations. Structural variants of the globin genes can lead to thalassemic gene combinations. There are also deletions of  $\beta$ -globin regulatory elements and the other genes in the  $\beta$ -globin cluster that lead to changes in expression of the gamma globin gene (hereditary persistence of fetal hemoglobin; HPFH). The  $\beta$ -globin gene cluster is also regulated by genes on distant chromosomes such as BCL11A, KLF1, and others.<sup>164,165</sup> The Globin Gene Server<sup>166</sup> continues to update the various hemoglobin variants regularly.

### $\beta$ -Thalassemia

The clinical phenotype and severity of  $\beta$ -thalassemia varies considerably. It mainly depends on the type and number of genetic defects of the alpha or beta globin genes and its regulatory regions. The major predictor of severity is the  $\alpha/\beta$ -globin chain imbalance with more severe disease in those genotypes with excess  $\alpha$ -globin and decreased  $\beta$ -globin production. The  $\alpha$ -globin chains produced in excess precipitate within the erythroid precursors resulting in ineffective erythropoiesis and hemolysis.<sup>167</sup> As such, a  $\beta$ -globin gene heterozygote predicted not to require transfusion might in fact require transfusions due to duplicated or triplicated  $\alpha$ -genes leading to a greater  $\alpha/\beta$ -gene imbalance than expected.

The  $\beta$ -thalassemias can be designated into four categories: silent carrier, trait/thalassemia minor, thalassemia intermedia, and thalassemia major (see Table 30.5). A newer disease classification commonly used includes two phenotype groupings: transfusion-dependent thalassemia (TDT) and nontransfusion-dependent thalassemia (NTDT). This newer designation is often used since overlap in disease severity (and therefore transfusion requirements) may exist over a lifetime, notably in individuals with thalassemia intermedia.  $\beta$ -Thalassemia silent carriers have no hematologic abnormalities but do have elevated hemoglobin A2 on hemoglobin electrophoresis. Individuals with  $\beta$ -thalassemia trait ( $\beta$ -thalassemia minor) have elevated A2 as well as mild anemia with microcytosis or microcytosis alone; they do not require RBC transfusions.  $\beta$ -Thalassemia intermedia presents with variable levels of anemia, but often is nontransfusion dependent (NTDT) in childhood. However, some individuals will go on later in life to require chronic transfusions (TDT) due to the increasing severity of anemia or complications of their disease.  $\beta$ -Thalassemia major presents early in life and is transfusion dependent (TDT).

Coinheritance of  $\beta$ -thalassemia and a  $\beta$ -globin structural variant (HbE) results in HbE thalassemia, which accounts for approximately one-half of all cases of severe  $\beta$ -thalassemia worldwide. The mutation responsible for HbE ( $\beta26$  Glu→Lys) results in abnormal RNA processing of the  $\beta$ -globin chain leading to decreased  $\beta$ -hemoglobin production and a structurally abnormal, mildly unstable hemoglobin molecule.<sup>168,169</sup> The clinical presentation of HbE thalassemia can vary widely from a mild asymptomatic anemia

**Table 30.5** Genotype and Classification of Beta Thalassemia and Alpha Thalassemia

Phenotype	Genotype	Clinical Severity
<b>Beta Thalassemia</b>		
• Normal	$\beta/\beta$	None
• Silent carrier	$\beta^0/\beta$ , $\beta^+/beta$	Asymptomatic
• Trait/thalassemia minor	$\beta^0/\beta$ , $\beta^+/beta$	Asymptomatic to mild microcytic anemia
• Intermedia	$\beta^+/beta$ , $\beta^0/\beta^0$ , $\beta^5/\beta^+$ , $\beta^5/\beta^0$ or in combination with gene duplications, deletional forms of $\delta\beta$ -thalassemia, increased $\gamma$ production, or $\delta\beta$ -thalassemia and HPFH and E $\beta^0$ -thalassemia	Late presentation, mild to moderate anemia, occasionally transfusion dependent
• Thalassemia major (Cooley's anemia)	$\beta^0/\beta^0$	Early presentation, severe anemia, transfusion dependent
<b>Alpha Thalassemia</b>		
• Normal	$\alpha\alpha/\alpha\alpha$	None
• Silent carrier	$\alpha^-/\alpha\alpha$	Asymptomatic
• Trait/minor	$\alpha^-/\alpha^-$ , $-\alpha\alpha$	Asymptomatic to mild microcytic anemia
• Hemoglobin H: deletional (H disease)	$-\alpha$	Mild to moderate anemia, Transfusion independent, Variable severity
• Hemoglobin H: non-deletional	$-\alpha^{ND}$ ( $-\alpha^S$ , Hb H-Constant Spring)	Moderate severity, transfusions possible
• Major (Bart's hydrops fetalis)	$-\alpha$	Possibly nonviable, immediate transfusion, chronic transfusion

to life-threatening anemia requiring lifelong chronic transfusions from infancy. The phenotype is influenced by the  $\beta$ -thalassemia mutation, the amount of fetal hemoglobin production, and the coinherited  $\alpha$ -genotype. The severity can evolve with age.<sup>168</sup> HbE homozygotes (HbEE) have prominent microcytosis along with hypochromia and target cells, but only mild anemia.

Individuals with  $\beta$ -thalassemia major present during infancy with progressive anemia, failure to thrive, and signs of extramedullary hematopoiesis (notably hepatosplenomegaly) as the fetal hemoglobin declines. Regularly transfused patients with thalassemia have complications primarily due to the increased absorption of iron from the gastrointestinal tract and iron derived from chronic transfusions.<sup>170</sup> Individuals with  $\beta$ -thalassemia intermedia have very heterogeneous clinical presentations. On one end of the spectrum are those with mild to moderate anemia who rarely or if ever require transfusions. On the other end are patients who are nontransfusion dependent during early childhood but subsequently become transfusion dependent during periods of erythroid stress (e.g., infections and pregnancy) or during adolescence or adulthood. Individuals with  $\beta$ -thalassemia intermedia who are not transfusion dependent still have morbidity associated with ineffective erythropoiesis, splenectomy, or many other complications listed in Table 30.6.<sup>164</sup> Due to increased gastrointestinal absorption of iron, many NTDT patients will require chelation even in the absence of transfusion. Consequently, iron overload remains one of the most significant complications in NTDT and TDT. Decisions about when to pursue chronic transfusions and/or splenectomy in these individuals are complex and must be individualized after careful assessment of their genotypes and clinical manifestations over several months.

### Transfusion goals for $\beta$ -thalassemia

Transfusion in  $\beta$ -thalassemia can alleviate symptomatic anemia, suppress ineffective erythropoiesis, improve growth and development, and reduce iron overload from increased gastrointestinal absorption. Even with identical genotypes, the baseline hemoglobin for the  $\beta$ -thalassemia syndromes is not predictable, but should be established for each child before the initiation of transfusion therapy. If the baseline is consistently below 6 or 7 g/dL, chronic transfusion therapy should be initiated. The goal for transfusion-dependent  $\beta$ -thalassemia is a pretransfusion hemoglobin of 9–10 g/dL (11–12 g/dL in individuals with heart disease), which typically requires transfusion every

**Table 30.6** Complications Seen in Patients with Transfusion-Dependent and Non Transfusion-Dependent Thalassemia<sup>164</sup>

- |   |                                     |
|---|-------------------------------------|
| • Growth and pubertal delay                 | • Thrombophilia and vascular events |
| • Hypoparathyroidism, hypothyroidism        | • Pulmonary hypertension            |
| • Left heart failure: cardiac hemosiderosis | • Hepatic fibrosis and cirrhosis    |
| • Hepatic failure                           | • Hepatocellular carcinoma          |
| • Viral hepatitis                           | • Hepatosplenomegaly                |
| • Diabetes mellitus                         | • Infections                        |
| • Hypogonadism                              | • Extramedullary hematopoiesis      |
| • Osteoporosis                              | • Osteoporosis                      |
| • Infertility, pregnancy                    | • Skin ulcers                       |
| • Hyperbilirubinemia, gall stones           | • Renal abnormalities               |

month in infants and young children, often increasing to every three weeks in adults.<sup>171</sup> If not splenectomized, patients may have hypersplenism or may be overtransfused to hemoglobin levels higher than necessary. Chelation becomes increasingly difficult with intensive transfusion therapy. Patients who have an annual transfusion requirement of greater than 200 mL/kg/year should be evaluated to determine if their transfusion requirement can be reduced.

### Other therapies for $\beta$ -thalassemia

Several pharmacological agents are being considered in thalassemia. While regular transfusion therapy is being considered, it is also essential to check if the patient qualifies for any clinical trials with new therapies or is eligible for hematopoietic stem cell transplant (HSCT). For adults over 18 years of age, luspatercept is a fusion protein that binds to TGF $\beta$  superfamily and augments late stage erythropoiesis. Luspatercept was recently approved for use for transfusion-dependent  $\beta$ -thalassemia based on the phase 3 double-blind, randomized, placebo-controlled trial demonstrating significantly reduced transfusion burden in TDT patients treated with luspatercept at 1.0–1.25 mg/kg every three weeks compared to placebo.<sup>172</sup> Other pharmacotherapies being considered include Mitapivat (activator of pyruvate kinase), VIT-2763 (ferroportin inhibitor), and TMPRSS6-LRx (antisense oligonucleotide targeting TMPRSS6). Gene editing trials are also ongoing.<sup>164</sup>

### **α-Thalassemia**

The clinical phenotype and severity of α-thalassemia also varies based on the number of genetic deletions along with the presence or absence of nondeletional mutations present on the alpha globin gene. In humans, the alpha gene locus is duplicated which results in individuals carrying four functional alpha chain genes (i.e.,  $\alpha\alpha/\alpha\alpha$ ). Alpha thalassemia is most commonly caused by full deletions of one or both α-globin genes. The  $\alpha^+$  thalassemia haplotype results when one of the two alpha globin genes are deleted on chromosome 16, whereas the  $\alpha^0$ -thalassemia haplotype occurs when both pairs of α-globin genes are deleted ( $\alpha^0$ -thalassemia,  $\alpha^-$ ;  $\alpha^0$ -thalassemia,  $-$ ). The two most common  $\alpha^+$ -thalassemia mutations are the 3.7 and 4.2 deletions, with highest prevalence in tropical and subtropical regions. Common  $\alpha^0$ -thalassemia variants include the  $-\text{SEA}$  mutation in Southeast Asia and the  $-\text{MED}$  mutation in the Mediterranean, reaching frequencies of approximately 5% in their respective regions. Less commonly, nondeletional α-thalassemia mutations caused by nucleotide deletions or substitutions exist, which can also ineffectively generate abnormal hemoglobin molecules (e.g., Hb Constant Spring, Hb Paksé). These nondeletional mutations may occur as single mutations or in combination with  $\alpha^+$ - or  $\alpha^0$ -thalassemia haplotypes ( $\alpha\alpha/\alpha^{\text{ND}}\alpha$ ,  $-\alpha/\alpha^{\text{ND}}\alpha$ , and  $-\alpha^{\text{ND}}\alpha$ , respectively).<sup>173</sup>

In the fetus, defective production of α-chains is reflected by the presence of excess γ chains, which form γ4 tetramers, called hemoglobin Barts. In adults, excess β-chains form β4 tetramers, called hemoglobin H (HbH). Because of their very high oxygen affinity, both tetramers cannot transport oxygen, and, in the case of HbH, its instability leads to the production of intraerythrocyte inclusion bodies and a variable degree of hemolytic anemia.<sup>173</sup>

The majority of patients with α-thalassemia syndromes will not require chronic transfusion therapy. Exceptions are those patients with HbH–Constant Spring ( $-\alpha^{\text{CS}}\alpha$ ) and infants with Hb Bart's hydrops fetalis ( $-/-$ ), who survived due to intrauterine transfusions (see Table 30.5). Single gene deletions ( $-\alpha/\alpha\alpha$ ) are not detectable without α-gene mapping. Alpha gene mutations that occur in *trans* ( $-\alpha/\alpha$ ) or *cis* ( $-\alpha/\alpha$ ), referred to as α-thalassemia trait (or α-thalassemia minor), are indistinguishable hematologically and can only be deciphered genetically. Individuals with α-thalassemia trait have hypochromia and microcytosis with or without mild anemia, and do not require transfusion.

Combinations of  $\alpha^0$ -thalassemia and  $\alpha^+$ -thalassemia can lead to a phenotype requiring RBC transfusions on an intermittent basis or chronically. HbH disease ( $-\alpha/-$ ) is the most common  $\alpha^0$ -thalassemia– $\alpha^+$ -thalassemia combination.<sup>174</sup> Patients with HbH disease rarely require transfusions, but may need transfusion during illnesses, pregnancy, or surgery. HbH disease manifests with a mild anemia and splenomegaly. In contrast, HbH–Constant Spring ( $-\alpha^{\text{CS}}\alpha$ ) is a much more severe disease with anemia, requiring intermittent or chronic transfusion, occasionally occurring early in life. Most patients will develop hypersplenism and thrombophilia. Thrombosis following splenectomy is common in this nondeletional form of HbH disease. Later in life, cholelithiasis and skin ulcers can occur. Both HbH disease and HbH–Constant Spring are in the NTDT group of thalassemia; however, some HbH–Constant Spring patients will require frequent or chronic transfusions later in life.<sup>175</sup> The most severe form of α-thalassemia is Bart's hydrops fetalis ( $-/-$ ). The affected embryo develops severe hypoxia in the third trimester and will not survive without intrauterine transfusions or exchange transfusion at birth. Other  $\alpha^0$  thalassemia mutations may cause fetal demise earlier in gestation. These infants require chronic transfusion therapy or HSCT if they survive.<sup>176</sup>

Similarly to β-thalassemia, decisions about when to pursue chronic transfusions and/or splenectomy in individuals with HbH disease and HbH–Constant Spring are complex and must be individualized over time. Monitoring during times of acute illness, infections, pregnancy, surgery, or rapid growth during childhood is required and is the best way to determine when RBC transfusions may be needed to treat severe anemia or to promote growth. For those patients requiring chronic transfusion, the goal should be a pretransfusion Hb of 9–10 g/dL (11–12 g/dL in individuals with heart disease), similarly to patients with transfusion-dependent β-thalassemia.<sup>175</sup>

### **Red cell enzymopathies**

Red cell enzymopathies are caused by alterations to genes that encode RBC enzymes. These congenital nonspherocytic hemolytic anemias are associated with defects in erythrocyte cellular metabolism that affect glucose, glutathione, or nucleotide metabolism.

#### **Glucose-6-phosphate dehydrogenase (G6PD) deficiency**

G6PD deficiency is the most common enzymopathy in humans.<sup>57</sup> G6PD catalyzes the first step of the hexose monophosphate shunt pathway which leads to NADPH production. NADPH provided by this pathway helps protect against cellular oxidative damage by supporting regeneration of reduced glutathione by glutathione reductase. Without maintaining high reduction potential in the RBC, oxidative membrane damage and hemolysis occur when the cells are presented with excessive oxidative stress.

G6PD has classical X-linked inheritance with the deficiency primarily affecting males, although females homozygous for the deletion or heterozygous with lyonization can be symptomatic. There are over 200 mutations leading to inactivation of the G6PD enzyme; most are single base mutations leading to amino acid substitutions and inactivation.<sup>57</sup> Since genetic variants can affect G6PD enzymes quantitatively and qualitatively, five classes of G6PD deficiency are described based on the level of residual enzyme activity and the hemolytic tendency (see Table 30.7). Class I is very rare with very low activity of G6PD and typically manifests as chronic nonspherocytic hemolytic anemia (CNSHA). Other variants (classes II and III) are associated with acute hemolytic episodes when subjected to oxidative stress.<sup>57</sup> Although there are numerous mutations leading to the inactivation of G6PD, two mutations are particularly common: one in areas of the African Diaspora and the other in countries surrounding the Mediterranean, Israel, India, and Indonesia. The African variant is G6PD (A–), which encodes 10–60% of normal G6PD enzyme activity. Individuals may experience intermittent hemolysis associated with significant oxidant stress from infections or exposure to certain

**Table 30.7** Classes of G6PD Deficiency

WHO Classification*	
<b>Class I</b>	Severely deficient (<1%); chronic non-spherocytic hemolytic anemia
<b>Class II</b>	Severely deficient (1–10% activity); mild, acute hemolytic episodes
<b>Class III</b>	Moderately deficient (10–60%); mild, acute hemolytic episodes
<b>Class IV</b>	Normal activity (60–50%); normal
<b>Class V</b>	Increased activity (>150%)

\* WHO classification proposed in 1971 and used universally since. Revision of this classification is currently under consideration which may group class II and class III variants together since their clinical manifestations are largely similar with wide overlap, with the exception that the acute hemolytic episodes tend to be more severe with class II variants than with class III variants.<sup>57</sup>

medications or fava beans.<sup>58</sup> The Mediterranean variant is the second most common G6PD variant allele. It results in <5% activity, and the acute episodes of hemolysis can be more severe. The severity of hemolysis depends on the type of trigger, dose of the exposure (in cases of fava bean or drugs), the level of residual enzyme activity in the patient, and the baseline anemia prior to hemolytic crisis. Numerous drugs have been implicated in the initiation of hemolysis in G6PD-deficient patients and have been risk-defined.<sup>57</sup> In severe hemolysis, transfusion may be urgent. However, a striking feature of G6PD-related acute hemolytic anemia is a rapid recovery due to a swift reticulocyte response.

A small proportion of G6PD mutations result in <1% activity. Individuals with these class I G6PD variants may suffer from severe neonatal jaundice and CNSHA of varying degree. Most individuals with CNSHA will have mild to moderate chronic anemia with reticulocytosis. Like other variants, the hemolysis can be exaggerated by exposure to oxidant stress from drugs, infections, fava beans, etc. Notably, some drugs with relatively mild oxidant potential in patients with class II and III G6PD variants may induce hyperhemolysis in patients with class I variants. It is important to note that blood donors are not routinely screened for G6PD deficiency. However, RBC units from G6PD-deficient donors may be associated with insufficient post-transfusion Hb increments or shorter in vivo survival in neonatal recipients and individuals with SCD, respectively.<sup>177,178</sup> Consequently, because of the potentially negative impact on transfusion efficacy, some have advocated for donor screening for G6PD deficiency to improve transfusion outcomes for vulnerable patient populations (i.e., premature infants, SCD, and/or other chronically transfused populations).<sup>178</sup>

### Pyruvate kinase deficiency

Pyruvate kinase deficiency (PKD) is the second most common inherited RBC enzymopathy after G6PD deficiency, but much less frequently observed. However, it is the most common enzymatic cause of hemolytic anemia due to an abnormality in the glycolytic pathway. There are four isoenzymes ( $M_1$ ,  $M_2$ , L, and R) found on two chromosomes. The gene for the L and R isoenzymes (PK-LR) on chromosome 1 (1q21) uses different promoters to produce the two isoenzymes. The gene for  $M_1$  and  $M_2$  isoenzymes (PK-M) on chromosome 15 (15q22), with alternate RNA splicing, produces these two isoenzymes.<sup>179</sup> The R isoenzyme is expressed exclusively in erythrocytes. PKD is inherited in an autosomal recessive pattern and is either caused by homozygous or compound heterozygous variants in the *PKLR* gene. PK-deficient RBCs cannot catalyze the conversion of phosphoenolpyruvate to pyruvate, impairing glycolysis and adenosine triphosphate (ATP) production. Reduced ATP levels impairs reticulocyte and RBC survival by altering cell rheology, making them susceptible to hemolysis, and increasing splenic uptake.<sup>180,181</sup>

Additionally, PK-deficient RBCs demonstrate increased accumulation of 2,3-bisphosphoglycerate, which shifts the oxygen dissociation curve to the right, thereby decreasing hemoglobin's oxygen affinity.<sup>182,183</sup> PKD has been reported worldwide, but higher frequencies are present in the Pennsylvania Amish and the Roma communities as a result of the founder effect.<sup>184</sup> The majority of *PKLR* mutations are missense substitutions. Among these, R510Q, R486W, and R479H are in patients from northern Europe and the United States, southern Europe, and the Amish communities, respectively.<sup>185</sup> Diagnosis of PKD should include PK enzyme activity and *PKLR* genetic testing as PKD is a heterogeneous disease with some large deletions, and intronic mutations can be difficult to identify.<sup>185</sup>

The clinical features of PKD are highly variable and include prenatal hydrops fetalis, severe neonatal jaundice, transfusion dependency, and asymptomatic anemia. Current treatment modalities are mostly supportive care with transfusions, splenectomy and chelation for those with iron overload. Complications occur irrespective of transfusion status. These include iron overload, bilirubin gallstones, extramedullary hematopoiesis, pulmonary hypertension, and thrombosis. The transfusion requirement can decrease with age (36% of children vs. 11% of adults), and as a result of splenectomy; additionally, fewer hemolytic crises are experienced in adults.<sup>185</sup> Transfusions to maintain an arbitrary Hb value should be avoided but rather should be based on the impact of hemolytic anemia on quality of life and energy level. There are ongoing clinical trials using mitapivat, a PK activator, in patients with PKD. A recent phase 2 study showed mitapivat improved Hb by a mean of 3.4 g/dL (range 1.1–5.8) in 50% of adults with PKD who were not regularly transfused.<sup>186</sup> An open-label clinical trial of mitapivat in transfusion-dependent patients with PKD was recently completed, and results are expected.<sup>187</sup>

### Red cell membrane disorders

The red cell membrane has a unique structure that is deformable without fragmentation and is rapidly responsive to stress changes. These properties are due to the structure of the lipid bilayer membrane and the underlying cytoskeleton. The lipid bilayer has an asymmetric distribution of phospholipids with phosphatidylserine (PS) localized to the inner layer. Both PS and internally located sphingomyelin interact with the spectrin and protein 4.1R anchoring the membrane to the cytoskeleton. Loss of this asymmetry, with PS translocated to the outer membrane, leads to phagocytosis and the membrane destruction seen in sickle cell disease and thalassemia. Key components of the membrane include band 3, glycophorin C, RhAG,  $\alpha$ - and  $\beta$ -spectrin, actin, and ankyrin.

### Hereditary spherocytosis

This is the most common RBC cytoskeletal disorder causing hereditary hemolytic anemia. It can affect all racial groups, but it is particularly common in northern Europeans where the prevalence is one in 1000–2500.<sup>188</sup> The inheritance is dominant in 75% and recessive in 25%. Mutations of ankyrin (ANK1), band 3 (SLC4A1), and  $\beta$ -spectrin (SPTB) genes are most commonly seen in autosomal dominant (AD) HS, while compound heterozygous defects affecting ANK1,  $\alpha$ -spectrin (SPTA1), or protein 4.2 (EPB42) predominate in autosomal recessive (AR) HS.<sup>189,190</sup> The phenotype–genotype correlation is dictated by the causative genetic variants, heterogeneity in the level of expression from splicing variants, and in erythropoiesis<sup>64,190</sup> (see Table 30.8). Current diagnostic options to correctly diagnose RBC membrane disorders include ektacytometry, flow cytometry, quantification of RBC cations and membrane proteins, along with confirmatory genetic testing.

**Table 30.8** Clinical Characteristics of Hereditary Spherocytosis

• Ankyrin	AD, AR, de novo	Mild to severe
• Band 3	AD	Mild to moderate
• $\beta$ -Spectrin	AD, de novo	Mild to moderate
• $\alpha$ -Spectrin	AR	Severe
• Protein 4.2	AR	Mild to moderate

The clinical severity of HS varies from symptom-free carrier status to severe hemolysis. The presence of anemia with reticulocytosis, spherocytes on the blood smear, jaundice, gallstones, splenomegaly, and a positive family medical history for similar findings is highly suggestive for a diagnosis of HS. Mild HS can be challenging to identify because individuals may have normal hemoglobin with no evidence of active hemolysis. Occasionally, mild HS can be exacerbated by illnesses that cause splenomegaly, such as infectious mononucleosis. All types of HS are likely to present with neonatal jaundice within the first 24 hours of life.

Severity of hereditary spherocytosis is sometimes categorized into mild, moderate, moderately severe, and severe depending on clinical and laboratory variables, such as hemoglobin, reticulocytes, bilirubin, transfusion frequency, response to splenectomy, among others (see Table 30.9). It is important to consider other possible diagnoses for chronic hemolysis if the blood smear appearances are not typical, particularly congenital dyserythropoietic anemia. Several cases have been misdiagnosed in the past, with the correct diagnosis being established only when patients fail to respond as expected to splenectomy or using genetic testing.<sup>191</sup>

### Hereditary elliptocytosis

Hereditary elliptocytosis (HE) has a worldwide distribution, but it is more common in malarial areas. HE and hereditary pyropoikilocytosis (HPP) result from mutations in the genes encoding for  $\alpha$ -spectrin,  $\beta$ -spectrin, or protein 4.1R. Defects in these genes reduce horizontal cytoskeletal integrity, thereby affecting the stability of red cell membrane, reduced deformability, and predisposing to hemolysis. HE is frequently asymptomatic, with no or mild hemolytic anemia, and results from monoallelic heterozygous mutations involving one of the above genes with corresponding altered or deficient cytoskeletal proteins. HPP is a more severe form of hemolytic anemia which results from biallelic HE-causing mutations. The most common form of HPP, frequently seen in individuals of African ancestry, results from compound heterozygous mutations involving an *SPTA1* HE-causing mutation along with a low-expression *SPTA1* allele (known as  $\alpha^{LELY}$ ). The  $\alpha^{LELY}$  allele leads to 50%  $\alpha$ -spectrin expression and is clinically silent even in the homozygous state. However, when coinherited with an *SPTA1* HE-causing mutation, neonatal jaundice, anemia, and increased poikilocytosis and fragmented RBCs on peripheral blood smear are frequently observed leading to a diagnosis of HPP in infants.<sup>64,192</sup> Children with HPP typically have moderate to transfusion-dependent anemia early in life, but their hemolytic anemia gradually improves after the first 1–2 years and evolves into an HE phenotype.<sup>64</sup>

### Southeast Asian ovalocytosis

Southeast Asian Ovalocytosis (SAO) is common in malarial regions of Southeast Asia and the Philippines, and has autosomal dominant inheritance. Given that only heterozygotes have been observed, the assumption is that homozygosity is incompatible with life. It is

caused by a 27 base pair deletion of band 3. This membrane disorder is relatively benign with neonatal jaundice with no or minimal transient hemolysis seen in newborns, and resolution in toddler years.<sup>193</sup>

### Hereditary stomatocytosis

These disorders lead to overhydrated hereditary stomatocytosis (OHSt) or dehydrated stomatocytosis (DHSt), otherwise called Hereditary Xerocytosis (HX). OHSt is characterized by an increase in intracellular sodium and water content that is not adequately compensated by reduced potassium. In HX, potassium leaks out of RBCs and is not compensated by an increase in intracellular sodium content.

Autosomal dominant OHSt is caused by a heterozygous missense mutation involving the *RHAG* gene, which codes for the RhAG protein that is part of band 3 complex of the RBC membrane. Patients with OHSt can present with mild to severe hemolytic anemia, reticulocytosis, a low MCH and MCHC, elevated MCV, and abundant stomatocytes along with occasional spherocytes on the blood smear.<sup>64</sup>

HX is also autosomal dominant hemolytic anemia characterized by gain of function mutations in *PIEZ01* or *KCNN4*. The former is a stretch-activated nonselective cation channel and the latter is a calcium-activated potassium channel (also known as Gardos channel). Defects in both these genes result in potassium leak, with no gain in sodium/water. The result is erythrocyte dehydration. This explains why some newborns with HX present with pseudohyperkalemia and perinatal edema. Patients with DHSt typically present with compensated hemolysis or mild anemia, reticulocytosis, a high MCH, MCV, high or high-normal MCHC, and xerocytes (dehydrated erythrocytes that have hemoglobin “puddled” at one end at the periphery) and occasional stomatocytes and target cells on the blood smear. Iron overload is seen even in those without a history of transfusion, especially in *KCNN4*-HX.<sup>64,194</sup>

In both these conditions, RBC transfusions are occasionally required if the anemia is severe, and monitoring for iron overload is required despite low transfusion burden. While splenectomy can partially ameliorate the anemia in OHSt, a high risk of thromboembolic complications postsplenectomy has been reported for OHSt and HX.<sup>64,195,196</sup> Senicapoc, a Gardos channel blocker that was originally designed for an SCD therapy but failed to show measurable clinical benefits, is currently being restudied in *KCNN4*-HX.<sup>197</sup>

### Transfusion protocols

#### Pretransfusion testing and RBC component preparation

Routine transfusion therapy requires ABO and RhD typing. However, extended RBC antigen typing is recommended for patients with SCD who have an increased incidence of RBC alloimmunization when receiving standard ABO/RhD-matched RBC transfusions (pooled prevalence: 35%; 95% CI, 19%–53%).<sup>117</sup> An extended RBC antigen phenotype or genotype (preferred) should be obtained at the earliest opportunity, optimally before first transfusion, for all patients with SCD. An extended RBC antigen profile should include C/c, E/e, K, Jk<sup>a</sup>/Jk<sup>b</sup>, Fy<sup>a</sup>/Fy<sup>b</sup>, M/N, and S/s, at a minimum.<sup>117</sup> This information is critical to identifying absent RBC antigens in the patient, a prerequisite for alloantibody formation, in order to provide antigen-negative RBC units for transfusion and to guide investigations when alloantibodies are suspected. More than two-thirds of the alloantibodies detected in SCD patients target Rh

**Table 30.9** Severity of Hereditary Spherocytosis

	Mild	Moderate to Moderately Severe	Severe
Hemoglobin	>11 g/dL	8–11	6–8 g/dL
Reticulocytosis	3–6%	>6%	>10%
Total Bilirubin	1–2 mg/dL	>2 mg/dL	>3 mg/dL

(primarily C and E) and Kell (typically K) antigens. A recent systematic review demonstrated significantly decreased rates of alloimmunization in SCD patients receiving prophylactic Rh(CcEe)- and K-matched RBCs with pooled alloimmunization incidence rate 0.40 (95% CI: 0.23–0.69) per 100 units phenotypically matched transfusions compared to 1.94 (95% CI: 1.28–2.94) per 100 ABO/Rh(D)-matched units transfused. Consequently, prophylactic Rh (CcEe) and K antigen matching is recommended for all SCD patients needing transfusion.<sup>115,117,198</sup> Extended antigen-matched RBC transfusions (CcEe, K, plus Jk<sup>a</sup>/Jk<sup>b</sup>, Fy<sup>a</sup>/Fy<sup>b</sup>, and S/s) are preferred in patients with history of alloantibodies in order to further minimize sensitization, but finding sufficient RBC units for some patients may be challenging. Although lower alloimmunization rates are seen in thalassemia patients (pooled prevalence: 11.4%; 95% CI: 9.3–13.9%),<sup>199</sup> prophylactic CcEe and K antigen matching is also recommended given that over 75% of the antibodies detected in thalassemia patients are also Rh and Kell antigens.<sup>198,199</sup> Additionally, similarly to SCD, several studies have suggested a reduction in alloimmunization risk in individuals with β-thalassemia when CcEe- and K-matching for RBCs is applied.<sup>198</sup> There are no standardized guidelines recommending prophylactic antigen matching for individuals with other hereditary hemolytic anemias.

Multiple commercially available semiautomated RBC genotyping platforms exist and provide advantages over standard serologic methods for antigen typing. These advantages include determining an extended RBC phenotype in recently transfused patients, simplified testing in patients with interfering allo- or autoantibodies, resolution of discrepant serologic typing results, and testing samples where typing antisera are not readily available.<sup>200</sup> In addition, most commercially available RBC genotyping platforms provide additional RBC phenotype information that may optimize antigen matching protocols particularly for patients with SCD. As an example, a GATA mutation in the DARC gene, which is common in individuals of African descent, only prevents expression of Duffy glycoprotein on erythrocytes while permitting expression in nonerythroid cells. SCD patients found to have a GATA mutation are not at risk for alloimmunization against Fyb despite typing as Fy(b-). These patients can safely receive Fy(b+) RBCs, which markedly expand the pool of compatible donors.<sup>200,201</sup> Another example includes patients identified by genotype with the hybrid *RHD\*DIlla-CE(4-7)-D*, which is also common in individuals of African descent. This hybrid *RHD-CE-D* encodes no RhD antigen but rather a partial C antigen. Patients found to have this hybrid *RHD* allele should receive C-negative RBCs when no conventional *RHCE\*Ce* or *\*CE* trans-allele is present to prevent allo-anti-C development.<sup>201,202</sup>

Fresh RBCs are postulated to have increased in vivo survival and potentially reduce the risk of alloimmunization. For example, higher alloantibody levels have been observed in mice transfused leukoreduced RBCs that were 14 days old compared to fresher units.<sup>203</sup> Although the benefit of providing fresh RBCs has been investigated in other patient populations,<sup>204</sup> it has not been extensively evaluated in patients with SCD, other hemoglobinopathies, or hereditary hemolytic anemias. Currently, there is no standard on RBC unit age restrictions for patients with hemoglobinopathies; however, some centers utilize protocols that recommend “freshest available” units, or units less than 10 days, 14 days, or 21 days.<sup>205</sup> Sickle trait-negative blood products are recommended for SCD patients, although a patient with a rare phenotype may receive sickle trait-positive units when necessary. Leukoreduced products

are indicated for all patients with hemoglobinopathies or hereditary hemolytic anemias. RBCs do not require irradiation for these patient populations unless the patient is undergoing HSCT. Units that have been leukoreduced are widely accepted to be “cytomegalovirus (CMV)-safe,” and there is no demonstrated need to issue units from CMV-seronegative donors if the units are leukoreduced. However, CMV negative units are recommended for the transfusion of patients during pregnancy, if available, to prevent congenital CMV in the fetus. No formal recommendations exist on whether CMV-seronegative patients undergoing HSCT should receive CMV negative units. Citing long-term retrospective studies demonstrating very low to no transfusion-transmitted CMV rates using leukoreduced blood products in these patients, many institutions encourage leukoreduced blood products in this population.<sup>206</sup> Washed RBC units are not indicated unless the recipient has had severe allergic transfusion reactions. Red cell units can be “split” by the blood bank to conserve the blood supply. This practice is more commonly used for pediatric patients whose transfusions are volume based rather than unit based.

### Simple transfusion

SCD patients may receive either simple or exchange transfusions. Simple transfusions are more commonly utilized in SCD patients because they can be performed with a minimal amount of clinical resources and infrastructure. Furthermore, only simple transfusions are used in patients with thalassemia and hereditary hemolytic anemias. The volume for simple transfusion is specifically calculated for pediatric patients rather than transfusion of entire units. A simple method of calculating red cell requirement is

$$\text{RBC milliliters (mL) to transfuse} = (\text{Hb}^d - \text{Hb}^c)(3 / \text{Hct}^u)(\text{Wt})$$

where Hb<sup>d</sup> is the desired hemoglobin, Hb<sup>c</sup> is the current hemoglobin, Hct<sup>u</sup> is the hematocrit of transfused RBC unit(s), and Wt is the weight of the patient in kilograms.<sup>207</sup>

There are some contraindications to simple transfusions. For example, this approach can lead to volume overload with cardiac insufficiency in older patients, those with cardiomyopathy, and/or those receiving rapid transfusion volumes greater than 20 mL/kg. In these instances, slowing the infusion rate (especially if patient is hemodynamically stable), close monitoring, and consideration of diuretics should be considered. Overtransfusion can lead to hyperviscosity and should be avoided in patients with hemoglobinopathies, particularly SCD. Although the Hb concentration that may cause morbidity in thalassemia is higher than in SCD, hyperviscosity can develop in both populations and can produce complications. In normal (HbAA) individuals, arterial oxygen delivery increases as Hb concentration increases to a maximum oxygen delivery at approximately 15 gm/dL (Hb<sub>max</sub>). Beyond this point, any increase in Hb concentration decreases the arterial oxygen delivery due to increased blood viscosity. For patients with SCD, the Hb<sub>max</sub> is shifted downward to 10–11 g/dL.<sup>118,208,209</sup> Consequently, although thalassemia patients tolerate Hb concentrations up to 15 gm/dL following transfusion, an Hb concentration >12 gm/dL in SCD patients following a simple transfusion can lead to hypertension, posterior leukoencephalopathy (PRES), or stroke.<sup>210</sup> These risks are increased during hypoxia if the percent hemoglobin S is greater than 30%. Evidence suggests that cerebral blood flow and oxygen delivery to the brain in SCD is not only dependent on the total Hb concentration but also on the percentage of HbS.<sup>211</sup> When the HbS level is <20% (i.e., post-transfusion

during chronic transfusion therapy), the total Hb concentration can generally be increased up to 12–13 g/dL without concerns for viscosity-related complications.<sup>118</sup> Therefore, the optimal recommended post-transfusion Hb concentration is approximately 12 g/dL for SCD patients undergoing chronic transfusion therapy but not recommended to exceed 10–11 g/dL in the acute setting when HbS is assumed to be >50%.

### **Red cell exchange**

Red cell exchange is often preferred for SCD in emergent situations when rapid HbS reduction is needed in patients with severe sickle manifestations and/or in patients with higher pretransfusion Hb levels to minimize hyperviscosity concerns. It is also utilized in the chronic transfusion setting to prevent iron overload or minimize iron burden in patient with hemosiderosis. Exchange transfusion is preferably performed by automated erythrocytapheresis but can be performed manually by phlebotomy of whole blood immediately before transfusion of RBCs (which can sometimes be diluted to a predetermined Hct), as described in the next section.

### **Manual exchange transfusion**

Manual exchange transfusions are used in both resource-poor countries as well as developed, resource-rich countries when access to apheresis equipment and/or trained personnel is limited. Partial manual exchange (PME) involves phlebotomy of approximately 5–10 mL/kg of whole blood immediately followed by simple transfusion. The volumes of phlebotomy and transfusion depend on patients' baseline Hb and tolerance, and the postexchange target Hb level.<sup>139,212</sup> Alternative approaches involve successive aliquots of whole blood being removed and replaced by reconstituted whole blood (RBCs diluted with either albumin or normal saline) to a desired Hct.<sup>213</sup> There is no universal standard technique for performing manual exchange transfusions for children or adults with SCD, and therefore different protocols exist among treatment centers. PME has been utilized to slow the progression of transfusional iron overload when used for chronic transfusion therapy, but is not as effective as automated red cell exchange (erythrocytapheresis) in this regard.<sup>139</sup>

### **Erythrocytapheresis**

Automated RCE (erythrocytapheresis) is the preferred transfusion method for many SCD patients when it is available. The advantages of erythrocytapheresis include the ability to maintain continuous isovolemia and predictably achieve a target post-transfusion Hb level and percentage of HbS independently of one another. As a result, hyperviscosity can be avoided, notably in patients with higher pretransfusion Hb levels. In addition, the procedure can effectively minimize iron accumulation when optimized in the chronic transfusion setting.<sup>139,140</sup>

Automated RCE can be performed via the conventional method or via a method that incorporates isovolemic hemodilution (IHD), also known as depletion exchange (117). IHD-RCE uses saline (or albumin) replacement to acutely lower the patient's Hct at the beginning of the apheresis procedure while maintaining isovolemia. This decreases the total RBC unit volume needed to attain the target HbS level and allows for the exchange procedure to be more efficient. Current apheresis devices have IHD-RCE capability programmed into the device, allowing it to be fully automated.<sup>214</sup> Although IHD-RCE is not advised in the acute setting when a rapid drop in Hb level may not be tolerated, IHD-RCE can be utilized in the chronic setting in order to potentially decrease the frequency of exchange transfusions by providing an

increased exchange efficiency.<sup>215</sup> However, there is a paucity of studies investigating the long-term safety of IHD-RCE compared to conventional RCE. Young children (<20–25 kg) undergoing automated RCE require a blood (custom) prime when the extracorporeal volume from the circuit exceeds 15% of their total blood volume. For this reason, they also should not receive IHD-RCE.

The major barriers to automated RCE most often include access to apheresis equipment and/or trained personnel and venous access. Although efforts should be made to use peripheral veins for apheresis procedures, central intravenous access is often necessary for both acute procedures and for patients requiring chronic erythrocytapheresis. Percutaneous temporary double-lumen hemodialysis catheters are used and placed in either the internal jugular (preferred), subclavian, or the femoral vein for patients requiring acute RCE. Tunneled and cuffed double-lumen high flow central venous catheters or double-lumen ports have both been effectively used in children and adults who require chronic erythrocytapheresis. These ports require large noncoring needles for apheresis. Ideally, these ports should only be used by the apheresis staff for RCE, and sterile access technique should be employed to prevent infection. High-dose heparin locks (1000 units/mL) and TPA instillations (1 mg/mL) for intraprocedural flow issues are commonly used line care measures. Typically 10 Fr or larger double-lumen catheters/ports are required for adults. The sizes and types of catheter/ports for pediatric patients are based on the weight of the patient; 7 Fr or larger double-lumen catheters are typically required for children between 10 and 20 kg.<sup>216</sup> Alternatively, a single-lumen high flow port may be used (as the access/draw line) with a peripheral intravenous (PIV) angio-catheter (as the return line). Preferred angio-catheter sizes for supporting apheresis include 18 gauge or larger for adults and 22 gauge or larger for children. Larger steel gauge needles are required for the access/draw line when erythrocytapheresis is performed solely via peripheral venous access.

Automated RCE is relatively safe, with few adverse events reported. Hypocalcemia can be avoided with the use of continuous calcium gluconate infusion at approximately 15–20 mg/kg/hour, with subsequent titration based on ionized calcium monitoring.<sup>217</sup> Nausea, vasovagal reactions, and post-RCE transient drops in platelet count below  $100 \times 10^3/\mu\text{L}$  have been reported.<sup>218</sup> Because automated RCE is associated with increased RBC utilization, concerns over alloimmunization have been raised. However, multiple studies have shown that RCE does not result in an increased incidence of alloimmunization compared to simple transfusion or PME despite additional donor exposures.<sup>139,219–221</sup>

### **Transfusion targets and monitoring**

With the exception of acute ischemic stroke in adults and children with SCD where a post-RCE target HbS <20% is recommended,<sup>118</sup> most post-transfusion targets in the acute setting relate to amelioration of sickle manifestations and not exceeding a total Hb of 11 g/dL to avoid hyperviscosity. For SCD patients receiving chronic transfusions for stroke prevention, guidance recommends a pretransfusion Hb level >9.0 g/dL and HbS level <30%;<sup>118</sup> once again, the post-transfusion Hb level target should not exceed 12 g/dL to avoid increased morbidity due to hyperviscosity. Transfusions are usually required every 3–4 weeks to maintain these parameters. The optimal HbS for prevention of other complications is not defined, but a pretransfusion HbS of <40–50% is often used. If the pretransfusion HbS is higher than the target despite simple transfusions at three-week frequency, especially in patients with a

high baseline Hb levels (i.e., >10 g/dL), transitioning to erythrocytapheresis rather than PME may help to maintain better HbS control.<sup>222,223</sup> Alternatively, the addition of hydroxyurea to patients who are chronically transfused has been shown to increase fetal Hb and total Hb, reduce HbS,<sup>224</sup> and potentially decrease transfusion requirements.<sup>225</sup>

The post-transfusion target Hct for patients receiving chronic erythrocytapheresis is dependent on the patient's pre-exchange Hct and HbS, and the degree of iron overload (if present). The goal of chronic erythrocytapheresis for iron overload management is not marrow suppression but rather reducing HbS. Consequently, for optimal iron overload management, the postexchange Hct should be approximately equal to the pre-exchange Hct level. This ensures a net zero iron balance for the RCE procedure.<sup>226,227</sup> In these instances, patients without preceding iron overload will not need iron chelation, and those with iron overload will have efficient chelation due to near-zero cumulative iron burden. Patients with a lower baseline Hct (<25%) probably should have postexchange Hct targeted at 27%, unless under certain circumstances of severe iron overload. Patients who are difficult to maintain at an HbS level under 30% may benefit from a higher postexchange targeted Hct in order to induce transient suppression of erythropoiesis. In patients with higher baseline Hct, IHD-RCE may also be utilized to further increase the exchange efficiency by reducing the postexchange fraction of HbS-containing cells (FCR) remaining.

The Hb target for patients with TDT and hereditary hemolytic anemias is higher than that for SCD patients. For TDT, the pretransfusion hemoglobin should be maintained between 9 and 10 g/dL. This may require monthly transfusion in infants and young children, with transfusions every three weeks in adolescent and adult patients. The post-transfusion Hb should be targeted at 12–13 g/dL. Hypersplenism from splenomegaly can lead to an increase in transfusion requirements. Splenectomy can reduce the annual RBC requirement and should be considered if the annual blood requirement is over 200 mL/kg/year. Prior to splenectomy, patients should be fully immunized against encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenza*, and *Neisseria meningitidis*). Luspatercept, which has been shown to decrease transfusion burden in adult TDT patients, may also be considered in patients with high annual blood requirement.<sup>172,228</sup>

All patients on chronic transfusions should have annual total blood requirement evaluated. Patients with greater than 200 mL/kg/year are difficult or impossible to treat for iron overload with chelation because of the high annual net iron burden from transfusion. Causes for such a high transfusion requirement should be explored, and strategies to decrease transfusion burden should be sought (i.e., in SCD, transition to chronic erythrocytapheresis; in thalassemia, consider splenectomy and/or use of luspatercept).

Baseline testing for HIV, hepatitis B (HBV), and hepatitis C (HCV), and liver function is recommended prior to initiation of transfusions and annually thereafter while maintained on chronic transfusion therapy. HBV immunization and booster vaccination should be administered in all patients who do not have serologic evidence of immunity irrespective of previous or future planned transfusions.<sup>229</sup> Virology testing should be repeated if there is a rise in transaminases, and patients with positive serology for HBV or HCV infections should be referred to a hepatology specialist and followed for hepatocellular carcinoma.<sup>230</sup> All chronically transfused SCD and transfusion-dependent thalassemia patients are candidates for HSCT, so offering HLA-typing for them and their full siblings is advised.<sup>231,232</sup>

## Transfusion complications

### Alloimmunization

Patients with SCD are more susceptible to developing RBC alloantibodies than any other multiply transfused patient population. Although the mechanism underlying increased susceptibility to alloimmunization is unclear, several possibilities have been proposed. Patients with SCD show evidence of increased inflammation at baseline which is accentuated during times of illness. Resultant changes to the innate and adaptive immune systems have been proposed to influence the development of RBC alloantibodies and autoantibodies. The chronic hemolysis in SCD, with resultant constitutively elevated plasma free heme and Hb, has been shown to induce proinflammatory effects on both the innate and adaptive immune systems. This chronic hemolysis and inflammation results in significant immune dysregulation observed in SCD patients and murine models. These effects include abnormal immune cell responses, specifically in regulatory B cells, regulatory T cells, and other T-cell subsets such as follicular T cells and TH17 cells, which have correlated with RBC alloimmunization.<sup>233–237</sup> Furthermore, alloimmunization risk has been shown to be increased when SCD patients are transfused during acute sickle-related events, which are marked by significant inflammation.<sup>238</sup>

A more obvious risk factor relates to greater RBC antigen disparity between donor and SCD recipients. Consistent with this are observations that SCD patients are disproportionately African/African American (or members of other minority groups), while blood donors are historically more often of European descent. Individuals of African descent have different blood group distributions relative to most blood donors, and the most common antibodies formed in SCD patients (against C, E, K, and Jk<sup>b</sup>) are related to the antigenic frequency discordance between donor and recipient (K+: 9% vs. 2%; E+: 35% vs. 24%; C+: 68% vs. 28%; Jk<sup>b</sup>+: 72% vs. 39%, respectively).<sup>239</sup> These findings have prompted the use of transfusion protocols that minimize donor/recipient antigenic disparities by supporting SCD patients' transfusions through RBC units from ethnically matched (i.e., African American) and/or antigen-matched donors.

Because of the high prevalence of RBC alloimmunization in transfused SCD patients as well as the preponderance of alloantibodies to C, E, and K antigens, which comprise almost two-thirds of the antibodies detected, multiple international expert panel guidelines recommend primary serologic matching for Rh (D, C/c, and E/e) and K antigens.<sup>115,117,198,229</sup> Despite this approach, SCD patients remain at high risk of forming alloantibodies to Rh epitopes due to increased prevalence of *RHD* and *RHCE* variants in this population which encode altered or partial Rh antigens.<sup>240,241</sup> These antibodies can be mistaken for autoantibodies, which are common in SCD patients,<sup>242,243</sup> since the patients serologically type as antigen-positive for implicated antibody. Many of these Rh antibodies have been associated with laboratory evidence of delayed hemolytic transfusion reactions or demonstrated decreased survival of transfused RBCs.<sup>240,244</sup> Consequently, in alloimmunized SCD patients, future transfusions should be with antigen-negative or extended genotypic-matched RBCs, which poses significant challenges to transfusion services in providing compatible RBCs for these patients.

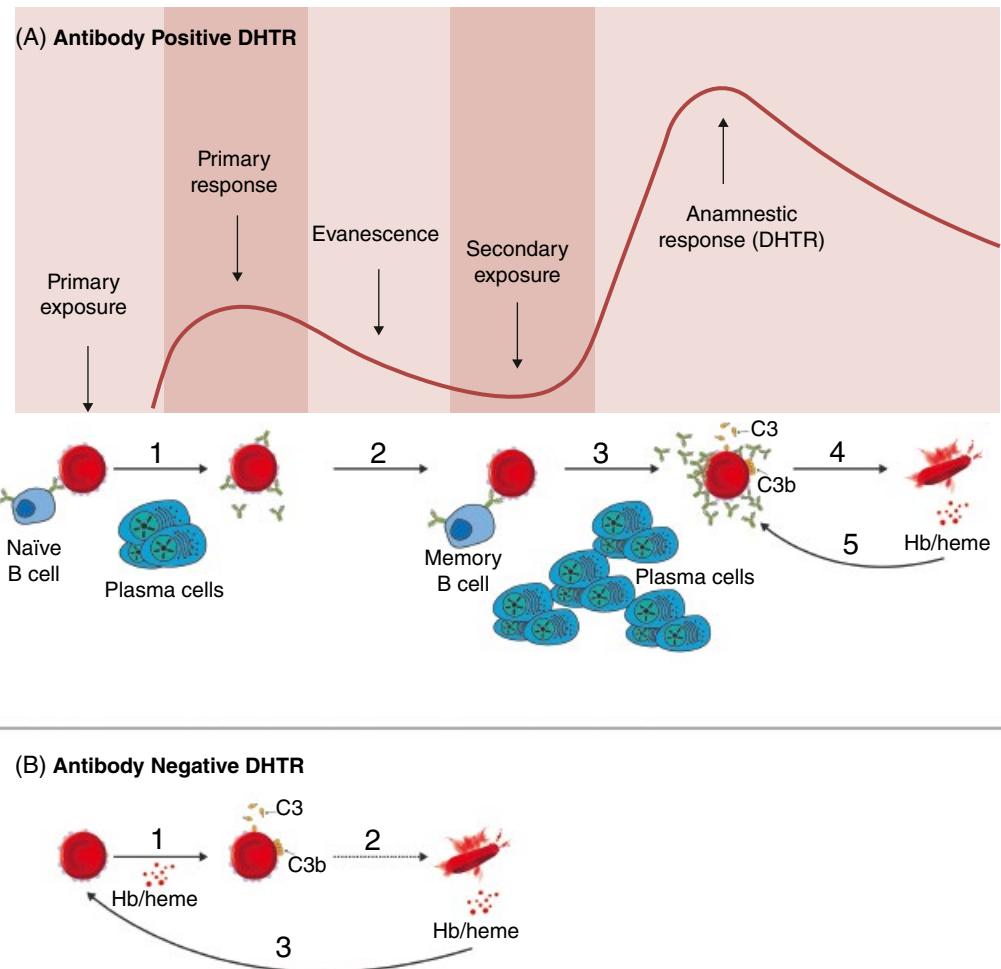

Alloimmunization should be considered, and an investigation for new antibodies should be undertaken, prior to transfusion in any chronically transfused patient if the pretransfusion Hb is significantly lower than baseline. Additionally, in SCD patients, a significant increase in HbS and reticulocyte count from baseline should also alert to a potentially new alloantibody. Autoantibodies

are known to obscure alloantibodies. Therefore, a high index of suspicion is needed to prevent delayed hemolytic transfusion reactions in patients who have an autoantibody because of the risk of an unidentified underlying alloantibody. RBC genotyping can facilitate complex antibody evaluations and guide RBC selection for these patients, who often require extended antigen-matched and/or rare RBC units.<sup>200</sup>

### Delayed hemolytic transfusion reactions and hyperhemolysis

In addition to significantly delaying the procurement of compatible RBCs for future transfusions, RBC alloimmunization increases the risk of potentially developing acute or delayed hemolytic transfusion reactions (DHTRs). DHTRs occur because more than one-third of RBC alloantibodies evanesce over time and fall below the level of detection by traditional blood bank serologic methodologies. When an individual is re-exposed through transfusion to

RBC antigens to which they have previously formed an antibody, immunological memory generated during the primary encounter can facilitate a rapid amnestic response resulting in the destruction of the transfused RBCs (see Figure 30.2).<sup>245</sup> SCD patients experience DHTRs at a significantly higher rate than other heavily transfused populations, with estimates of 4.4–7.7% of episodically transfused adult SCD patients experiencing at least one lifetime DHTR.<sup>246,247</sup> SCD patients transfused for acute complications are particularly more prone to DHTRs compared those receiving chronic transfusions, with reported incidences of 3.5–4.2 DHTRs per 100 transfusions compared to ≤0.1 DHTR per 100 transfusions, respectively.<sup>246–248</sup> However, the true incidence of DHTRs in SCD patients may actually be higher since many DHTRs go undiagnosed because they mimic common complications of SCD, such as vaso-occlusive crisis (VOC). A high index of suspicion is needed because DHTRs in SCD patients are associated with high mortality due to the potential for hyperhemolysis, a life-threatening phenomenon in

**Figure 30.2** Pathophysiology of delayed hemolytic transfusion reactions. (A) Antibody positive DHTR. Naive B cells are activated, proliferate, and differentiate into plasma cells upon initial exposure to RBC alloantigen (1). Antibody evanescence results from the lack of continued RBC antigen stimulation with subsequent diminution of circulating activated B cells but persistence of a memory B cell subset (2). Upon re-exposure to RBC alloantigen, memory B cells activate, proliferate, and differentiate into plasma cells resulting in a more robust antibody response (3). Antibodies engage with RBC alloantigens, with resultant alternative complement pathway activation and intravascular hemolysis (4). Subsequent release of plasma free heme and hemoglobin can contribute to continued complement activation and hyperhemolysis (5). (B) Antibody negative DHTR. Hemolytic transfusion reactions can result in the absence of detectable antibody and may in part be driven by heme-induced alternative complement pathway activation on transfused and autologous RBCs<sup>1</sup> and intravascular hemolysis.<sup>2</sup> Subsequent release of plasma free heme and hemoglobin can contribute to continued complement activation and hyperhemolysis.<sup>3</sup> Source: Based on Thein SL et al. (2020).<sup>245</sup>

which both transfused RBCs and the patient's own sickle erythrocytes are destroyed. Such hyperhemolysis has been shown to progress to ACS, hepatic impairment, renal failure, and death in 50%, 35%, 10%, and 6% of cases of DHTR in adults with SCD, respectively.<sup>249</sup> Although, less commonly seen, hyperhemolysis can occur in other populations, such as patients with thalassemia<sup>250</sup> as well as those without hemoglobinopathies.<sup>251</sup> For currently unknown reasons, select patients with SCD can also develop hyperhemolysis during acute sickle complications in the absence of recent transfusion (Figure 30.2).<sup>252,253</sup>

The most common presenting symptoms of DHTR include hematuria, pain (which is often indistinguishable from a typical VOC), fever, and symptoms of anemia, which occur up to 21 days after a transfusion. Laboratory findings include a significant drop in the total Hb, often below the pretransfusion level, a rapid decline of post-transfusion HbA level with a concomitant increase in the HbS, hemoglobinuria, relative reticulocytopenia or reticulocytosis, and a significant lactate dehydrogenase (LDH) rise from baseline.<sup>248,249</sup> Studies have failed to identify new RBC antibodies or a positive direct antiglobulin test (DAT) in approximately 30% of DHTRs in SCD patients.<sup>245,249</sup> Therefore, clinicians must rely on other laboratory and clinical findings in patients who have been recently transfused in order to make a reliable diagnosis of DHTR. In addition, RBC antibody evaluations should be completed at presentation and repeated at regular intervals for approximately three months from the diagnosis of DHTR in order to detect delayed formation of new antibodies that can inform antigen-negative unit selection for future transfusions. Some experts have recommended the use of a validated risk assessment nomogram for diagnosing DHTRs in adult SCD patients. This nomogram requires total Hb, HbA, and HbS levels to be obtained within 48 hours of an acute transfusion and again at the time a patient represents with symptoms concerning for a DHTR. A DHTR is deemed highly likely when a significant decrease in HbA (>50%) and/or in total Hb levels (>30%) relative to the post-transfusion values are observed, regardless of RBC antibodies being detected.<sup>247,254</sup>

Early recognition of a DHTR is critical to avoid additional transfusions, which may exacerbate the hyperhemolysis, and to initiate salvage treatment. There have been no prospective studies to guide therapy for patient with hyperhemolysis; however, immunosuppressive therapy with IVIG, corticosteroids, rituximab, and eculizumab have been used. High-dose erythropoietin with or without IV iron has also been recommended.<sup>117</sup> Recent studies have implicated alternative complement pathway activation in severe cases of DHTR with hyperhemolysis, and have shown reversal of complement activation, reduction in hemolysis, and rapid clinical improvement in SCD patients treated with an anti-C5 complement-blocking antibody.<sup>255,256</sup> Transfusions with extended antigen-matched RBCs should be reserved for patients experiencing life-threatening anemia.<sup>117</sup> Patients should be monitored for hypertension and fluid overload when they are receiving intensive therapy including transfusions for hyperhemolysis due to an association between transfusion, corticosteroid use, hypertension, intracranial hemorrhage, and stroke.<sup>257</sup>

Although DHTRs are not completely preventable, their incidence can be significantly reduced. Judicious use of transfusions and providing prophylactic antigen-matched RBCs when transfusions are indicated can decrease the incidence of alloimmunization, which poses an increased risk of subsequent DHTRs. Reliable communication within and between institutions, as well as discouraging patients from receiving multisite transfusions, can minimize the

likelihood of missing transient alloantibodies and re-exposure to evanesced alloantibodies. Lastly, identifying patients at high-risk for DHTRs (i.e., heavily alloimmunized patients and/or those with a history of past DHTRs) may inform the use of preventative measures and/or alternatives to transfusions when transfusions are being considered.<sup>245,248</sup>

### Iron overload

RBC units contain approximately 0.8 mg of iron per mL, most of which cannot be excreted from the body.<sup>258</sup> Consequently, a direct link can be observed between transfusion therapy and iron loading. Patients with TDT on a typical chronic transfusion schedule accumulate iron at a rate of 0.3–0.6 mg of iron/kg/day. Because of lower post-transfusion Hb target levels, SCD patients receiving chronic simple transfusions accumulate iron at a slightly lower rate (0.25–0.45 mg of iron/kg/day). The net iron accumulation can be minimized to a near iron-neutral balance in SCD patients by using chronic erythrocyapheresis, rather than simple transfusions.<sup>226</sup> Another key difference in iron loading between patients with SCD and thalassemia relates to the primary site of RBC destruction. In thalassemia, the hemolysis is predominantly within the bone marrow due to ineffective erythropoiesis, whereas in SCD the hemolysis is predominantly intravascular. Many patients with NTDT and some patients with other hereditary hemolytic anemias may also eventually develop iron overload despite low or no transfusion burden because of increased iron absorption due to ineffective erythropoiesis.

Ineffective erythropoiesis is a particular form of anemia which results in increased iron absorption from the gut and release of iron stores from macrophages and hepatocytes into circulation due to downregulation of hepcidin. Hepcidin negatively regulates cellular expression of ferroportin, a membrane transporter for iron entry into the circulation. Elevated erythroferrone secretion by an increased population of erythroblasts within the bone marrow results in the downregulation of hepatic production and increased expression of ferroportin. The resulting iron load is deposited into organs rather than being used to generate more erythrocytes.<sup>259</sup> Ineffective erythropoiesis, resulting in increased iron absorption, is the primary reason why many patients with NTDT eventually develop iron overload despite low transfusion burden. Hepcidin is also increased by inflammation. The proinflammatory state in SCD and its influence on iron overload have also been described and contrasted with that of thalassemia.<sup>226</sup> Hepcidin regulation is partly responsible for the decreased effects of iron loading in SCD compared to thalassemia and other hereditary anemias characterized by ineffective erythropoiesis.<sup>260</sup>

Nontransferrin bound iron (NTBI) and labile plasma iron (LPI), a highly reactive Fe<sup>2+</sup> subspecies of NTBI, rise considerably when the transferrin saturation reaches 60%.<sup>258</sup> Increases in NTBI and LPI are associated with tissue damage from iron overload. In fact, NTBI/LPI deposition in the liver, heart, and endocrine organs results in most of the significant morbidity from iron overload. Iron deposition in endocrine organs can result in growth failure, pubertal delay, diabetes, hypothyroidism, hypoparathyroidism, and hypogonadism. Hepatic fibrosis, cirrhosis, and hepatocellular carcinoma related to cumulative iron exposure can manifest later in life. Left ventricular dysfunction, congestive heart failure, and cardiac arrhythmias are the leading cause of death from iron overload. Due to the chronic inflammatory state and lack of ineffective erythropoiesis, there is less transferrin saturation and less NTBI in SCD compared to thalassemia. However, SCD patients

on chronic or recurrent episodic transfusions are also at risk for iron overload with subsequent liver, endocrine, and/or cardiac dysfunction, and therefore should be monitored and treated similarly to thalassemia patients.

### Monitoring and treatment of iron overload

Monitoring and management of iron overload are an essential part of the treatment of patients with thalassemia, SCD, and hereditary hemolytic anemias requiring chronic or episodic transfusion. Recommendations for monitoring and treating iron overload are largely extrapolated from thalassemia guidelines. Transfusional iron burden should be monitored with serum ferritin levels, as well as liver and cardiac MRI. Serum ferritin is routinely available, but it results in inaccurate determination of iron loading when used alone, especially in SCD patients who are in a chronic proinflammatory state.<sup>261</sup> Therefore, following serial trends in serum ferritin are more informative than single results. Measurement of hepatic iron historically required liver biopsy; however, this has been largely replaced by noninvasive, magnetic resonance imaging (MRI) techniques. Liver iron quantification by R2 and R2\* MRI techniques has been shown to correlate well with liver iron content (LIC) determined by liver biopsy.<sup>262</sup> LIC should be measured by R2-MRI every 1–2 years in patients on chronic transfusions and/or if serum ferritin is consistently greater than 1000 ng/mL.<sup>117,171</sup> Cardiac T2\* MRI represents the gold standard for monitoring cardiac iron accumulation, not only because it allows the estimation of cardiac iron burden, but also because it can reliably evaluate cardiac function.<sup>171,263,264</sup> Cardiac T2\* MRI evaluation is recommended every 6–24 months in TDT patients based on the degree of existing iron overload and the patient's risk for cardiac dysfunction.<sup>171</sup> While less common in SCD patients, iron-induced cardiomyopathy is detectable in about 2.5% of those who are chronically transfused.<sup>265</sup> Consequently, while cardiac iron overload screening is not warranted for all chronically transfused SCD patients, it should be considered for individuals with a high iron burden (LIC >15 mg/g dry weight) for two years or more, history of exceptionally high LIC, evidence of end organ damage resulting from transfusional iron overload, or evidence of cardiac dysfunction.<sup>117</sup> It is advised to assess endocrine function including thyroid, parathyroid, pancreas, adrenal, pituitary glands, and bone density every 1–2 years for TDT.<sup>171</sup>

Iron chelation therapy (ICT) is typically initiated within 1–2 years of starting chronic transfusions, after 10–20 cumulative RBC units (>120 mL/kg), or when the serum ferritin is greater than 1000 ng/mL or the LIC is 7 mg/g dry weight or greater. ICT is typically titrated to maintain serum ferritin less than 1000 ng/mL and LIC less than 7 mg/g dry liver weight.<sup>266</sup> Continued rising iron levels should prompt an evaluation of ICT dose and compliance, the annual transfusion requirement (mL/kg/year), and liver function. Compliance with ICT is probably the most important factor in

reducing the morbidity of chronic transfusion therapy.<sup>267</sup> Frequent evaluation of compliance and counseling is necessary in most patients for effective therapy. The goal of ICT is to provide as much chelation exposure per 24 hour period as possible to reduce the toxic effects of NTBI/LPI.

There are currently three iron chelators approved for use in the United States. These include deferoxamine (DFO), deferasirox (DFX), and deferiprone (DFP). Although the side effects differ for each iron chelator, their adverse effects are all generally more likely when ICT doses are high relative to the level of iron overload.

Deferoxamine (DFO or Desferal®) has a short half-life and therefore only chelates iron during the time infused. DFO is licensed for patients above the age of two years and is administered subcutaneously as an 8–12 hour infusion at least five times a week as monotherapy. Depending on the degree of iron overload, the standard dose range is 20–40 mg/kg/day for children and up to 50–60 mg/kg/day for adults. Dosing should not exceed 40 mg/kg/day until growth has ceased in children.<sup>171</sup> Side effects of DFO are greater with lower levels of iron, which is why therapy is not started until serum ferritin levels reach 1000 ng/mL and why attention is required to avoid over-chelation below 1000 ng/mL. Ascorbic acid (vitamin C) 2–3 mg/kg/day (100–250 mg maximum) is given orally during DFO.

## CHAPTER 31

# Autoimmune hemolytic anemias and paroxysmal nocturnal hemoglobinuria

Christopher A. Tormey<sup>1</sup> & Alexa J. Siddon<sup>1,2</sup>

Hemolysis, which is the pathologic destruction of red blood cells (RBCs), can manifest secondary to many underlying disorders including vascular/mechanical problems, microangiopathic processes, congenital disorders of hemoglobin or the RBC membrane, and/or with the absence of critical enzymes. One of the most common means by which RBCs are destroyed is via the immune system, with two of the most important immune-mediated disorders being autoimmune hemolytic anemia (AIHA) and paroxysmal nocturnal hemoglobinuria (PNH).

Although AIHA and PNH share the feature of shortened RBC survival, and both involve immune-mediated cellular clearance, the mechanisms underlying these diseases are distinct as are the tools used for their diagnosis and treatment. Therefore, the aim of this chapter is to provide a comprehensive review of AIHA and PNH, with a particular emphasis on pathophysiology, approach to diagnosis, an overview of how these diseases are medically addressed, and finally challenges these disorders present in the setting of transfusion therapy.

## Autoimmune hemolytic anemias (AIHAs)

### Overall classification

The term AIHA is broad and does not refer to a single disorder but rather reflects a number of unique entities with the common feature of generation of autoantibodies against self-antigens present on the RBC surface. AIHAs are further classified or categorized according to either the reactivity phase (i.e., temperature) of the associated autoantibody or by their association with drug administration. As detailed in Table 31.1, there are three broad subtypes: warm AIHA, cold AIHA, and drug-induced immune hemolytic anemia (DIIHA).

Accordingly, warm AIHA is due to autoantibodies that optimally bind to donor or self RBCs at 37 °C (and typically are of IgG class). On the other hand, in cold AIHA, autoantibodies demonstrate highest reactivity and avidity for donor/self at temperatures below 37 °C. However, it is important to note that because some of these cold antibodies can demonstrate a property called broad thermal amplitude, they can be clinically significant in day-to-day life. As

discussed in detail later in this chapter, cold AIHA is further subdivided into two additional entities, largely dependent on the type of autoantibody mediating hemolysis: cold agglutinin disease (CAD), mediated by IgM class autoantibodies, and paroxysmal cold hemoglobinuria (PCH), mediated by IgG autoantibodies.<sup>1</sup>

The other major category of AIHA is associated with pharmacologic therapy. In DIIHA, autoantibodies (largely IgG in class) are induced by, or against, a drug or its metabolite. As detailed later, induced drug-related autoantibodies can mediate RBC destruction via several pathways.

### Warm autoimmune hemolytic anemia (WAIHA)

#### Epidemiology

The incidence of WAIHA is approximately 1–3 cases in 100,000 individuals per year.<sup>2–4</sup> Therefore, WAIHA is the most common type of immune-mediated clearance, accounting for about 80% of all AIHAs.<sup>5</sup> Individuals of all ages, from the first to the eighth decade of life, can be affected by AIHA (although the median age of onset is the sixth decade of life).<sup>4,6–11</sup> Some genetic factors may be at play in WAIHA, with prior studies demonstrating disease associations with HLA-B loci, as well as some “protection” from WAIHA among individuals expressing HLA-DQ6.<sup>11</sup>

#### Pathophysiology

WAIHA can be considered a primary disorder (that is, idiopathic in nature and not associated with any other disease) or arise as a secondary process in the context of another medical issue. Common diseases giving rise to secondary WAIHA include other autoimmune diseases (e.g., rheumatoid arthritis and systemic lupus erythematosus), lymphoproliferative disorders (e.g., chronic lymphocytic leukemia), infectious processes (e.g., viral illness), and immune dysregulation (e.g., common variable immunodeficiency and stem cell transplant).<sup>2,4,7–11</sup> In pediatric patients in particular, there is a strong association between genes driving primary immunodeficiencies and WAIHA.<sup>11</sup>

**Table 31.1** Classification of the Autoimmune Hemolytic Anemias**Warm Autoimmune Hemolytic Anemia**

- Autoantibodies with optimal reactivity at 37 °C
- Usually an IgG (sometimes due to IgA) autoantibody
- Etiologies
  - Primary: idiopathic
  - Secondary
    - Malignancies: leukemia, lymphoma, ovarian tumors
    - Autoimmune/connective tissue disorders: systemic lupus erythematosus
    - Immune dysregulation disorders, e.g., common variable immunodeficiency
    - Infectious diseases, e.g., HIV, respiratory pathogens

**Cold Autoimmune Hemolytic Anemia****I. Cold Agglutinin Disease**

- Autoantibodies with optimal reactivity at 0 °C, with higher thermal amplitudes in clinically significant disease
- Usually an IgM autoantibody
- Etiologies
  - Primary: idiopathic
  - Secondary: B-cell neoplasms, *Mycoplasma pneumoniae*, and infectious mononucleosis

**II. Paroxysmal Cold Hemoglobinuria**

- Autoantibodies with biphasic reactivity: binding of antibody at cold temperatures and hemolysis at 37 °C
- A particular IgG autoantibody called Donath–Landsteiner or biphasic hemolysin
- Etiologies
  - Primary: idiopathic
  - Secondary: tertiary syphilis, upper respiratory tract infection of viral origin

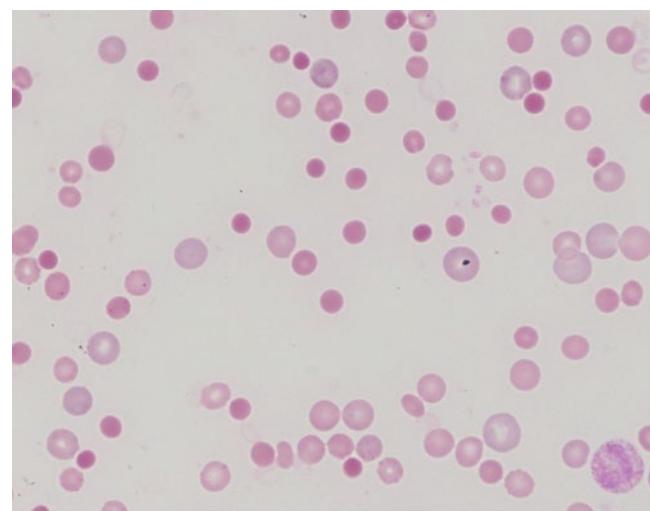

**Drug-Induced Immune Hemolytic Anemia**

- Autoantibodies usually reactive at warm temperatures
- Pathophysiologic mechanism
  - Drug adsorption mechanism
  - Immune complex mechanism
  - Autoimmune induction mechanism

Cases of WAIHA generally are split evenly among primary versus secondary causes in adults.<sup>4</sup> Most patients with primary or secondary disease are female.<sup>2,4,7–11</sup> Warm AIHA may also occur in association with thrombocytopenia, a combination known as Evans syndrome. Platelet destruction in this syndrome is a form of immune thrombocytopenia.<sup>12</sup>

Before delving into the specific pathophysiology of WAIHA, it is worthwhile to briefly review the mechanisms by which RBCs are hemolyzed *in vivo*; these mechanisms are important to understanding aspects of disease associated with WAIHA as well as the other immune-mediated hemolytic entities discussed in this chapter.

Overall, there are two distinct mechanisms of immune-mediated RBC destruction: extravascular hemolysis and intravascular hemolysis.<sup>9</sup> Macrophages located in the spleen and liver are largely responsible for extravascular hemolysis. The spleen is the most common site of extravascular clearance<sup>13</sup> since there is an opportunity for extensive interactions between antibody-coated red cells and macrophages created by the movement of red blood cells from the cords of Billroth through tiny gaps in sinusoidal walls to gain entry to the sinusoids.<sup>14</sup> However, the liver also participates in extravascular hemolysis when large amounts of IgG coat the red cells. This mechanism is important in asplenic patients.<sup>13</sup> On the other hand, intravascular, immune-mediated hemolysis is driven near-exclusively by complement fixation and direct cellular lysis.<sup>9</sup> While this section discusses each of these pathways in detail in the context of warm AIHA, these pathways are active in all potential forms of immune-mediated hemolysis.

**Figure 31.1** Common peripheral smear findings in warm autoimmune hemolytic anemia including microspherocytosis.

The hemolysis of warm AIHA usually proceeds via the extravascular mechanism since warm autoantibodies are typically IgG class and coat the RBC surface at 37 °C.<sup>9</sup> The antibody-coated red cells then circulate to the spleen and liver where macrophages adhere to the Fc portion of the IgG bound to the red cells.<sup>9,13</sup> Once bound to macrophages, the antibody-coated red cells are subjected to either complete or partial phagocytosis by the macrophage. Complete phagocytosis results in the removal of the antibody-coated red cells from circulation. Partial phagocytosis, which is more common,<sup>15</sup> results in the removal of a portion of the red cell membrane and the formation of microspherocytes (Figure 31.1).<sup>9</sup> Microspherocytes are released back into the circulation but have a decreased life span.<sup>15</sup> After a brief period of circulation, they pass back through the spleen where they are destroyed.<sup>16</sup>

The degree of extravascular hemolysis depends on the subclass of IgG, quantity of bound IgG, and antibody specificity. There are four subclasses of IgG: IgG<sub>1</sub>, IgG<sub>2</sub>, IgG<sub>3</sub>, and IgG<sub>4</sub>. Macrophage Fc receptors have the highest affinity for IgG<sub>1</sub> and IgG<sub>3</sub> subclasses.<sup>17,18</sup> Macrophages have variable affinity for IgG<sub>2</sub>, but they have the lowest affinity for IgG<sub>4</sub>. Accordingly, the most common subclasses of IgG found in clinically significant WAIHA are IgG<sub>1</sub> and IgG<sub>3</sub>, followed by IgG<sub>2</sub>. Subjects with IgG<sub>4</sub>-coated RBCs typically do not demonstrate significant hemolysis.<sup>1</sup>

Based on macrophage affinity, one might suspect that the greatest degree of extravascular hemolysis would be observed when red cells are coated by IgG<sub>1</sub> and IgG<sub>3</sub> subtypes. Although this is partly true, in the case of IgG<sub>1</sub>, the quantity of immunoglobulin coating each red cell also plays a role in the degree of hemolysis. Studies suggest that at least 1200 IgG<sub>1</sub> molecules<sup>17,18</sup> must coat each red cell before macrophages can effectively bind and subsequently phagocytose them. Consequently, there is a demonstrated relationship between the quantity of IgG<sub>1</sub> sensitizing the red cells and the severity of AIHA.<sup>19</sup> In contrast, IgG<sub>3</sub> is associated with hemolysis even when the quantity coating the red cells is too low to be detected by a direct antiglobulin test (DAT),<sup>1</sup> which is an average of 330–400 molecules.<sup>20,21</sup> In the case of IgG<sub>2</sub>, the situation is more complex. The gene that encodes the Fc receptor for IgG<sub>2</sub> on macrophages has two alleles, resulting in

differences in affinity. As a result, some people have macrophages with an Fc receptor that has a low-affinity for IgG<sub>2</sub>, and some are endowed with a receptor that has high affinity. Those individuals with high-affinity receptors for IgG<sub>2</sub> have the capacity to destroy IgG<sub>2</sub>-coated red cells, whereas those with low-affinity receptors rarely demonstrate IgG<sub>2</sub>-mediated hemolysis. With IgG<sub>2</sub> antibodies, the destruction of red cells is also influenced by antigen specificity. For example, studies have shown that IgG<sub>2</sub> alloantibodies against blood group A antigen lead to hemolysis, while hemolysis is not seen with IgG<sub>2</sub> antibodies directed against Rh antigens.<sup>22</sup> Despite the findings of differing Fc receptor affinity and IgG<sub>2</sub> alloantibody specificity, the role of IgG<sub>2</sub> autoantibodies in autoimmune hemolysis remains unclear. In summary, IgG<sub>1</sub> and IgG<sub>3</sub> antibodies are the primary mediators of red cell destruction in patients with AIHA, while IgG<sub>2</sub> antibodies are less important.<sup>1</sup>

Although WAIHA usually proceeds via the extravascular hemolysis mechanism, in some individuals presenting with severe hemolysis there may also be evidence of intravascular hemolysis,<sup>9</sup> the second pathway by which RBCs can be destroyed by the immune system. Intravascular hemolysis occurs when antibodies coating RBCs are capable of fixing and activating complement. In this setting, RBC destruction occurs by activation of the classical complement pathway, with ultimate formation of a membrane attack complex (MAC), resulting in pores in the RBC membrane. MAC formation eventually leads to cell swelling and finally lysis.<sup>9</sup>

The ability of antibody-coated RBCs to activate complement depends on many biological factors. In the setting of WAIHA, a largely IgG-driven process, important determinants of complement activation include the subclass and quantity of IgG coating the red cells. As with extravascular hemolysis, subclasses IgG<sub>1</sub> and IgG<sub>3</sub> are most commonly implicated in intravascular hemolysis as they are thought to be more efficient at fixing and activating complement than other IgG subclasses.<sup>23</sup> In addition, studies have demonstrated that a high density of cell-bound IgG is required to produce intravascular hemolysis,<sup>24</sup> likely due to the need for two IgG molecules to be in close proximity to allow for binding and activation of the complement system. Since a high number of IgG molecules are required to coat the RBCs before, by chance, two are in close proximity, the overall density would be expected to correlate with complement activation.<sup>13,25</sup>

Ultimately, despite attempts to divide hemolysis discretely into extravascular and intravascular mechanisms for the purpose of understanding the pathophysiology of AIHA disorders, they do not always occur uniformly in clinical situations. As such, and although extravascular hemolysis predominates in WAIHA, up to one-quarter of cases may demonstrate both forms of hemolysis.<sup>49</sup>

### Clinical features

WAIHA has a spectrum of clinical presentations. Severe anemia as a result of hemolysis can present with varying degrees of fatigue, fever, dizziness, angina, dyspnea, and flank pain, the latter most often correlating with a component of intravascular hemolysis. On the other hand, some patients will have a more slow, indolent course and only present to their physician with mild signs/symptoms. The severity of the onset and disease largely depends on the rate of hemolysis and the rate of decrease in hematocrit and hemoglobin. In chronic, lower grade (primarily extravascular) hemolytic anemia, the pace of the disease may allow for physiologic compensation and, therefore, less severe symptomatology and later presentation for clinical care. Patients may also develop jaundice, pallor, or dark

urine consistent with hemoglobinuria, causing them to seek care. Hepatosplenomegaly is present in approximately half of all WAIHA cases and may be particularly notable in WAIHA secondary to lymphoproliferative disorders.<sup>4,7,26</sup> Patients with idiopathic AIHA have been shown to be at increased risk for venous thromboembolism.<sup>7,27-29</sup> Since about half of WAIHA cases are due to secondary causes, the clinical presentation of the underlying cause may predominate.

### Laboratory findings

Complete blood counts will demonstrate typical features of anemia.<sup>30,31</sup> In a large case series of AIHA (with most reported patients demonstrating WAIHA), the median hematocrit was 24% and often associated with substantial reticulocytosis.<sup>4</sup> In cases of Evans syndrome, the platelet count is also low.<sup>12</sup> Other commonly encountered findings include elevated lactate dehydrogenase (LDH) and total/indirect bilirubin.<sup>4,31</sup> In cases with features of intravascular hemolysis, lab studies may demonstrate hemoglobinemia, hemoglobinuria, and decreased haptoglobin.<sup>4,31</sup> The peripheral blood smear typically shows evidence of extravascular hemolysis in the form of microspherocytes (Figure 31.1).<sup>31</sup> Due to the relatively short lifespan of microspherocytes, their presence in the peripheral blood should be taken as evidence for ongoing hemolysis.<sup>16</sup> Indirect evidence of bone marrow compensation, in the form of increased polychromatophils (morphologic evidence of reticulocytes) and even nucleated red blood cells (when hemolysis is brisk), may also be seen in the peripheral blood smear.

### Immunohematology findings

Serologic evaluation confirms that the hemolytic process is immune mediated. Both direct and indirect antiglobulin tests (DATs and IATs, respectively) may offer contributory findings. DATs use the patient's RBCs as well as polyspecific reagents, including both anti-IgG and anti-C3 (C3b and/or C3d). DATs are typically positive in patients with warm AIHA with findings as follows: +IgG alone is demonstrated in upward of 70–75% of WAIHA, with +IgG in combination with +C3 in about 25% of cases.<sup>32-37</sup> Complement alone is rarely found in pure warm AIHA mediated by IgG (Table 31.2).<sup>32,36,37</sup>

When the DAT demonstrates IgG, eluates can be performed. This laboratory technique essentially strips off the IgG antibody that is coating the patient's RBCs and attempts to reproduce the reactivity with separate donor/reagent commercial RBCs in an IAT-type reaction.<sup>33</sup> The expected IAT findings for an eluate in the setting of WAIHA is panagglutination, defined as reactivity with essentially all donor cells tested.

IATs can also be performed using the patient's serum or plasma. These reactions are performed via tube, gel, or solid phase methods at 37 °C, and typically also demonstrate IgG class autoantibodies in the serum or plasma that are pan-reactive against donor/reagent cells.<sup>33</sup> Reactivity against self is also demonstrable in IAT testing via the autologous control (autocontrol) test (i.e., patient plasma/serum incubated with the patient's own RBCs).<sup>33</sup> However, and notably, IATs are not as sensitive a marker for autoantibodies in the setting of WAIHA as compared with the DAT; IATs may be negative if the autoantibody is not present in high titer and/or the majority of it is adsorbed onto the patient's RBCs. Only when the amount of autoantibody exceeds the binding capacity of the patient's RBCs will the antibody be detectable in the patient's serum or plasma. Although upward of 95–97% of patients with WAIHA will have a positive

**Table 31.2** Typical Serologic Features of Autoimmune Hemolytic Anemia

	Warm Autoimmune Hemolytic Anemia	Cold Agglutinin Disease	Paroxysmal Cold Hemoglobinuria
Direct antiglobulin test	IgG only or IgG and C3; less commonly, C3 only	C3 only	C3 only
Immunoglobulin class	IgG, rarely IgA	IgM	IgG biphasic hemolysis
Eluate	IgG	Nonreactive	Nonreactive
Serum	IgG agglutinating red cells at the antihuman globulin phase, panagglutination	IgM agglutinating antibody, often with titers >1000, reacting at 30 °C in albumin	IgG biphasic hemolysis or Donath–Landsteiner antibody
Antibody specificity	Rh (most commonly)	I, i	P

Source: Based on Parker and Tormey (2017);<sup>32</sup> Petz and Garratty (1980);<sup>36</sup> Sokol et al. (1992).<sup>37</sup>

DAT, only 50–90% of patients will have a positive IAT, depending on the testing methodology.<sup>2,33</sup>

IgG-class autoantibodies in plasma/serum, or those eluted from RBCs, frequently demonstrate panagglutination when tested against commercially available reagent/donor RBCs. But what is the target of this pan-reactivity? Recently, studies have revealed that one highly conserved antigen system predominates as the target of panagglutinins—the external loops of the core RBC membrane protein band 3.<sup>38</sup> This helps to explain why autoantibodies appear reactive against essentially all donor/reagent cells in testing since this antigen/complex is found in >99% of individuals.

Occasionally, rather than demonstrating complete panagglutination, warm autoantibodies may demonstrate apparent blood group antigen specificity; these specificities are more often and more clearly seen in the plasma/serum as compared to the eluate.<sup>33</sup> This can present challenges for blood banks in truly differentiating between alloantibodies and autoantibodies. Clues that one may be dealing with an autoantibody rather than an alloantibody are a positive autocontrol (i.e., patient demonstrating reactivity against self) as well as phenotypic testing that indicates a patient expresses the antigen in question on their RBCs (in other words, if the detected reactivity were due to an alloantibody, one would expect the target antigen to be *lacking* on the patient's own RBCs). The most common specificities seen with autoantibody reactivity are antigens within the Rh blood group system, with autoantibodies described as demonstrating “e-like,” “C-like,” or other Rh-like specificity.<sup>33,39</sup>

Importantly, recent genetic studies have shown that Rh antigenic variants are common, particularly in patients of African descent. Since these Rh genetic variants can be associated with induction of clinically significant alloantibodies, transfusion services could potentially mistake an alloantibody for an autoantibody since patients with genetic Rh variants may demonstrate apparent normal/wild type antigen expression by *serological* methods. Because the presence of alloantibodies to Rh antigenic variants has treatment implications regarding provision of matched RBCs, if there is any doubt about whether reactivity seen is of autoantibody or alloantibody nature, then correlation with genetic studies is prudent.<sup>40</sup>

### DAT-negative warm AIHA

In up to 5% of patients with warm AIHA, the DAT is negative<sup>32–35</sup> indicating either the quantity of bound IgG is too low to be detected by a DAT, the bound autoantibody is not of the IgG immunoglobulin class, the hemolysis is being mediated by some other immune mechanism (e.g., cell-based cytotoxicity), the patient possesses very low affinity autoantibodies, or that the antibody-coated cells get rapidly destroyed and cleared and are therefore not detected by the DAT. Depending on subclass,

relatively few IgG molecules on the RBC surface can result in hemolysis, yet this number may be insufficient to produce a positive DAT.<sup>32</sup> Additionally, and although IgG is the most common immunoglobulin class associated with WAIHA, other immunoglobulin classes have been shown to cause AIHA, including IgA and IgM; these immunoglobulin classes are not detectable by routine DAT reagents (unless they are capable of fixing complement).<sup>9</sup> For example, in 14% of warm AIHA cases, IgA was found coating the red cells.<sup>41</sup> It should be noted that cases solely attributable to IgA autoantibody are rare (less than 1%) and often IgG and/or IgM are found in combination with IgA.<sup>42</sup>

In patients presenting with clinical features highly suggestive of warm AIHA but with negative serological testing, extended investigation should be performed because DAT-negative cases often respond to therapy for WAIHA. One means for assessing whether very low levels of IgG may be present in DAT negative cases is to perform elution studies on the patient's RBCs; as a test that concentrates antibodies, eluates may help to reveal low-level IgG reactivity.<sup>32,33</sup> Polybrene- or polyethylene-glycol-modified direct RBC assays may also be a more sensitive means for detection of low levels of IgG on the RBC surface.<sup>32</sup> Ultimately, if no auto-IgG can be demonstrated by these serological methods, then consideration could be given to using flow cytometry-based assays, or methods to identify surface IgA or IgM; however, these methods are rarely available and typically only offered in limited reference labs in the United States and internationally.<sup>32</sup>

### Positive DAT results in patients without hemolytic anemia

Confirmation of the immune-mediated cause of a suspected WAIHA should be sought and serology performed to determine the type of autoantibody that is coating RBCs. However, it is worth noting that disproportionate weight should not be placed on the results of the DAT. Up to 0.1% of healthy donors and 8% of general hospitalized patients were found to demonstrate a positive DAT in the absence of signs of hemolysis.<sup>43</sup> Although a positive DAT can provide supportive evidence for WAIHA in a patient with hemolysis, it is not independently indicative of the disease. Common causes of false-positive DATs (that is, positive assays in the absence of hemolysis) include polyclonal hypergammaglobulinemia, RBC rouleaux, intravenous immune globulin administration, antiphospholipid syndrome, and technical errors.<sup>32</sup> Therefore, the results of a DAT may be confirmed by eluate studies and, further, should always be interpreted in the context of the total clinical and laboratory picture.

### Treatment

Treatment in WAIHA is aimed at relieving clinical symptoms (e.g., symptomatic anemia) and transfusion dependence; typically, such treatment consists of immunosuppression and, as needed, transfusion support.<sup>44,45</sup> For secondary cases, addressing the

underlying disease also helps mitigate hemolysis. Treatment approaches are provided in more detail below.

### Corticosteroids

The primary initial treatment for warm AIHA is glucocorticoids.<sup>4,44</sup> A standard therapeutic approach for adults includes prednisone 1–2 mg/kg per day orally or an approximately equivalent dose of methylprednisolone via the intravenous route. Per a recent international expert consensus panel,<sup>44</sup> this therapy should generally be trialed for 2–3 weeks, with dose reduction if the patient shows an adequate response, and with treatment ceased within six months if hemolysis is no longer evident.

The efficacy of corticosteroid therapy is likely related to several factors. Steroids have been shown to have an early effect on tissue macrophages, leading to less efficient clearance of IgG- and C3-coated red blood cells within the first few days of therapy.<sup>46</sup> Steroids also affect antibody avidity and ultimately lead to a decrease in antibody production.<sup>47–49</sup>

If clinical relapse does occur, or if only a poor response is attained after the first few weeks of glucocorticoid therapy, then consensus guidance suggests initiation of other forms of immunosuppression, as described in the following sections.

### Monoclonal antibodies—rituximab and alemtuzumab

Rituximab is a genetically engineered monoclonal antibody against CD20. It targets B-cell precursors and mature B-cells. Consensus guidance, as well as other reported experience, recommends implementation of rituximab (1000 mg on Days 1 and 15, or 375 mg/m<sup>2</sup> weekly for four weeks) either in conjunction with corticosteroids as a first-line therapy, or alternatively, as a second-line therapy for cases of WAIHA failing to respond to first-line treatment.<sup>4,44,45,50–54</sup> Use of anti-CD20 as a single-agent therapy has been described in several case studies and retrospective reports, where it has been found to be efficacious in both adults and children with WAIHA resistant to therapy, including some patients with Evans syndrome.<sup>55–64</sup>

Alemtuzumab, a monoclonal anti-CD52 antibody that appears to modulate T-cell activation, has been used both as single-agent therapy and in combination with rituximab. However, its application to WAIHA has only been reported in a handful of papers, with side effects including immunosuppression and infections.<sup>65–67</sup> Current international guidance suggests implementation of anti-CD52 therapy only for refractory cases due to these risks.<sup>44</sup>

### Splenectomy

Splenectomy should be reserved for patients who show no response to corticosteroids, rituximab, or other pharmacological therapies.<sup>44</sup> While this procedure can be nearly as clinically effective as steroids<sup>45</sup> with 60–70% response within two weeks,<sup>50,51</sup> unfortunately many patients who clinically respond to splenectomy still require steroid therapy albeit at lower doses.<sup>52</sup> Despite an initial response, late clinical relapses are also still seen in some patients. These relapses are thought to be due to enhanced antibody production as well as increased clearance of antibody-coated red cells by the liver.<sup>7,49</sup>

It should be remembered that postsplenectomy patients are particularly vulnerable to infection by encapsulated bacteria. When these infections occur, patients can rapidly progress to septic shock due to an inability to efficiently clear the bacteria. Overwhelming sepsis represents a medical emergency with a risk of 3.2% and a

mortality rate of 1.4% in postsplenectomy patients.<sup>53</sup> If spleen removal is undertaken, then pneumococcal and meningococcal vaccines are strongly recommended to prevent infection and mortality in these patients.

### Other immunosuppressive and cytotoxic therapies

Treatment with azathioprine, mycophenolate, cyclophosphamide, antiplasma cell therapies (e.g., bortezomib), and danazol have demonstrated efficacy in reducing autoantibody formation and increasing hemoglobin levels.<sup>4,44,45,68,69–78</sup> However, these approaches are generally reserved for cases of WAIHA that are refractory to the aforementioned therapies.

The role for intravenous immunoglobulin (IVIG) remains unclear and is not recommended as a first- or second-line therapy by recent consensus guidance;<sup>44</sup> only 40% of patients respond to this therapy,<sup>79</sup> and the response is typically only sustained if IVIG infusions are continued on a chronic basis.<sup>80</sup>

Therapeutic plasma exchange may be used as a temporizing measure. However, it is neither effective nor practical for long-term treatment, particularly since IgG is only marginally removed by exchange and therefore should be reserved for severe or refractory cases. Severe warm AIHA is considered a Category III indication for plasma exchange therapy by the American Society for Apheresis (ASFA), suggesting that the optimal role of apheresis has not been established for this disease with only case reports and case series demonstrating (variable) efficacy.<sup>81</sup>

### Transfusion management

Support of patients with WAIHA often requires RBC transfusions for severe and/or life-threatening anemia. Due to the broad reactivity of autoantibodies in this disease, serologic evaluation to select appropriate RBC for transfusion can be complex and time-consuming. Sometimes transfusion is clinically required before the serologic workup is complete. Frequently, even after completion of the serologic workup, RBCs selected for transfusion are still incompatible with the patient's plasma. This finding should not be surprising given that most antibodies found in the patient's plasma/serum are broadly reactive panagglutinins. Transfusion of RBCs to a patient in true clinical need should not be delayed due to inability to find compatible RBC units. In fact, most patients with WAIHA show no adverse response to transfusion of serologically incompatible blood,<sup>82–84</sup> and the survival of transfused incompatible units is comparable to that expected for the patient's own RBCs.

When assessing the need for transfusion, it is helpful to recall that patients with chronic anemia have a long history of physiologic compensation. They may appear hemodynamically stable even with life-threatening anemia. The onset of confusion in a patient with worsening anemia and/or reticulocytopenia should warrant immediate transfusion. Even young adults and children with gradual onset of anemia should be transfused to maintain a hemoglobin level above 4 mg/dL; higher hemoglobin levels are needed for older patients and patients with cardiovascular disease.<sup>85</sup>

### Selection of blood for transfusion

ABO discrepancies and difficulty with Rh typing can arise in association with warm autoantibodies. When ABO discrepancy occurs, accurate ABO typing cannot proceed until the IgG autoantibody coating the red cells is removed. Rh typing may also be problematic,

although the use of monoclonal reagents may improve results in the setting of immunoglobulin-coated RBCs. When transfusion is urgent, group O RBC components can be issued and administered, even if ABO typing is incomplete.

In many patients with autoantibodies, their history of transfusion or pregnancy allows for the possibility of an alloantibody in addition to their autoantibodies. Underlying alloantibodies have been seen in up to 40% of patients with AIHA.<sup>82,86,87</sup> Thus, the identification of alloantibodies that may be obscured by the presence of a panreactive autoantibody is of great importance. The use of adsorption techniques is required for the removal of panagglutinins from the patient's plasma/serum so that any underlying alloantibodies can be tested against commercially available red cells for identification. Unfortunately, recent studies have shown that practices vary widely in the United States with regard to antibody identification in this setting, and there is no standard best practice.<sup>88</sup>

Autologous adsorption, utilizing the patient's own RBCs to draw off autoantibody, is a useful technique in patients who have not been transfused or undergone stem cell transplant in the last three months.<sup>88</sup> If the patient has been recently transfused or transplanted, allogeneic adsorptions may be required.<sup>89,90</sup> Adsorption techniques, particularly allogeneic adsorptions, are complex, labor intensive, and time consuming.<sup>86</sup> Therefore, they may be incomplete when a transfusion is clinically necessary.

Identifying the patient's phenotype aids in the provision of appropriate blood for transfusion by focusing the serological evaluation only on those alloantibody specificities the patient is capable of making. In some cases, it may be necessary or more expedient to infer the patient's phenotype from their genotype. Phenotypically matched RBC units should be safe for transfusion even when the alloantibody workup is unenlightening.<sup>87</sup> In addition, the provision of phenotype-matched blood may prevent the formation of alloantibodies, which may be seen in higher rates in patients with autoimmune disorders.<sup>91,92</sup>

Ultimately, most individuals with warm autoantibodies will not have fully crossmatch compatible RBC units available, and "least crossmatch incompatible" RBC units will be necessarily issued.<sup>93</sup> Certainly, such RBC units should be matched for any alloantibodies identified, either historically or by auto/alloadsorption techniques. As noted previously, some autoantibodies will mimic blood group antigen specificity.<sup>38</sup> While providing RBC units negative for these antigens may be associated with better *in vitro* compatibility by crossmatch techniques,<sup>38</sup> it is generally not necessary to match for these antigens in transfusion practice, particularly for more urgent needs.<sup>82</sup> For cases with severe or florid RBC hemolysis, it may be prudent to attempt what has been sometimes described as an "*in vivo*" crossmatch, wherein incompatible RBCs are infused slowly via a small "test" dose (15–20 mL at a slow rate), with subsequent observation for hemolysis or other symptoms. If said test dose is tolerated without issues, then the remainder of the unit can be infused at a regular rate with close observation.

Finally, and in the absence of symptomatic anemia, there is no distinct threshold at which patients with AIHA should be transfused. Decisions should be made, and products should be selected based on clinical need, comorbid conditions, and degree of compensation at the time of presentation.<sup>4,93</sup>

## Prognosis

Historically, the outcome of warm AIHA was poor, with a 38% mortality rate in the 1950s–1960s.<sup>26</sup> While treatments have dramatically improved over the past 60 years and WAHIA is often considered a mild-to-moderate condition, mortality can be still be

seen from severe disease or complications such as thromboembolic events or infection (secondary to therapy) in up to 5% of adult WAHIA patients.<sup>4,94</sup> The prognosis for children remains excellent,<sup>95–97</sup> with most experiencing self-limited disease.<sup>98,99</sup>

## Cold autoimmune hemolytic anemia

Many individuals will possess cold autoantibodies. However, most of these autoantibodies are benign and not associated with hemolysis. Those antibodies that are responsible for cold AIHA are unique in that, while they are strongly reactive at cold temperatures (i.e., 1–4 °C) they also demonstrate the property of reacting at warmer temperatures closer to core body temperature, a phenomenon known as broad thermal amplitude. Thus, within body parts more likely to be colder than core temperature (e.g., an extremity or tips of fingers, toes, ears, and nose), RBC–antibody interaction occurs and clinically significant hemolysis may ensue.

Unlike WAIHAs, cold AIHA is not a single entity but rather is further subdivided into the CAD and PCH, the unique features of which are described below.

## Cold agglutinin disease

### Epidemiology

CAD is rarer than WAIHA, but is considered overall the second most common immune-mediated hemolytic anemia, accounting for 15–25% of cases of AIHA and showing a slight female predominance.<sup>3,36,100</sup> In a large study of patients with CAD, 61% of patients were female, and the median age at diagnosis was 72 years;<sup>101</sup> this relative female preponderance and older age at the time of onset have been confirmed in other studies.<sup>100</sup>

### Pathophysiology

The primary driver of CAD is cold-reactive, IgM class autoantibodies. Such antibodies have been largely found to be encoded by the *IGH4-34* immunoglobulin heavy chain gene and are often associated with a monoclonal paraprotein of IgM class in serum.<sup>100</sup> Once formed, RBCs are coated with said IgM autoantibodies with binding classically at temperatures <37 °C. Such temperatures can be found in extremities, where autoantibody–RBC interaction occurs in the setting of environmental cold exposure.

Once bound, IgM fixes and activates the classical pathway of complement, leading to the generation and binding of C3 to the RBC surface. If a critical amount of C3 is generated by complement activation, the formation of the MAC may proceed, leading to cell lysis and intravascular hemolysis.<sup>9,100</sup>

If, on the other hand, the IgM has a narrower range of activity (or thermal amplitude), or individuals are relatively complement-deficient (e.g., in the setting of liver disease or recent complement consumption), intravascular hemolysis will be less likely. In these cases, C3 will be formed and bound below the amount needed to form the MAC.<sup>102,103</sup> C3-coated red cells circulate to the spleen and liver where macrophages recognize C3b, an opsonin, and RBCs are then phagocytosed resulting in primarily extravascular hemolysis.<sup>9</sup>

Simultaneously, complement regulatory proteins work to inactivate C3 bound to RBCs. Those RBCs whose bound complement has been inactivated will still circulate through the spleen and liver, although the spleen will not recognize the inactive bound complement.<sup>9</sup> The liver will recognize the inactive bound complement and

sequester these RBCs, frequently allowing them to return to the circulation after a period of time.<sup>100</sup> Thus, when hemolysis in CAD occurs by way of the extravascular system, it is generally at a decreased pace and lesser degree, as compared to intravascular hemolysis. In fact, extravascular hemolysis is the more common pathway in CAD, with only about 15% of patients demonstrating evidence of intravascular lysis.<sup>100</sup> Unlike extravascular RBC clearance in warm AIHA, in CAD, it more commonly occurs in the liver, likely via Kupffer cells.<sup>9,10</sup>

Although the pathways of intravascular and extravascular hemolysis in IgM-mediated CAD are discussed as separate entities for the purpose of understanding, in reality these pathways are often not discrete during disease flares. The percentage of hemolysis accounted for by each mechanism will depend on the titer of IgM, thermal amplitude of reactivity, immune competence of the patient, complement reserve/activity, and resultant number of RBCs with sufficient complement activation for MAC formation.<sup>9,10</sup>

Like WAIHA, CAD can be a primary/idiopathic disorder or can be associated with another disease and therefore be a secondary form of hemolysis. Common disorders that may give rise to, or be associated with, CAD include infectious processes (with a classical association with *Mycoplasma pneumoniae* infection) and lymphoproliferative disorders (e.g., lymphoplasmacytic lymphoma), among other entities.<sup>100</sup>

### Clinical features

As with other types of AIHA, patients with CAD present with symptoms of progressive anemia.<sup>104</sup> Given the pathophysiology, it is not surprising that there is an association between the thermal amplitude of the IgM autoantibody and severity of symptoms. Those patients having autoantibodies with a high thermal amplitude (i.e., immunologically reactive at higher temperatures) are more likely to have severe symptoms of hemolysis.<sup>105</sup> Those with low thermal amplitude, the more common occurrence, typically demonstrate an indolent course with a slower hemolytic rate.<sup>105</sup> Thermal amplitude is further described in Table 31.3. In either case, the anemia can be exacerbated by exposure to cold temperatures, such as during the winter or in a cold operating room, with acute hemolytic crises accompanied by frank hemoglobinuria. In addition, as with warm AIHA, the quantity of IgM, as measured by

titration, is associated with the degree of hemolysis and observable symptoms. A higher titer autoantibody is more likely to be clinically significant.

On physical examination, patients with CAD may demonstrate pallor and jaundice, consistent with hemolytic anemia. Acrocyanosis of the tip of the nose, ears, fingers, and toes is commonly reported with cold exposure<sup>101</sup> and resolves with warming.<sup>104</sup> Unlike warm AIHA, hepatosplenomegaly is not a major feature.<sup>101</sup> In patients with secondary CAD due to an underlying process, whether it be a malignancy or infection, the symptoms associated with the underlying disease may predominate.

Some other complications of CAD may also be seen. For instance, and not unlike WAIHA, there have been reports of increased thromboembolic events in severe CAD, possibly attributable to RBC destruction.<sup>100</sup> However, while such events have been seen in severe cases of CAD, there is insufficient evidence suggesting that thrombotic events are common in chronic or milder forms of this disease.

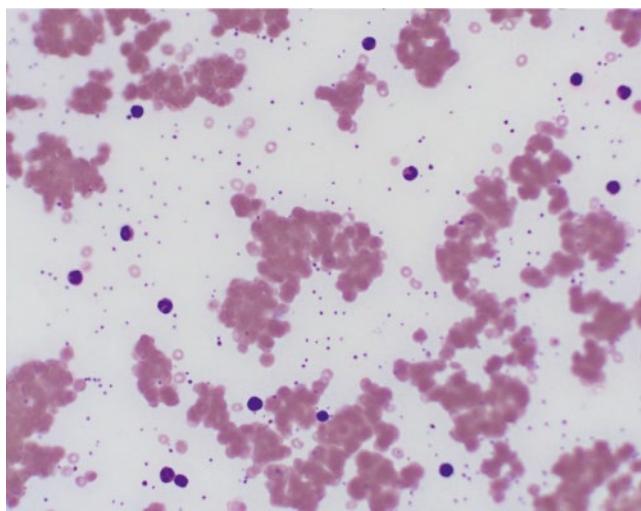

### Laboratory findings

The first noticeable finding may actually be observed at the time of collection of a blood sample, which may demonstrate "clumping" and a gelatinous appearance as it cools from body to room temperature. The agglutination may be reversible by warming the sample. If the specimen cools prior to receipt in the lab or throughout the process of automated testing, spurious results such as macrocytosis or marked elevations in the RBC index mean corpuscular hemoglobin concentration (MCHC) may be encountered.<sup>31,106</sup> These spurious results also provide early suggestion of this diagnosis. In order to avoid preanalytical testing problems, it is often necessary to maintain blood samples at 37 °C from the time of their collection, with immediate delivery to the laboratory for analysis. Otherwise, routine hematologic evaluation will reveal anemia with decreased hemoglobin; studies have shown that individuals with chronic CAD will possess median hemoglobin levels of 8–10 g/dL, although more profound anemia can be encountered.<sup>100</sup> The peripheral blood smear will show agglutination with the formation of irregular aggregates or clumps of RBCs (Figure 31.2). Other commonly encountered findings include elevated LDH and total/indirect bilirubin.<sup>4,31</sup> In cases with predominant features of intravascular hemolysis, lab studies may also demonstrate hemoglobinemia, hemoglobinuria, and decreased haptoglobin.<sup>4,31</sup>

**Table 31.3** Examples of Titer and Thermal Amplitude Studies in Cold Agglutinin Disease

Patient Specimen Dilutions	1:2	1:4	1:8	1:16	1:32	1:64	1:128	1:256	1:512
Adult donor RBCs*	4+	4+	4+	4+	4	4+	3+	2+	1+
"Cord" donor RBCs*	4+	3+	2+	1+	0	0	0	0	0
Incubation Temperature	4 °C	10 °C	15 °C	20 °C	25 °C	30 °C	35 °C	37 °C	40 °C
Adult donor RBCs*	4+	4+	4+	4+	3+	2+	1+	0	0
"Cord" donor RBCs*	4+	1+	0	0	0	0	0	0	0

\* Both adult and "cord" donor cells may be used in thermal amplitude and titer studies, or an adult or cord cell line may be chosen after initial titer studies depending on the strength of reactivity observed and the likely specificity of an autoantibody. In the demonstrated case, both cord and adult cells show similar reactivity at 4 °C, but as temperatures increase, the cold autoantibody in question reacts more strongly with adult cells, implying I-specificity, as can be seen in idiopathic cold agglutinin disease or acquired cold agglutinin disease associated with *Mycoplasma pneumoniae* infection. Given the reactivity to temperatures in excess of 25–30 °C, this cold agglutinin would be considered clinically significant.

**Figure 31.2** A typical example of peripheral blood smear findings in cold agglutinin disease, including large clusters of red cell agglutinates.

### Immunohematologic findings

In CAD, the cold-reactive, IgM autoantibodies (and/or their effects on RBCs) will be demonstrable in the blood bank. The DAT will be characteristically negative with monospecific IgG reagent but will be positive with C3 reagent (Table 31.2).<sup>32</sup> Eluate studies are typically not performed as they are not indicated in the setting of negative IgG DAT results. Instead, the possibility for IgM autoantibodies is further investigated by performing cold agglutinin titers and thermal amplitude measurements (Table 31.3).<sup>31</sup> Notably, thermal amplitude is the single most important determinant of the clinical significance of a cold agglutinin, followed by its titer.<sup>31</sup>

Thermal amplitude measurement is carried out across a range of temperatures up to 37 °C. Once reactivity is shown at temperatures above 28 °C, then said autoantibody should be considered potentially clinically significant. Moreover, while cases of clinically significant CAD are most often associated cold autoantibodies having a titer >>1:1000 (at least one study has shown that the median titer in CAD is 1:2048),<sup>100</sup> hemolysis can occur at titers as low as 1:64.<sup>31,100,107</sup> Because healthy individuals may have low-titer cold autoantibodies, it is important to avoid misidentifying a patient with another cause for anemia as CAD based upon low-titer antibodies, hence the reliance on thermal amplitude as the main indicator of clinical significance.

Cold screens or panels, testing the patient's serum/plasma against cord blood cells (possessing the i antigen) as well as adult RBCs (possessing the I antigen), can be used to determine if the autoantibody demonstrates blood group antigen specificity. The most frequent antibody specificities are anti-i or anti-I, with auto-anti-i most often associated with infectious mononucleosis/Epstein–Barr virus infection and auto-anti-I with *Mycoplasma pneumoniae* infection.<sup>108</sup> Other antigen specificities such as Pr have also been demonstrated, albeit rarely.<sup>31,33,109</sup>

IAT studies are less frequently impacted by cold agglutinins as incubation steps during pretesting can help eliminate the reactivity of many cold autoantibodies, even those that are clinically significant. Therefore, serum/plasma testing for cold autoantibodies is most often negative after incubation steps, allowing for the relatively straightforward identification of underlying/concomitant alloantibodies.<sup>33</sup>

### Positive cold agglutinins in patients without hemolytic anemia

Cold reactive autoantibodies are commonly found in normal individuals. As with warm AIHA, the serologic findings in suspected CAD should always be correlated with clinical presentation so as not to overstate their importance. Cold reactive autoantibodies in the absence of hemolysis are not diagnostic of CAD.<sup>33,100</sup>

### Treatment

Per recent international consensus guidance,<sup>44</sup> therapy for CAD depends upon the subclassification of the disease (i.e., primary vs. secondary) and patient symptoms. Various treatment approaches are briefly outlined below. Treating underlying diseases in secondary forms of CAD also helps to resolve hemolysis.

### Avoidance of cold

For many patients, particularly those with mild or asymptomatic disease, watchful waiting and avoidance of cold exposure are reasonable approaches to therapy. Many patients with mild, chronic anemia are able to use this simple tactic to avoid transfusions or targeted therapy for prolonged periods of time. Should cold exposure be unavoidable (e.g., in the setting of hypothermic surgery), warming techniques should be considered.<sup>110</sup> Notably, while broad thermal amplitude/clinically significant cold autoantibodies can be problematic in the setting of hypothermic surgery, a recent analysis indicated that, in general, clinically *insignificant* cold autoantibodies rarely cause complications in this setting and routine screening for such benign cold autoantibodies is not recommended preoperatively.<sup>111</sup>

### Monoclonal antibody therapy—rituximab and eculizumab

Should patients be more actively symptomatic or transfusion dependent, international consensus guidance, and other published experience, suggests rituximab as a reasonable first-line therapy.<sup>44,111</sup> One recommended dosing regimen is 375 mg/m<sup>2</sup> for four weeks at 7-day intervals, with prospective studies suggesting response rates of 50–80% with this approach.<sup>44,101,111–118</sup>

Consensus guidance also discusses first-line medical approaches for emergent/life-threatening situations in the setting of severe CAD (as anti-CD20 therapy will not result in an immediate reversal of symptoms or hemolysis). In such circumstances, and given the complement dependence of CAD, guidance recommends the use of anticomplement therapies such as the anti-C5 antibody, eculizumab, in conjunction with transfusion and/or apheresis.

### Cytotoxic/chemotherapeutic agents

Some guidance documents and studies recommend the addition of bendamustine (90 mg/m<sup>2</sup> Days 1 and 2 for cycles at 28-day intervals) to rituximab, as either part of first-line therapy or in cases of rituximab-only failures.<sup>44</sup> The addition of fludarabine to rituximab has also been reported as another second-line approach.<sup>44</sup> Antiplasma cell therapies (e.g., bortezomib),<sup>44</sup> which target mature antibody-secreting plasma cells that are not typically susceptible to anti-CD20 therapeutics such as rituximab, as well as chlorambucil have been used with some success.<sup>44,68</sup> If CAD remains refractory to all of the aforementioned approaches, then the consideration of other forms of therapy (e.g., ibrutinib) or enrollment in a clinical trial (e.g., those examining other forms of complement inhibition) may be warranted.<sup>44</sup>

### Other therapies

Therapeutic plasma exchange may be used as a temporizing measure, such as prior to surgery, but body temperature must be

maintained at 37 °C and the use of an inline blood warmer is strongly recommended.<sup>81</sup> The IgM autoantibodies in CAD have a larger intravascular volume and are more efficiently removed by apheresis than the IgG autoantibodies causing WAIHA. Based predominantly on evidence from case reports, ASFA has deemed severe CAD as a Category II indication for plasma exchange, indicating that apheresis is an acceptable second-line therapy.<sup>81</sup> It may also be trialed in cases of emergent/urgent or life-threatening disease.<sup>44</sup>

In contrast to WAIHA, treatments such as IVIG,<sup>39</sup> splenectomy,<sup>44,100</sup> and glucocorticoids<sup>44,100,103</sup> are rarely useful in patients with CAD. Treating underlying diseases in cases of secondary CAD is often helpful in resolving hemolysis.

### Transfusion management

Supportive care of patients with CAD occasionally includes RBC transfusion, particularly for severe, symptomatic anemia. Transfusion may be episodic and routine for those with well-controlled, mild, or chronic disease. Alternatively, it may be urgent for those presenting with an acute exacerbation due to cold exposure or intractable disease.

As with WAIHA, serology evaluation can be challenging, adding a layer of complexity to provision of appropriate blood components. For instance, accurate ABO typing in patients with CAD can be difficult as this analysis relies on RBC agglutination as an end point. Because the blood from patients with this disease agglutinates as the temperature declines and sometimes even at room temperature, cold agglutinins can interfere with ABO interpretation.

Warm washing of red cells to remove the IgM autoantibody may be utilized to facilitate accurate ABO typing. Ultimately, group O RBCs can be transfused if ABO typing cannot be reliably determined. For patients with a positive antibody screen, the distinction between a cold agglutinin reactive at room temperature and possible underlying alloantibodies must be made. As discussed previously, the use of a prewarming technique, where the patient sample is warmed before being tested against an antibody panel of commercially available red cells, may prove useful. If cold reactivity persists even after these steps, then other techniques (e.g., adsorption of the IgM in the patient plasma/serum with rabbit erythrocyte stroma [RESt] or destruction of the IgM with dithiothreitol) may be warranted.

One can attempt to determine the specificity of the autoantibody; often, and as mentioned previously, the antibody demonstrates specificity against the I or i antigen. However, this is mostly an informational undertaking and it is not necessary to transfuse blood that is negative for these specific antigens.

Finally, during actual administration of RBCs, patients should be kept warm. Transfusion with the use of a blood warmer is typically recommended to avoid cooling core body temperature and precipitating hemolysis,<sup>44</sup> although this step has not been definitively proven to be required.

### Prognosis

The prognosis for CAD is better than for WAIHA. Many patients have CAD as a transient problem following an infection and subsequently recover without recurrences. Other patients have a chronic, indolent course. However, there are reports of severe and even fatal CAD in the literature.<sup>120,121</sup>

## Paroxysmal cold hemoglobinuria

### Epidemiology

PCH is among the rarest forms of immune-mediated hemolysis, accounting for about 2% of all AIHAs.<sup>36</sup> It is most commonly seen in children, with a slight male > female predominance.<sup>6</sup> When

syphilis was more common, PCH was also seen in adults in association with tertiary infection. As the incidence of syphilis declined, so too did the incidence of PCH.

### Pathophysiology

In PCH, the responsible autoantibody is an unusual cold-reactive IgG autoantibody, called a biphasic hemolysin, or Donath–Landsteiner antibody. Unlike most IgG antibodies, this antibody binds to RBCs at cold temperatures and in the process irreversibly binds complement. At warmer temperatures, the antibody no longer stays bound. However, complement remains bound and becomes activated, leading to the formation of the MAC and resulting in intravascular hemolysis.

Similar to other AIHAs, PCH can be a primary/idiopathic disorder (extremely rarely) or much more commonly arise secondary to another disease. At present, PCH occurs most often in association with viral infections in children (e.g., upper respiratory illness) or following vaccination in that same population.<sup>6</sup> In adults, and other than the historical association with tertiary syphilis, it can occasionally arise secondary to autoimmune or lymphoproliferative disorders, among other entities.<sup>44</sup>

### Clinical features

The typical presentation is a child with a recent history of upper respiratory tract infection, generally noted a week or two before presentation.<sup>6</sup> Such individuals may demonstrate jaundice, pallor, fatigue, and/or fever, as well as report urine color changes.<sup>6</sup> Hepatosplenomegaly is not generally a prominent feature. Given the cold-dependent nature of the autoantibodies involved, a history of cold exposure triggering signs/symptoms may be reported.<sup>6</sup>

### Laboratory findings

PCH often presents with laboratory evidence of anemia, which may be quite severe due to intravascular hemolysis.<sup>122,123</sup> Reticulocytosis may be present, but there can also be reticulocytopenia. Otherwise, common lab findings include elevated LDH and total/indirect bilirubin as well as undetectable haptoglobin, consistent with a picture of intravascular hemolysis.<sup>4,31</sup> Hemoglobinemia and hemoglobinuria are also characteristically present.<sup>4,31</sup> The peripheral blood smear can demonstrate findings associated with hemolysis, including microspherocytes as well as fragmented forms. Erythrophagocytosis may also be seen (Figure 31.3).<sup>31</sup>

### Immunohematology findings

In patients with PCH, routine DATs are characteristically positive for C3 and negative for IgG; eluate studies are also negative. Although PCH is an IgG-mediated process, because of the exquisitely temperature-dependent nature of the autoantibody routine DAT studies do not demonstrate IgG, but only remnant RBC-bound complement (Table 31.2).<sup>31,33</sup> Similarly, and because of the cold-reactive nature of the IgG autoantibody, IAT studies are also traditionally negative. Like autoantibodies in other forms of AIHA, PCH autoantibodies demonstrate specificity for select RBC antigens, with the P antigen being the target of most Donath–Landsteiner antibodies.

A unique serological assay, called the Donath–Landsteiner test, can be useful to cinch a suspected diagnosis of PCH.<sup>31</sup> This test confirms the biphasic nature of this antibody. As detailed in Table 31.4, the patient's serum is reacted against donor RBCs with and without normal serum (as a fresh source of complement) at various temperatures, including one reaction that takes the specimen from cold to warm.<sup>31,33</sup> Hemolysis occurring in this latter

specimen (Figure 31.4), along with the absence of hemolysis in tubes maintained at only cold or warm temperatures, confirms a Donath–Landsteiner antibody and a diagnosis of PCH. Critically important to this assay is using a freshly collected serum specimen that is maintained at warm temperatures and immediately delivered to the lab for processing such that the reactivity of the cold-dependent antibody is preserved in vitro.<sup>31</sup>

### Treatment

Although the presentation is dramatic, the majority of cases of PCH in children are self-limited and abate as the triggering illness resolves. Therefore, young patients with PCH primarily require supportive care (potentially including RBC transfusion) and cold avoidance during their acute illness. Adults with chronic or more severe disease may benefit from immunosuppression; rituximab has been reported to be successful in such cases.<sup>44</sup> Glucocorticoids and complement inhibition (e.g., eculizumab) may also be an option for more severe or refractory cases,<sup>44</sup> although there is very limited evidence on outcomes with this approach.

### Transfusion management

Since the disease is typically self-limited, transfusion is usually only required in the acute hemolytic phase.<sup>6,44</sup> Selection of RBCs appropriate for transfusion is aided by the fact that the causative

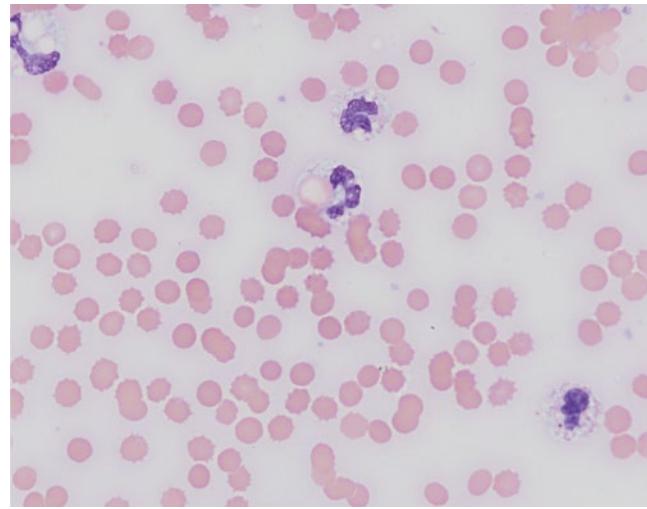

biphasic autoantibody does not often interfere with pretransfusion compatibility testing given its cold-reactive nature. Despite most PCH autoantibodies demonstrating specificity for the P antigen, P-antigen-negative RBC units are scarce. From an empirical perspective, if the patient is maintained in a warm environment and RBC units are infused via an approved blood warmer, then randomly selected donor RBCs should suffice without exacerbating hemolysis. As with other forms of AIHA, small “test” doses of RBCs may be warranted to see if units are well tolerated before increasing infusion rates.

### Prognosis

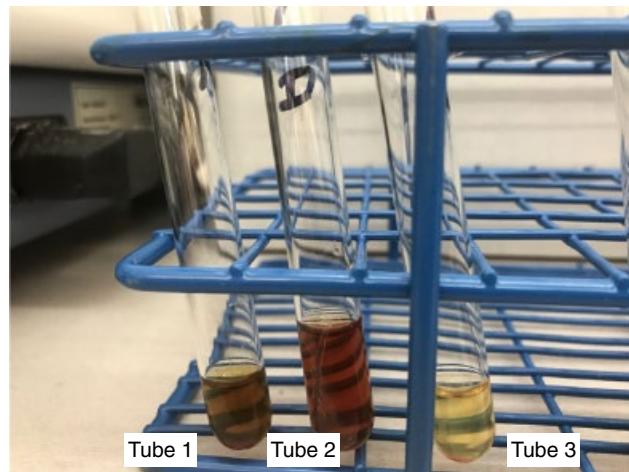

The prognosis is excellent, with the disease in its secondary form most commonly following a self-limited course over a few days to weeks in most cases. The greatest risk to patients is in the acute phase when they may present with severe anemia and require transfusion and supportive treatment.

### Mixed AIHA

In addition to the outlined distinct entities of WAIHA and CAD, some patients present with elements of both forms of these disorders, and therefore this disease process is called mixed AIHA. While there may be a predominance of one type over another, laboratory and clinical findings ultimately overlap and present a picture as outlined in previous sections on WAIHA and CAD.

**Figure 31.3** Erythrophagocytosis in a case of paroxysmal cold hemoglobinuria. This case was associated with a strongly C3+ DAT, intravascular hemolysis, and onset following adenovirus infection.

**Figure 31.4** Positive Donath–Landsteiner test in specimens cooled and then warmed to body temperature; Tube 1 (with supernatant hemolysis) reflects patient's serum + donor RBCs; Tube 2 (also with supernatant hemolysis) reflects patient's serum + donor RBCs + donor serum to supplement complement; and Tube 3 is a control tube, showing no hemolysis in the supernatant.

**Table 31.4** The Donath–Landsteiner Test: Serological Aspects and Expected Outcomes in a Patient with Paroxysmal Cold Hemoglobinuria (PCH)

	Tube 1*	Tube 2*	Tube 3*
<b>Contents</b>	Pt serum + donor RBCs	Pt serum + donor RBCs + fresh donor serum**	Donor RBCs + fresh donor serum [CONTROL]
<b>Specimen</b>	-30 min @ 1–4 °C	-30 min @ 1–4 °C	-30 min @ 1–4 °C
<b>Incubation</b>	-60 min @ 37 °C	-60 min @ 37 °C	-60 min @ 37 °C
<b>Results</b>	Mild–moderate hemolysis in supernatant	Moderate–severe hemolysis in supernatant	No hemolysis in supernatant

\*In parallel, each of the steps is repeated, only with variation in incubation steps. That is, another set of experiments are performed with Tubes 1–3 maintained at 1–4 °C only for 90 minutes and another set of experiments are done with Tubes 1–3 maintained at 37 °C only for 90 minutes. In cases of true PCH, no hemolysis should be observed in these parallel experiments, as the Donath–Landsteiner antibody only causes hemolysis in biphasic testing, that is when the temperature is increased from cold to warm.

\*\*Fresh serum is added in Tube 2 to supplement complement; this is done in case individuals are relatively complement-deficient at the time of testing due to complement consumption in the days leading to their presentation and testing.

Mixed AIHA comprises approximately 7% of all cases of idiopathic AIHA.<sup>124</sup> Like all other forms of immune-mediated hemolysis previously discussed, it can be primary or secondary to another disease process (e.g., autoimmune disease).<sup>125</sup>

While a relatively rare type of AIHA, this entity is a potentially hard-hitting form of disease, with many reported cases demonstrating severe symptom onset including fulminant, and sometimes fatal, hemolysis.<sup>44,126,127</sup> Like other AIHAs, mixed-type hemolysis can also be associated with complications beyond RBC destruction including thromboembolism.<sup>127,128</sup> As such, consensus guidance suggests an aggressive treatment approach combining corticosteroids with rituximab as a first-line therapy.<sup>44</sup> Nonetheless, relapse and/or refractoriness are common. Despite the mixed nature of the autoantibodies involved, splenectomy appears to be ineffective and avoidance of this procedure is recommended.<sup>44</sup> From a transfusion management perspective, guidance as outlined above following a combined approach for WAIHA and CAD is advised with the use of “least incompatible” RBC units frequently required as is the use of a blood warmer for infusion.<sup>127</sup>

## Drug-induced immune hemolytic anemia

### Epidemiology

Drug-induced immune hemolytic anemia (DIIHA) can occur in any age group and may be seen in association with a wide variety of medications, including prescription drugs, over-the-counter medications, herbal formulations, and toxins (Table 31.5).<sup>129–133</sup> The most commonly implicated drug class in current practice is antibiotics and, within this group, cephalosporins are very frequent drivers of DIIHA.<sup>129</sup> Among more recently introduced classes or agents of therapy, there have been increasing reports of immune checkpoint inhibitor medications also driving forms of DIIHA.<sup>131–133</sup> In a large case series of DIIHA, the odds ratio for developing immune hemolytic anemia was significantly increased with cotrimoxazole (trimethoprim/sulfamethoxazole), fludarabine, lorazepam, and diclofenac.<sup>130</sup> Notably, drug-induced/drug-associated RBC antibodies have also been detected in healthy blood donors.<sup>132</sup>

## Pathophysiology

DIIHA can be thought of as drug dependent (i.e., requisite for the drug to interact with the RBC surface in order for hemolysis to ensue) or drug independent (i.e., hemolysis can occur without the drug directly interacting with the RBC surface; autoantibodies are induced by the drug-immune system interaction with RBCs as a bystander).<sup>129–133</sup> Drug-independent hemolysis often closely mimics WAIHA, while drug-dependent hemolysis can be further divided into (1) the drug adsorption mechanism/model and (2) the immune complex mechanism/model.<sup>129</sup> We tackle each of these independently to review their distinct pathophysiologies.

In the drug-dependent/drug adsorption mechanism, thought to be the most common form DIIHA,<sup>129</sup> the drug attaches to the RBC surface. The resultant antibody formed is directed against the drug, with antibody binding to the drug while it is still bound to the red cell membrane. The entire antibody-drug-coated RBC compound is then cleared, typically via extravascular hemolysis. The prototypic drug associated with this mechanism is penicillin.<sup>129</sup>

In the drug-dependent/immune complex mechanism,<sup>9</sup> circulating drug stimulates the immune system to produce antibody directed against the drug. The antibody binds to the circulating drug, and the resulting immune complex can then bind to a red cell. It is unknown whether binding to the red cell is specific or nonspecific. The RBCs, coated by antibody-drug complexes, are typically removed via brisk, intravascular hemolysis. The prototypic drug for this mechanism is quinidine.

In the drug-independent mechanism, the drug induces autoantibody formation.<sup>129,132</sup> The resulting immune-mediated hemolytic anemia is essentially serologically and clinically indistinguishable from WAIHA. The autoantibody may persist even after the offending drug has been discontinued. The prototypic drug demonstrating this mechanism of immune hemolytic anemia is  $\alpha$ -methyldopa, a medication used in the past to treat hypertension.<sup>9,129,132</sup>

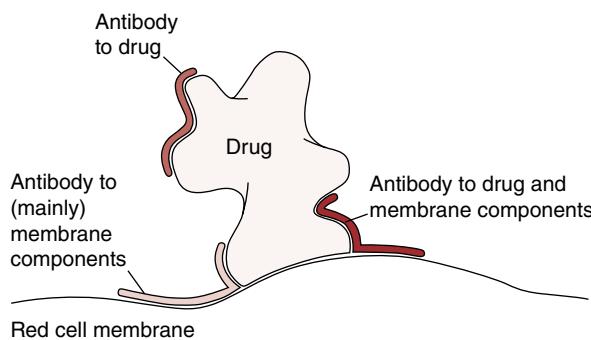

Finally, another relatively new concept in DIIHA is that of nonimmunological protein adsorption or NIPA.<sup>129,132</sup> In brief, drug-RBC interaction does not result in a drug-induced antibody per se, but drug interaction with, and binding to, the RBC

**Table 31.5** Classes of Drugs Associated with Drug-Induced Immune Hemolytic Anemia and Examples of Agents within Those Classes

Drug Classes		Some Reported Examples
Most Common	Antimicrobials, antivirals, and antifungals	Acyclovir, cefazolin, cefotetan, chloramphenicol, cloxacillin, isoniazid, ketoconazole, penicillin, rifampin, tazobactam, tetracycline, trimethoprim/sulfamethoxazole, and quinine
	Antineoplastics	Alemtuzumab, bendamustine, carboplatin, cladribine, fludarabine, imatinib, interferon, melphalan, methotrexate, oxaliplatin, rituximab, and vincristine
	NSAIDs and analgesics	Acetaminophen, apazone, aspirin, diclofenac, dipyrone, ibuprofen, mefenamic acid, methadone, nabumetone, and naproxen
	Antihypertensives and antiarrhythmics	Buthiazide, captopril, furosemide, hydralazine, methyldopa, procainamide, triamterene, and quinidine
	Immunosuppressants	Cyclosporin, hydrocortisone, lenalidomide, and tacrolimus
	Antihistamines	Antazoline, chlorpheniramine, cimedtidine, and ranitidine
	Antidiabetics	Chlorpropamide, insulin, tolbutamide, mesartoin, and phenytoin
	Anticonvulsants	Carbamazepine, cyclofenil, and diethylstilbestrol
	Endocrine system medications	Fluorescein, iomeprol, and metrizoic acid
	Imaging dyes	Carbromal and lorazepam
	Sedative-hypnotics	Nomifensine
	Antidepressants	Streptokinase
Least Common	Thrombolytic	Cianidanol
	Antidiarrheal	

Source: Based on Garratty (2012);<sup>129</sup> Garbe *et al.* (2011);<sup>130</sup> Michot *et al.* (2019).<sup>131</sup>

Data were compiled from several sources.<sup>129–133</sup> Drugs involved may cause hemolysis by one or more of the mechanisms discussed in the text and described in Figure 31.5.

**Figure 31.5** Proposed unifying theory of drug-induced antibody reactions. The thick lines represent antigen-binding sites of the drug-induced antibody. Antibodies may be made to the drug (producing in vitro reactions typical of a drug adsorption [penicillin-type] reaction), the membrane components or mainly membrane components (producing in vitro reactions typical of an autoantibody), or part-drug, part-membrane components (producing an in vitro reaction typical of the immune-complex mechanism).<sup>129</sup> This unifying theory was proposed by George Garratty, Ph.D. (1935–2014), who made significant contributions to the study of drug-induced immune hemolytic anemias. Source: Garratty (2004). Reproduced with permission.

membrane rather results in red cells being targeted for clearance by cellular components of the immune system (e.g., macrophages). These surface modifications may also give rise to changes in the RBC membrane sufficient enough to cause positive DAT results, although no specific antibody is ultimately identifiable.<sup>129,132,133</sup>

Although the explanation of these mechanisms as discrete entities is helpful to understand the many ways in which drugs, antibodies, and RBCs can interact, some patients have laboratory findings that overlap with more than one mechanism. A unifying theory was therefore proposed by Dr. George Garratty, which argues that the antibodies against the drug itself, against the red cell membrane, or components of both could be present simultaneously (Figure 31.5).<sup>123,132,133</sup> The specificity of the formed antibodies and immune reaction depends on the site of interaction between the drug and RBC. The unifying theory explains how patients may present with clinical evidence of multiple simultaneous pathophysiology of DIIHA.<sup>129,132</sup>

### Clinical features

The clinical presentation of DIIHA can be broad, ranging from mild anemia to severe hemolysis with hemoglobinemia and hemoglobinuria, as well as renal failure. As previously described, the hemolysis produced by the drug-independent mechanism is often indistinguishable from WAIHA. Moreover, while it is typically thought that DIIHA is most likely to impact individuals who have only recently started a new medication (i.e., in recent days to weeks), drug-induced hemolysis has also been reported to spontaneously develop in individuals on long-standing, chronic drug regimens.<sup>133</sup> Minimally, a patient should be actively taking a drug, or should have taken a drug within the prior 2–3 weeks, for DIIHA to be considered on the differential diagnosis.<sup>133</sup>

### Laboratory findings

DIIHA presents with laboratory evidence of anemia, which may be severe when there are components of intravascular hemolysis. Like all other AIHAs, common lab findings include elevated LDH and

total/indirect bilirubin.<sup>4,31</sup> Hemoglobinemia and hemoglobinuria also occur when DIIHA is associated with intravascular clearance.<sup>4,31</sup>

### Immunohematology findings

As with pathophysiology, the serologic findings can be divided according to the mechanism of DIIHA.

### Drug-dependent hemolysis—adsorption and immune complex

Starting with drug-dependent/drug absorption models, the DAT is positive in these patients, most commonly revealing IgG-only positivity.<sup>9,31,129,133</sup> Standard eluates and IATs are classically negative. Thus, the patient presenting with signs/symptoms of hemolysis with a positive DAT but negative IAT and eluate should raise suspicion for drug-dependent hemolysis.

When drug-dependent/drug adsorption DIIHA is suspected, further testing can be carried out to confirm this hypothesis. Traditionally, additional testing involves treating donor/reagent commercial RBCs with a solubilized form of the suspected drug.<sup>31</sup> Drug-treated RBCs (as well as untreated, control RBCs) are reacted with the patient's plasma/serum, as well as an eluate from the patient's RBCs. Positive reaction (plasma/serum +/- eluate) with drug-treated reagent RBCs, and negative reactions with untreated RBCs, is strongly suggestive of drug-dependent/drug-adsorption-mediated DIIHA.<sup>31</sup>

In cases of intravascular hemolysis presumed to be due-to-drug-dependent/immune complex mechanisms, the DAT is usually positive for complement. Similar to drug dependent/drug adsorption, the IAT or eluate may be positive if drug is added to the reaction, but this may not always be the case.<sup>31</sup>

Despite its great utility in evaluation for DIIHA, drug-dependent testing has some basic limitations. For instance, the process of drug treating RBCs may induce some false-positive results, not unlike that described in NIPA.<sup>31</sup> False negatives are also a concern; patients are often on multiple drugs and only one or two may be initially suspected to be driving hemolysis. Therefore, if initial candidate drugs fail to yield conclusive results and hemolysis continues, then it is reasonable to consider other drugs the patient is taking or has taken. Finally, hemolysis may not necessarily be attributable to a parent drug but rather one of its metabolites. Such scenarios can be very difficult to assess via in vitro testing and may cause a metabolite-dependent antibody to be missed.

### Drug-independent hemolysis

When patients demonstrate evidence of the drug-independent hemolysis, the serologic findings are essentially indistinguishable from those of WAIHA, with a DAT most commonly positive for IgG only as well as demonstration of panagglutinins in eluates, and panreactivity in IAT. These autoantibodies may persist after the drug is discontinued.<sup>129–135</sup>

In drug-independent cases, laboratory testing to definitively prove drug involvement in hemolysis becomes extremely complex. In fact, many drug-independent cases may be misclassified as primary WAIIHA due to the overlap in clinical and laboratory features. Because there is no drug bound to the RBC surface, drug-treated RBC assays are of no particular use in helping to establish the diagnosis. In these cases, clinical teams must entertain a broad differential and remember to include DIIHA on their list.

### Treatment

Treatment is aimed primarily at discontinuing the causative drug. Corticosteroids are often given, although there are only empirical data to support their use.<sup>133</sup> Intravenous immune globulin may also

be warranted in severe cases.<sup>133</sup> As in essentially all cases of DIIHA, if there is a strong clinical suspicion for this disorder (even with negative testing), then consideration must be given to stopping any drug that may have triggered the reaction.

### Transfusion management

Transfusion support may be necessary for patients presenting with severe anemia and guidance is similar to that discussed earlier for other forms of AIHA. In the case of hemolysis persisting even after discontinuation of the offending drug, as is presumed to be due to the autoimmune induction mechanism, a prolonged period of transfusion support may be required.

### Prognosis

The prognosis is generally excellent for this form of AIHA; full resolution of hemolysis is expected in many cases with drug cessation and/or immunosuppression. Notably, the offending drug or toxin must be avoided indefinitely to avoid provoking future immune stimuli and hemolysis.

### Paroxysmal nocturnal hemoglobinuria (PNH)

PNH is a rare type of hemolytic anemia that can present with thrombosis and bone marrow dysfunction on top of RBC destruction.<sup>136</sup> It is a clonal disorder of hematopoietic stem cells with its biochemical pathogenesis based in a somatic gene mutation.<sup>137</sup> The somatic mutation ultimately decreases the availability of an enzyme required for the synthesis of the anchor molecule, glycosylphosphatidylinositol (GPI), responsible for binding numerous proteins to the external surface of RBCs. Two of the affected proteins, which are responsible for the majority of symptoms seen in PNH, are the complement-regulatory proteins CD55 and CD59. Without GPI binding of CD55 and CD59 to the cell surface, RBCs lack their normal defenses against complement activation (primarily the alternative pathway) and have increased sensitivity to complement-mediated lysis.

### Epidemiology and risk factors

PNH is rare, occurring at a rate of approximately 1–10 cases per million people.<sup>138,139</sup> It has been diagnosed in patients of all ages.<sup>140,141</sup> The median age at diagnosis is early thirties.<sup>141–143</sup> Pediatric cases account for only 10% of reported cases of PNH.<sup>144,145</sup> No apparent gender predilection has been identified.<sup>142</sup>

Although PNH can occur de novo, virtually all patients demonstrate some degree of bone marrow failure.<sup>136</sup> Likewise, RBCs or granulocytes deficient in GPI-linked molecules, such as CD55 and CD59, are identified in a large number of patients with bone marrow disorders such as aplastic anemia and, to a lesser extent, low-risk myelodysplastic syndrome (MDS).<sup>142,146</sup> The leading hypothesis for this close association is that there is a selective growth advantage for PNH clones in these disorders; however, the exact etiology of PNH clones in these patients remains unclear.<sup>146–149</sup> Additionally, the finding of PNH clones may not always be clinically significant. In aplastic anemia and MDS, PNH clones are so commonly found that screening for undetected clones is not routinely recommended in patients with these disorders.<sup>150,151</sup> In most cases, the percentage of abnormal cells is so small that clinical symptoms are not observed and therapy for PNH is not indicated.<sup>146</sup> Furthermore, the stem cell mutations underlying PNH can even be found at a low frequency in healthy controls.<sup>152,153</sup> Therefore, many questions

remain unanswered, including what leads to multipotent stem cell mutations, why the clones sometimes expand to a high enough percentage to cause clinical disease, and why bone marrow failure exists in virtually all cases.

Although paroxysms of hemolysis may occur without preceding risk factors, it is generally agreed that factors leading to complement activation can trigger hemolytic episodes. In a person with underlying mutations giving rise to PNH clones, infection, trauma, pregnancy, and surgery are examples of known triggers of complement activation that can initiate a PNH paroxysm.<sup>154</sup>

### Pathophysiology

PNH is a clonal disorder of multipotent hematopoietic stem cells that ultimately causes increased sensitivity to complement in its progeny cells. In virtually all cases, a somatic mutation in the X-linked phosphatidylinositol glycan class A (PIG-A) gene underlies the disorder. The PIG-A gene encodes for the PIG-A enzyme, which is needed in the first step of biosynthesis of the GPI anchor molecule.<sup>137</sup> GPI anchor molecules are needed to bind numerous proteins to the external surface of hematopoietic cells.<sup>137</sup> The majority of symptoms seen in PNH are due to the lack of binding of two of the affected proteins, CD55 and CD59. These complement-regulatory proteins are normally needed on the external surface in order to neutralize complement activation. CD55 accelerates the destruction of C3 convertase, reducing the activation of complement component C3 which limits extravascular hemolysis by macrophages in the spleen and liver.<sup>155</sup> CD59 prevents the MAC from completing pore production in the lipid bilayer of the cell which, if it were unimpeded, would produce cell lysis through hypertonic swelling.<sup>156</sup> In brief, the PIG-A mutation leads to decreased or absent GPI molecules,<sup>137</sup> which, in turn, results in decreased or absent localization of proteins such as CD55 and CD59<sup>136</sup> to the cell surface and, ultimately, increased cell sensitivity to complement-mediated destruction.

Two conditions must be met in order for the mutation to cause clinical symptoms: it must occur in a multipotent hematopoietic stem cell, and the stem cell carrying the mutation must undergo clonal expansion.<sup>152,157</sup> Evidence for the former requirement is that rare, circulating blood cells with PNH mutations can be seen in healthy blood donors<sup>152,153</sup> and low-frequency PNH clones in MDS rarely, if ever, lead to clinical disease.<sup>136,158</sup> Mutations in these cases appear to arise in hematopoietic cells without self-renewal capacity. If the mutation occurs in a multipotent hematopoietic stem cell, it will result in hematopoietic progeny (e.g., RBCs, white blood cells, and platelets) that also harbor the mutation.<sup>136</sup> Patients with aplastic anemia, unlike those with MDS, more commonly develop PNH because mutations in these patients arise from multipotent hematopoietic stem cells.<sup>136</sup> Yet it is not enough that the mutations occur in a cell capable of creating progeny in all hematopoietic lineages. Low-frequency mutations do not cause clinical disease.<sup>146</sup> On the contrary, patients with greater than 20–25% of their neutrophils and greater than 3–5% of their RBCs lacking CD55 and CD59 surface proteins are more likely to demonstrate clinical signs of hemolysis and require specific treatment than those with lower values.<sup>146</sup> Likewise, patients with a higher proportion of PNH neutrophils (and monocytes) are more likely to demonstrate thrombosis,<sup>159</sup> with neutrophil clone sizes greater than 50% being highly predictive of thrombotic risk.<sup>160</sup> Although there are several purported hypothe-

ses,<sup>153,161–166</sup> the mechanism by which PNH cells can achieve clonal expansion remains unknown.

The ultimate clinical effect of having a sizeable PNH cell population depends on the type of surface protein and cells affected. Affected RBCs show CD59 that is either decreased (called type II PNH RBCs) or absent (called type III PNH RBCs) and, as a result, are exquisitely sensitive to intravascular hemolysis from complement activation. They also show decreased or absent CD55, causing them to be incapable of blocking C3 activation and making them vulnerable to extravascular hemolysis in the spleen and liver.

On the other hand, in platelets, the increased sensitivity to complement resulting from lack of CD55 and CD59 results in their inappropriate activation with a resulting increased risk of thrombosis.<sup>167</sup> In affected leukocytes, the absence of a receptor for urokinase-type plasminogen activator (also GPI-linked) reduces the potential of these cells to convert plasminogen to plasmin.<sup>168</sup> The decreased formation of plasmin, which has a significant role in fibrinolysis, may also lead to increased risk of thrombosis.<sup>169,170</sup> Although all patients with PNH are at risk for thrombosis, there is increased risk with larger PNH clone size.<sup>142</sup> When thrombosis occurs in PNH patients, it often does so in atypical locations such as the portal circulation, although the reason is unclear.<sup>136</sup>

Secondary effects of sizeable PNH clonal populations are also seen. Increased intravascular hemolysis leads to large amounts of free hemoglobin, which overwhelm the normal mechanisms of clearance, such as binding by haptoglobin.<sup>171,172</sup> The circulating free hemoglobin in plasma then scavenges and reacts with nitric oxide.<sup>172,173</sup> The depletion of nitric oxide is thought by some to contribute to arterial constriction, decreased blood flow to organs, kidney damage, and pulmonary hypertension.<sup>174</sup> However, others have speculated that chronic kidney disease in PNH is due to tubular damage caused by microvascular thrombosis<sup>175–177</sup> and iron deposition from hemolysis.<sup>136</sup> Microthrombi may also contribute to pulmonary hypertension.<sup>136</sup> Decreased nitric oxide may also lead to smooth muscle dystonia manifested as chronic dysphagia, abdominal pain, and erectile dysfunction.<sup>178</sup>

In patients with PNH clones and clinical hemolysis, the hemolysis typically occurs at a chronic baseline rate punctuated by episodic periods of an increased hemolytic rate. The pathophysiology of these episodic exacerbations of hemolysis is thought to be due to enhanced complement activation in certain situations; infection, trauma, pregnancy, surgery, strenuous physical activity, and alcohol use are examples of known triggers.<sup>154,179</sup> Additionally, the repletion of iron in a deficient patient is a known trigger of PNH exacerbations; it is thought to cause increased hemolysis by increasing the number of PNH clones.<sup>180</sup> Thus, both enhanced complement activation and increased PNH clone size may form the background upon which a PNH paroxysm occurs.

Finally, although the PIG-A mutation described is prototypical for and present in the vast majority of PNH cases, other mutations have been described.<sup>181,182</sup>

## Clinical findings

PNH classically presents with the triad of hemolytic anemia, thrombosis, and bone marrow dysfunction.<sup>136</sup> Because the clinical findings are variable, three clinical categories of PNH have been described. In classical PNH, patients frequently have >50% PNH granulocytes, and episodic hemolytic anemia accounts for the majority of the clinical picture. These patients may present with fatigue, jaundice, and a history of dark urine, consistent with

hemoglobinuria. The hemoglobinuria may be nocturnal as implied by the disease's moniker; however, it may also occur at other times. These patients are also the most likely to develop thrombosis.<sup>136</sup> The second category of PNH is clinically apparent disease occurring in the context of bone marrow disorders, most frequently aplastic anemia. In the context of an underlying bone marrow disorder, patients with PNH also present with symptoms of anemia. However, the anemia is more likely due to bone marrow failure, and these patients tend to demonstrate fewer symptoms suggestive of hemolysis (jaundice and dark urine). They often have low platelet counts and a lower risk of thrombosis. The third category is subclinical PNH. By definition, these patients are asymptomatic<sup>136</sup> and typically have less than 10% PNH RBCs or granulocytes in peripheral blood.<sup>136,150</sup> The discrete assignment of this disease into three clinical categories may be useful for understanding the variable clinical presentations, but it is not perfect. A particular point of confusion not addressed by these categories is that some element of bone marrow failure underlies virtually all PNH cases.

As mentioned above, patients with PNH clones and clinical hemolysis experience a chronic baseline rate of RBC destruction punctuated by episodes of increased hemolysis in the setting of known triggers.<sup>154,179</sup> Thrombosis is rarely the presenting symptom of PNH,<sup>183</sup> but it is common over the course of the disease and seen in up to 40% of patients.<sup>179</sup> Additionally, thrombi are the most common life-threatening complication in PNH.<sup>159,177</sup> The thromboses in PNH patients are often in atypical locations, most commonly affecting abdominal and cerebral vasculature, with veins more often affected than arteries. Commonly affected abdominal veins include the hepatic, portal, mesenteric, and splenic veins. The sagittal and cavernous sinuses are the most frequently affected cerebral vasculature. Overall, the most common site of thrombosis in these patients is the hepatic veins;<sup>136</sup> thrombi in this location cause a decrease in the normal flow of blood out of the liver, a process termed Budd-Chiari syndrome.<sup>184,185</sup> Despite frequently presenting in these atypical locations, thrombosis may occur in any site, and deep venous thrombosis, pulmonary emboli, and dermal thrombi are relatively common.<sup>136</sup> When thrombosis does occur, it tends to be progressive despite anticoagulant therapy.<sup>159,177</sup>

Patients with PNH may also present with symptoms of increased smooth muscle tone, manifested by chronic dysphagia, abdominal pain, and erectile dysfunction.<sup>178</sup> Over time, these patients may develop renal insufficiency and pulmonary hypertension. There is greater than a sixfold increase in risk of developing chronic kidney disease in PNH patients.<sup>175</sup> Although clinically significant pulmonary hypertension in PNH is rare, testing for terminal probrain natriuretic peptide<sup>186</sup> and transthoracic Doppler echocardiography<sup>187</sup> indicates that pulmonary hypertension is present in approximately half of these patients.

Most patients with PNH demonstrate a chronic illness that persists without therapy. Interestingly, a small subset of patients, up to 15% in a recent study, may achieve spontaneous, long-term remission.<sup>140</sup>

## Laboratory findings

Along with the variable clinical presentation of PNH, the associated laboratory findings vary as well. In classical PNH, which includes patients with intravascular hemolysis and the highest risk of thrombosis, one can expect to find anemia, reticulocytosis, elevated LDH,<sup>137</sup> elevated total bilirubin, and decreased haptoglobin. Bone

marrow evaluation demonstrates an overall hypercellular marrow with erythroid hyperplasia but no karyotypic abnormalities.<sup>150,188</sup> Patients with PNH in the context of an underlying bone marrow disorder also have anemia, but their laboratory results are typically dominated by the effects of bone marrow failure more so than intravascular hemolysis. These patients may have severe thrombocytopenia, normal or only mildly elevated LDH,<sup>136</sup> normal or only mildly elevated bilirubin,<sup>189</sup> and lower levels of reticulocytes than patients with classical PNH.<sup>136</sup> Patients with subclinical PNH have normal or only modestly aberrant blood counts.<sup>136</sup>

Peripheral blood smear findings are also variable and nonspecific, including a broad array of anisocytosis and poikilocytosis.<sup>190</sup>

## Immunohematology findings

### Blood bank testing

In PNH, the DAT and IAT are classically negative.<sup>189</sup> Nonetheless, patients undergoing eculizumab therapy may have a positive DAT for another reason; although this therapy prevents the formation of the MAC and intravascular lysis, it does not prevent C3 coating of RBCs.<sup>191–193</sup>

### Acidified serum test (HAM test)

The earliest confirmatory test for PNH was the acidified serum test or HAM test (named after its developer, Thomas Ham).<sup>194</sup> In this assay, RBCs are combined with acidified serum. PNH RBCs are more sensitive to complement and more likely to undergo lysis in the presence of acid, and spectrophotometry is utilized to quantify the amount of free hemoglobin that is liberated. This test is easy to perform, inexpensive, and reliable, but it cannot quantify the number of PNH cells present.<sup>195</sup> Also, a positive test is not specific for PNH and may be seen in other disorders leading to enhanced sensitivity to complement (such as congenital dyserythropoietic anemia type II [HEMPAS] where hemolysis is produced by an anti-HEMPAS antibody that binds complement).<sup>23</sup> Currently, due to more sensitive and specific results from flow cytometry, the HAM test is not widely used or recommended as a first-line diagnostic strategy.

### Flow cytometry

Because of its sensitivity and specificity for detection of PNH clones, flow cytometric testing has become the gold standard in the diagnosis of this entity. Classically, flow cytometry of the peripheral blood is aimed at detecting a marked reduction, or absence, of the GPI-anchored proteins, CD55 and CD59, on RBC or granulocyte surfaces. Monoclonal antibodies that bind each of these GPI-anchored proteins are tagged with a fluorescent label and combined with a patient sample, allowing the detection of cells capable of binding the antibody. This analysis provides useful information regarding the quantity of cells lacking or deficient in CD55 and CD59 as well as the strength of expression of these proteins on the cell surface.<sup>195</sup> In normal patients, all RBCs and granulocytes demonstrate strong expression of CD55 and CD59. In patients with PNH, by contrast, flow cytometry will demonstrate a variable proportion of red cells and/or granulocytes lacking CD55 and CD59 in addition to a population of cells with strong expression of these surface proteins.<sup>195</sup> Flow cytometry of monocytes and granulocytes may be more accurate, as their numbers are not affected by recent red blood cell transfusions or hemolysis. Lymphocytes can normally show variable expression of GPI-anchored proteins and are therefore undesirable for use in PNH diagnosis.<sup>195</sup> Ideally, PNH should be confirmed with findings of

decreased or absent GPI-anchor proteins in two or more cell lines.<sup>188,196</sup>

In recent years, flow cytometry testing for PNH has evolved to include fluorescent aerolysin (FLAER) in the analysis, which is also aimed at detecting a marked reduction or absence of GPI-anchored proteins. FLAER is based on the finding that GPI-anchored proteins can bind a bacterial toxin called aerolysin. PNH cells lack GPI-anchored proteins and therefore do not bind the aerolysin toxin. By tagging the aerolysin toxin with a fluorescent label, the amount of cells capable of binding the toxin and the strength of binding can be quantified (Figure 31.6).<sup>197</sup> The sensitivity of FLAER is much higher than that achieved with a CD55- and/or CD59-based assay.<sup>198</sup> The detection rate is further improved when the FLAER reagent is combined with fluorescent labeled antibodies for GPI-anchored proteins on granulocytes and monocytes.<sup>195</sup> Specifically, current recommendations use CD24 to specify GPI-anchored proteins on granulocytes and CD14 on monocytes (Figure 31.6).<sup>198</sup> RBCs are not commonly included in analysis with a FLAER assay as they express glycophorin, which is capable of weakly binding aerolysin and thus affecting assay accuracy.<sup>197</sup> Peripheral blood flow cytometric analysis is preferred to that of bone marrow for routine analysis as it represents an analysis of cells that are more homogeneous with respect to stage of maturation and expression of GPI-anchor proteins.<sup>195</sup>

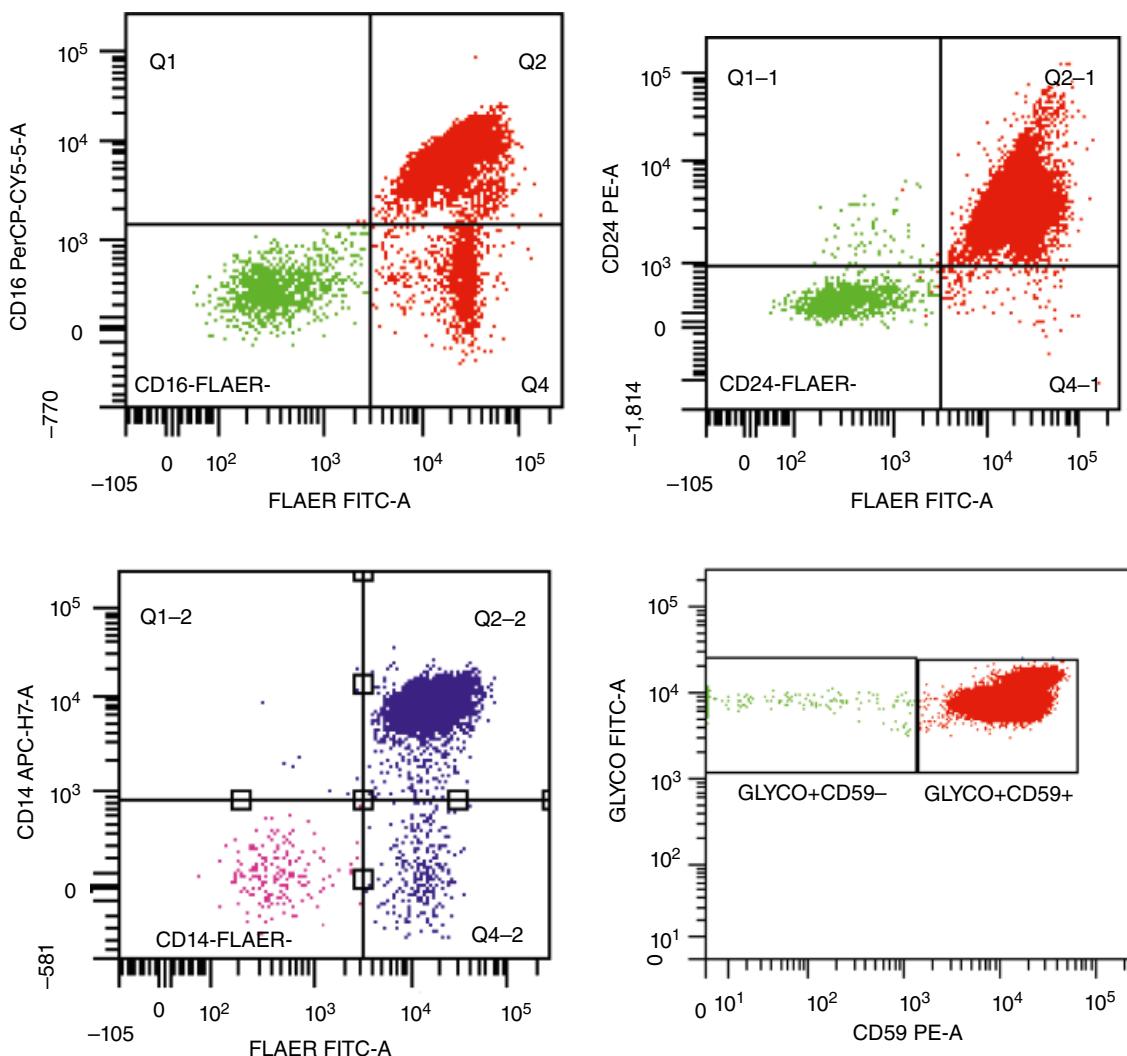

### Treatment

In treating PNH, the choice of therapy (or therapies) depends on the type of symptoms the patient is experiencing (hemolysis vs. thrombosis) as well as the degree of anemia. Indeed, therapy does not need to be initiated in an asymptomatic patient found to have PNH clones; these patients can be actively monitored for the development of symptoms.

### Anticoagulants and thrombolytic agents

Historically, anticoagulants represented one of the mainstays of therapy in PNH. Use of prophylactic anticoagulants has been recommended when >50% of neutrophil clones demonstrate the PNH phenotype.<sup>199–203</sup> Problems with anticoagulant therapy are nonetheless noted in the setting of PNH, including their lack of complete efficacy in preventing thrombotic events—in fact, the risk of thromboembolism in PNH remains high even with prophylaxis.<sup>177,202</sup> Additionally, anticoagulants increase the risk of bleeding, which may be compounded when patients also have thrombocytopenia.<sup>201</sup> Therefore, some experts recommend against routine prophylactic use of anticoagulants.<sup>201</sup> Nonetheless, patients with other underlying risks for thrombosis such as pregnant patients or patients undergoing a recent surgery and with prolonged immobilization should still be considered for prophylactic anticoagulation.<sup>201</sup> Unfortunately, even in patients with a history of thrombosis, anticoagulants are not always successful.<sup>150,188</sup>

Particular attention should be paid to clone size and symptoms of abdominal or chest pain. The risk of thrombotic events has been shown to correspond with clone size. In addition, patients with abdominal or chest pain have a greater risk of thrombosis.<sup>142</sup> Thrombolytic therapy with tissue plasminogen activator may be life-saving in severe thrombus formation, such as Budd-Chiari syndrome.<sup>203</sup>

**Figure 31.6** Examples of flow cytometric dot plots in a patient with paroxysmal nocturnal hemoglobinuria. The upper left and right panels demonstrate loss of GPI-linked proteins and/or anchors on granulocytes (CD16- and FLAER-; CD24- and FLAER-; these populations = PNH clone), while the lower left panel demonstrates loss of GPI-linked proteins and/or anchors on monocytes (CD14- and FLAER-; this population = PNH clone). Finally, the lower right panel demonstrates diminished-to-outright-loss of CD59 on red blood cells (this population = PNH RBC types II and III). Source: Based on Brodsky *et al.* (2000)<sup>197</sup> and Sutherland *et al.* (2018).<sup>198</sup>

### Eculizumab

Eculizumab is a monoclonal IgG antibody that binds to the C5 complement protein, thereby inhibiting the formation of the MAC<sup>204–207</sup> and reducing intravascular hemolysis of RBCs in patients with PNH.<sup>188</sup> Importantly, PNH patients receiving eculizumab also demonstrate thrombotic event rates that decline independent of anticoagulant therapy,<sup>203</sup> making eculizumab the recommended therapy for the majority of patients with PNH and thrombosis.<sup>204–209</sup> Despite these data, the discontinuation of anticoagulants in patients undergoing eculizumab is controversial,<sup>201</sup> and anticoagulants are still used in 70% of patients with PNH and a history of thrombotic event.<sup>142</sup>

Beyond thrombosis prevention, PNH patients on eculizumab show reduced utilization of RBC transfusions,<sup>176,204,207,208</sup> lower LDH levels,<sup>204,207</sup> and less nitric oxide depletion,<sup>191</sup> abdominal pain,<sup>208</sup> pulmonary hypertension,<sup>186</sup> and surgery-triggered hemolysis.<sup>210</sup> Eculizumab also leads to improvement in time-dependent renal function<sup>204</sup> and quality-of-life scores.<sup>186,205,206</sup>

Survival rates are significantly increased both in the short term and long term.<sup>176,204</sup> The reduction of LDH level is sustained over the course of treatment.<sup>204</sup> However, since PNH is a clonal process, this complement-inhibiting drug is not curative,<sup>211</sup> and therapy must be continued for life.<sup>137</sup> Some suggest prescribing eculizumab for patients with symptoms of hemolysis that are not managed by transfusion alone;<sup>212</sup> others use eculizumab in patients with fatigue that affects quality of life, transfusion dependence, thrombosis, frequent symptoms associated with smooth muscle dystonia (dysphagia, abdominal pain, or erectile dysfunction), renal insufficiency, or end-organ disease complications.<sup>188</sup> Its use may be particularly indicated in the perioperative period<sup>210,213</sup> or for pregnant patients.<sup>214–217</sup> See the “Special clinical situations” section later in this chapter for details.

Despite its successes, not all patients respond to eculizumab therapy, and some have persistent symptoms and chronic need for RBC transfusion.<sup>211</sup> Some patients who failed to respond were

found to have specific mutations of C5.<sup>218</sup> Other patients experienced continued extravascular hemolysis due to continued accumulation of C3 on the surface of RBCs.<sup>191,192,219</sup> Further support of this mechanism is the observation of positive DATs with anti-C3 reagent in patients undergoing eculizumab treatment.<sup>211</sup> Eculizumab does not treat underlying bone marrow failure.<sup>211</sup> Overall, eculizumab is well tolerated<sup>171,175,177,186,204–206,220</sup> with the occurrence of adverse events decreasing over time. There is no evidence for cumulative toxicity.<sup>204</sup> Notably, though, its use is associated with an increased risk of infection, particularly serious meningococcal infections. Meningococcal vaccine must be administered two weeks prior to treatment, patients' vaccination status should be kept up to date per current medical guidelines, and they should be followed for signs of infection to expedite prompt antibiotic treatment.<sup>207</sup> Ordering providers should be aware that Eculizumab is very costly, currently averaging over \$400,000 per year of treatment.<sup>211</sup>

### Hematopoietic cell transplantation

The only potentially curative therapy for PNH is allogeneic hematopoietic cell transplantation. However, transplantation using either bone marrow or peripheral blood stem cells as the graft source<sup>221</sup> is associated with substantial morbidity and mortality<sup>222–224</sup> including high rates of rejection, side effects from the preparative regimen, and graft-versus-host disease.<sup>221</sup> Hematopoietic cell transplantation is considered for patients with severe clinical symptoms who are unresponsive to eculizumab therapy or for whom eculizumab therapy is not an option due to cost or lack of availability.<sup>136</sup> Using bone marrow as a source of stem cells may lead to a lower incidence of graft-versus-host disease as compared to using peripheral blood.<sup>224</sup> Nonmyeloablative conditioning regimens show promise for improved outcomes and reduced morbidity and mortality.<sup>221,225–228</sup>

Hematopoietic cell transplantation may also be indicated for the treatment of the patient's underlying bone marrow disorder, independent of PNH.

### Immunosuppressive therapy

Patients with underlying bone marrow disorders, such as aplastic anemia, are more likely to receive immunosuppressive therapy with cyclosporine and/or antithymocyte globulin<sup>142</sup> than other PNH patients. Immunosuppressive, but not bone-marrow-suppressive, therapy is likely the most effective therapy in patients with underlying bone marrow disorders. Corticosteroids may reduce hemolysis and improve anemia in some patients, but they carry an added risk of long-term toxicity.<sup>188</sup> In addition, others have reported little success of corticosteroid therapy in patients with underlying bone marrow disorders,<sup>150</sup> and their use is therefore becoming less common.

### Other therapies

Given that eculizumab is successful in most PNH patients, but that some continue to have extravascular hemolysis due to C3 deposition, novel therapies targeting C3 and other components of the complement activation pathway are being tested in vitro and in animal models, with promising results.<sup>229–231</sup> For instance, ravulizumab is a new C5 inhibitor that is noninferior to eculizumab and may help to decrease breakthrough hemolysis.<sup>232</sup>

In patients with marked hemolysis, the replacement of iron (for iron-deficient patients), vitamin B<sub>12</sub>, and folate to support production of new RBCs may be indicated on a case-by-case basis;

iron replacement, however, should be done judiciously, given some reports of iron replacement triggering hemolysis as discussed earlier in this chapter.<sup>180</sup>

### Special clinical situations

Complement activation is triggered by infection, trauma, pregnancy, and surgery.<sup>154,210</sup> Therefore, the use of eculizumab may be particularly indicated in the perioperative period<sup>210,213</sup> or for pregnant patients.<sup>214–217</sup>

### Pregnancy

As previously discussed, pregnant patients with PNH frequently experience thrombosis. The risk of thrombosis in the setting of PNH is exacerbated by the hypercoagulability of pregnancy. Anticoagulant therapy may be an appropriate strategy to reduce morbidity and mortality during pregnancy. Eculizumab may also be useful and safe in pregnancy. The molecule is a hybrid IgG<sub>2</sub> and IgG<sub>4</sub>, and IgG<sub>2</sub> does not cross the placenta well.<sup>233</sup> However, only a handful of case reports on the use of eculizumab in pregnant PNH patients exist, and there is great heterogeneity in the use of therapy prior to pregnancy, time of discontinuation (either during or following pregnancy), and concomitant use of anticoagulant therapy.

Teratogenic effects of eculizumab have not been observed.<sup>214–216</sup> Fetal outcomes to date have been good.<sup>214–217</sup>

### Elective surgery

A few reports of perioperative eculizumab use suggest it may be helpful in preventing hemolytic paroxysms. One group reported successful cardiopulmonary bypass surgery in a PNH patient on maintenance therapy,<sup>213</sup> whereas another reported prevention of hemolysis using peri-operative induction with eculizumab for distal gastrectomy.<sup>210</sup>

### Underlying bone marrow disorders

Asymptomatic patients with PNH clones do not need to be treated for PNH. Many of these patients have underlying bone marrow disorders, such as aplastic anemia or MDS, and therapy should be targeted toward those conditions instead of PNH.<sup>188,214</sup>

### Children

PNH in children is rare; reports on their treatment are therefore also rare. Studies on the use of eculizumab in children have suggested that its use is safe and effective.<sup>234</sup>

### Transfusion management

Historically, blood transfusions were a mainstay of therapy for PNH patients with moderate-to-severe hemolysis and anemia. RBC administration is still recommended for patients with severe, symptomatic anemia. Unlike AIHAs, however, special testing and selection of specific RBCs for transfusion are not required in PNH unless the patient develops one or more alloantibodies (as can be seen with chronic transfusion needs). RBC components do not typically need special modifications, such as washing or irradiation, unless there are other reasons for these indications (e.g., irradiation for a PNH patient who has undergone stem cell transplantation). Leukoreduced components are recommended to help minimize febrile nonhemolytic transfusion reactions and human leukocyte antigen (HLA) alloimmunization. Previous reports of the need to

wash RBCs have been discredited because the hemolysis reported with unwashed cells was most likely due to minor incompatibilities. Platelet transfusion may also be given for a variety of clinical indications, including the treatment of sequelae in patients with thrombocytopenia undergoing anticoagulant and/or thrombolytic therapy.

### Prognosis

The 10-year survival rate for PNH patients in the past 50 years was poor, at about 50% from the 1940s–1970s.<sup>140,143,176</sup> More recently, the 10-year survival rate for PNH was 75%.<sup>235</sup> Further, one study showed that patients treated with eculizumab had similar survival as compared to age-matched controls.<sup>176</sup>

### Summary

Acquired disorders of hemolysis, such as AIHAs and PNH, can present myriad clinical, diagnostic, and transfusion medicine challenges. Knowledge of these entities, including their patho-

physiology, informs the treatment of these entities. The transfusion medicine community must also keep apprised of major therapeutic developments for these disorders as such treatments can also impact laboratory- and transfusion-related care.

## Background

In Western countries, in the late 1960s and early 1970s, hemolytic disease of the fetus and newborn (HDFN) was a common disease. Overt fetal or neonatal hemolysis, dominated by D alloimmunization, caused marked anemia. Severely affected neonates were often unstable at birth and required multiple exchange transfusions to avoid kernicterus. Furthermore, HDFN was associated with considerable neonatal morbidity and mortality.

In the affected fetus, anemia is the most important pathological component of HDFN. The anemia causes increased fetal erythropoiesis, which, in severe cases, leads to erythroblastosis with widespread extramedullary hematopoiesis and many nucleated red cells (erythroblasts) in the circulation. If untreated, the most severe stage of erythroblastosis, hydrops fetalis, can lead to stillbirth and is characterized by severe anemia, hypoproteinemia, and massive edema. Bilirubin, by virtue of being lipophilic, crosses the placenta during pregnancy and is removed by the mother's liver. However, after birth, the immaturity of the neonate's liver leads to decreased clearance of bilirubin; plasma levels of unconjugated bilirubin can quickly become high enough to cause serious central nervous system damage. Thus, both anemia and hyperbilirubinemia may cause long-term physiological perturbations in the newborn.

In severe erythroblastosis, the examination of a blood film will show numerous nucleated red cells, but only a few spherocytes due to the rapid destruction of the red cells (e.g., serious anti-D HDFN). In less severe HDFN, spherocytes will dominate the blood film, and only a few nucleated red cells are observed (e.g., ABO HDFN). This explains why the examination of a blood film can be helpful in neonates with pronounced jaundice.<sup>1</sup> Persistent or prolonged jaundice in neonates is a common feature of HDFN and is frequently associated with cholestasis.

Accurate diagnosis of HDFN is important for the current as well as future pregnancies. In the absence of appropriate antepartum screening, monitoring and treatment, the consequences for the fetus or neonate can be severe. However, with appropriate prenatal therapy, red cell mass is maintained, and fetal erythropoiesis is suppressed. For that reason, today most neonates with HDFN who receive appropriate prenatal care present with neither neonatal jaundice nor anemia of clinical importance at birth, and very few

require exchange transfusion postpartum. However, the newborn may present with anemia after the first two weeks of life because of suppression of erythropoiesis caused by intrauterine transfusions (IUT) and the continued presence of hemolyzing maternal antibodies. Additionally, strategies to prevent HDFN, as detailed later in this chapter, have become an important component of prenatal care.

## Immune-mediated HDFN

### HDFN due to ABO incompatibility

The occurrence of O, A, B, and AB blood groups vary among different ethnicities<sup>2–4</sup> (Table 32.1). Accordingly, maternal-newborn ABO incompatibility ranges from 31% in those of European ancestry to 50% in patients of Asian descent. Today, ABO incompatibility is the leading cause of HDFN in high-human development index (HDI) countries.<sup>5</sup> HDFN resulting from ABO incompatibility generally occurs in the offspring of women of blood group O because anti-A, anti-B, and anti-A,B antibodies of the IgG subclass are far more common in mothers who are group O when compared to those who are group A or B.<sup>6</sup> The frequency of HDFN caused by ABO incompatibility has been estimated to be about 1 in 150 births.<sup>1</sup> The higher frequencies of ABO HDFN reported in Africa and Saudi Arabia are likely related to more potent anti-A and anti-B in maternal circulation due to environmental factors, as well as relatively strong expression of A and B antigens on fetal red blood cells.<sup>7</sup>

ABO antibodies are formed independent of antigen exposure during pregnancy or transfusion. Thus, the first ABO-incompatible infant of a mother is potentially at risk. Fortunately, on fetal red cells, A and B antigens are generally not fully developed and remain few and unbranched until the age of 2–4 years.<sup>8</sup> This allows antibody-coated cells to remain in circulation longer, when compared to anti-D mediated HDFN. Additionally, ABO antigens are expressed on virtually all cells in the body, whereas the D antigen is restricted to red cells. Thus, anti-D is “focused” to red cells, whereas anti-A and anti-B are absorbed by tissues and neutralized by soluble A and B substances in plasma. These features may in part explain why ABO HDFN is generally self-limiting and causes mild to

moderate neonatal jaundice presenting in the first 24 hours of life. In the absence of significant red cell destruction, hemoglobin may be normal or only slightly low.<sup>7</sup> Hemolysis severe enough to cause hydrops is exceedingly rare.<sup>9</sup> However, in ethnic groups that express strong (many and branched) A and B antigen sites, severe anemia, nucleated red cells, and significant neonatal morbidity can be observed.<sup>1</sup>

### HDFN due to unexpected red blood cell antibodies

Nearly all IgG antibodies against red blood cell (RBC) antigens expressed on fetal red cells have been associated with HDFN. HDFN frequency and severity, however, vary. The prevalence of antibody specificities depends on when the study was conducted and the ethnicity of the study population. For instance, the D-negative phenotype is more common in populations of European ancestry (15–17%), less common in those of African descent (8–9%), and rare in those of Asian descent (<1%).<sup>4,8</sup> Where the D-negative phenotype is common, the prevalence of alloanti-D after delivery of D-positive infants was once approximately 16%.<sup>10</sup> Today, routine antepartum and postpartum prophylactic Rh immune globulin (RhIG) administration has reduced the frequency of D alloimmunization to 0.28% to <0.1%.<sup>10–12</sup> Nonetheless, anti-D remains the most common cause of severe HDFN in populations of European ancestry.<sup>1</sup> The next most frequently reported clinically significant alloantibodies associated with HDFN are anti-c, anti-E, and anti-K1.<sup>13</sup> The presence of anti-K1 may be especially concerning because it can cause severe fetal anemia through both direct hemolysis and inhibition of fetal erythropoiesis.<sup>14</sup> Antibodies directed against other antigens in the Rh, Kell, Duffy, Kidd, and MNS blood group systems rarely cause severe HDFN.<sup>13</sup>

The frequency and specific antibody that cause HDFN vary with the population studied (Table 32.2). The clinical severity of HDFN is associated with both antibody specificity and the fetal expression of the RBC antigen (Figure 32.1). For instance, in Chinese women anti-M is the most commonly identified alloantibody. The natural history of anti-M HDFN is generally benign,<sup>13,15</sup> but severe HDFN associated with IgG anti-M has been disproportionately reported in Asian populations in Taiwan,<sup>16</sup> China,<sup>17</sup> Japan,<sup>18</sup> and India,<sup>19</sup> suggesting that racial and genetic factors may impact clinical outcome. Severe HDFN mediated by anti-M has been postulated to be caused by rapid intravascular hemolysis and suppression of erythropoiesis, similar to anti-K1, given that the M antigen is fully expressed in early erythroid precursors.<sup>17,18</sup> Another explanation for severity is concurrent placental disease that allows increased transplacental transport of pentameric anti-M antibodies that are too large to cross healthy placental tissue.<sup>20,21</sup>

### Immunology and mechanism of HDFN

Development of immune-mediated HDFN requires maternal IgG antibodies that can cross the placenta and are directed against paternally derived antigens expressed on fetal red cells. This principle explains why most naturally occurring antibodies to carbohydrate antigens, such as ABO, Hh, and Ii, are unlikely to cause HDFN. These antibodies form without prior exposure to allogeneic red cells as a result of the wide distribution of their cognate antigens in nature. Antibodies to these blood groups are predominantly the IgM isotype, which typically do not cause HDFN as they cannot cross the placenta. Additionally, maternal RBC antibodies directed against paternal antigens that are also expressed on placental tissue are adsorbed by the placenta and do not reach the fetus, reducing the chances of causing HDFN. Furthermore, the I antigen and antigens of the Lewis and P systems are almost entirely lacking on fetal cells; thus, even if corresponding antibodies crossed the placenta, they would not cause HDFN.<sup>23</sup>

Except in the case of ABO, HDFN is primarily mediated by antibodies that are incited by maternal alloimmunization to prior red cell antigen exposure. The precursor event to most forms of clinically significant HDFN is maternal sensitization during previous pregnancies.<sup>24</sup> The immune response to peptide antigens (e.g., D) typically requires T-cell facilitation and is dominated by the IgG class of antibodies. Because the D antigen is extraordinarily immunogenic and induces high-affinity anti-D IgG, it has historically been the major cause of HDFN in Western countries. In alloimmunized pregnancies, maternal IgG antibodies cross the placenta in an active process dependent upon the interaction between maternal IgG and syncytiotrophoblast Fc receptors, which is most active in the third trimester.<sup>7</sup> After transplacental passage, maternal IgG antibodies coat fetal red cells and induce effector cell mediated destruction. Pathogenicity is influenced by many factors including antibody affinity, isotype, subclass, and post-translational modifications. Specifically, the amount of IgG-Fc glycosylation has been associated with the clinical outcomes of anti-D-, anti-c-, anti-E-, and anti-K-mediated HDFN.<sup>25,26</sup>

### Monitoring and management of sensitized pregnancies

In high-HDI countries, the implementation of routine antibody detection and ABO/Rh typing of pregnant women allow for the detection of patients at risk of HDFN. These processes have paved the way for closer surveillance, timely therapy, and improved outcomes. Due to prenatal testing in high-HDI countries, HDFN caused by sensitization to D or other alloantigens is rare; consequently, ABO incompatibility is the leading cause of HDFN and is typically clinically mild. Unfortunately, the implementation of the

same level of routine antenatal antibody detection has not been possible in all lower-HDI countries.

A positive antibody detection test (commonly referred to as the antibody screen) in a pregnant woman warrants additional investigation, and, if indicated, further antepartum monitoring and treatment of the affected fetus. Antibody titration by tube or gel (e.g., column agglutination technology) is the laboratory test typically used for antepartum monitoring. Gel platforms are reported to be more sensitive than the classic tube method, but there is significant interlaboratory variability regardless of testing method.<sup>27</sup> Correlation of antibody titration with clinical severity and outcome are mainly limited to anti-D. Antibody-dependent cellular cytotoxicity (ADCC) has been described as a method to distinguish clinically significant from clinically insignificant antibodies, but is infrequently used in clinical practice<sup>13</sup> as it lacks specificity and is

limited in availability. As such, antibody titration remains the most widely used laboratory test to assess for the risk of potentially significant HDFN and determine the need for additional noninvasive clinical fetal monitoring. Typically, serial antibody titrations are performed until a critical threshold is reached. This threshold may vary depending on the antigen specificity and the facility performing the titration. Ideally, titrations should be performed in parallel with previous samples to ensure the validity of any changes in concentration. Historically, a titer of 1:8 has been considered the critical threshold for anti-K1, but the presence of anti-K1 of any titer may possibly be clinically significant.<sup>28</sup> The critical titer for anti-D ranges from 1:8 to 1:32. For other antibodies, the critical titer may be either a twofold or greater increase in titer during pregnancy and/or a final titer of 1:16 to 1:32; however, these metrics vary, and additional monitoring may be indicated prior to a “critical

titer" being achieved. If there is a history of HDFN, the utility of antibody titers in subsequent pregnancies is less clear; therefore, noninvasive fetal monitoring is recommended rather than performing serial antibody titrations. It should also be noted for anti-M, which is typically, but not always, IgM-only or predominantly IgM, additional testing can be performed to detect and distinguish the titers of IgM versus IgG subtypes.<sup>13</sup>

### **Primary prevention**

The two triggers for maternal sensitization are fetal-maternal hemorrhage (FMH) during pregnancy and RBC transfusion. Both events expose the woman to nonself-RBC antigens and can lead to alloimmunization. As previously noted, the stimulus for maternal RBC sensitization causing severe HDFN has been shown to be mostly due to prior pregnancy (83%). However, up to 3% of cases have been attributed to previous RBC transfusion, while 14% have an unknown cause of sensitization.<sup>24</sup> Protection from D sensitization is the reason for the common practice of reserving D-negative RBC products for females of childbearing age (often an age cutoff of <50 years) when there is not enough time for pretransfusion testing during emergencies or when there is a critical shortage of D-negative RBCs. A more thorough and logical strategy for primary prevention is to provide phenotypically matched or alloantigen negative RBCs to women of childbearing potential for all clinically significant RBC antigens in addition to D. This type of strategy is common for patients with hemoglobinopathies, such as sickle cell disease, where RBCs are prophylactically matched for at least K1, C, c, E, and e to prevent RBC sensitization. The benefits of this practice include decreased risk of delayed hemolytic transfusion reactions and hyperhemolysis, as well as improved availability of compatible blood for future transfusions. In otherwise healthy females of childbearing potential, however, this practice has not demonstrated clear, direct benefit in prevention of severe HDFN when patients seek care from different facilities with different transfusion matching policies. In those circumstances, any potential benefit of providing antigen-matched RBCs to prevent maternal alloimmunization and HDFN appears diluted. However, a study in one European country with a national transfusion policy and a nationalized blood inventory suggests that providing K1 negative blood to female transfusion patients is associated with lower rates of anti-K1 detection in pregnant women, although the number of fathers positive for the K1 antigen was low.<sup>29</sup> Therefore, the prevention of alloimmunization caused by transfusion would require universal adoption of extended matching; however, this practice is not yet established, nor feasible, in most regions and countries.

### **Prevention of D alloimmunization in an exposed pregnancy**

For pregnant women, many countries recommend testing maternal blood type (ABO and D), as well as screening for unexpected RBC IgG antibodies in the first trimester.<sup>30,31</sup> First trimester screening has been shown to be approximately 75% sensitive for clinically significant RBC antibodies; however, sensitivity varies by antibody specificity.<sup>13</sup> In some countries, repeat screening for D-negative mothers is recommended between 28 and 29 weeks gestation, prior to administration of RhIG in potentially affected pregnancies, as late RBC alloimmunization may also occur.<sup>30,32</sup> Repeat screening for D-positive mothers is often performed at this time as well since up to 27% of severe cases of HDFN cases occur in infants of D-positive mothers.<sup>33</sup> Good communication between clinicians and the laboratory performing assessments of maternal specimens is critical to

distinguish between active anti-D alloimmunization and anti-D reactivity resulting from passively administered RhIG as RhIG is not indicated in the former case.<sup>34</sup>

Though the precise mechanism by which RhIG prevents D alloimmunization remains elusive,<sup>35</sup> postnatal administration of RhIG alone to D-negative mothers of D-positive infants has been shown to decrease the rate of D sensitization by 85–95%.<sup>36</sup> National recommendations for antenatal RhIG administration include administration at time of potential FMH, such as amniocentesis or miscarriage, and routine administration in the third trimester due to potentially undiagnosed FMH, though the public health benefits of this latter practice have not been shown to be statistically significant.<sup>37</sup>

Not all D-negative mothers require routine RhIG administration. If paternity is confirmed, paternal D type, fetal RHD genotyping from maternal sera, or paternal RHD molecular zygosity testing when the father is D-positive may guide clinicians in their evaluation of the risk of D sensitization.<sup>38</sup> Non-invasive molecular assays for the RHD gene from cell-free fetal DNA found in maternal peripheral circulation have been implemented in a number of European countries to identify D-positive fetuses early in pregnancy.<sup>39–41</sup> Cell-free fetal RHD assays offer a sensitivity of >99.3% at 10–11 weeks gestation and >99.9% at 24–26 weeks gestation. National programs built around this testing approach have been shown to limit unnecessary RhIG administration to D-negative mothers.<sup>42,43</sup> This technology has also been applied to other RBC antigens implicated in HDFN.<sup>44</sup>

Weak D is the category of D polypeptides that are derived from *RHD* alleles with genetic variations that generally affect trafficking to the cellular surface. Mothers with certain types of weak D mutations may be spared unnecessary RhIG administration as they do not form an anti-D.<sup>45</sup> The most common forms of weak D, types 1–3, fall into this category; molecular weak D genotyping can distinguish weak D types 1–3 from other D variants. Further evidence suggests that weak D types 4.0 and 4.1 may be treated similarly, as these mutations have not been associated with hemolytic transfusion reactions or HDFN due to anti-D.<sup>46</sup> Given the cost savings in avoiding unnecessary RhIG administration, the added expense of targeted molecular testing could be cost neutral, as well as avoid the overuse of a potentially limited supply of RhIG.<sup>47</sup>

Despite RhIG administration, there are some D-negative mothers who still become sensitized and form an anti-D, although the reasons for apparent failures are not clear. One possibility is inadequate RhIG prophylaxis. Two tests are generally used to quantify FMH at parturition and guide RhIG dosing. Initial testing uses the erythrocyte rosette test. If negative, a standard dose of RhIG is given to the at-risk mother within 72 hours of parturition because this dose should cover up to 10 mL of D-positive fetal erythrocytes in maternal circulation. However, when the rosette test is positive, indicating >10 mL of FMH, additional quantitative testing is needed. Typically, the Kleihauer-Betke test is used, although there are other tests that can also quantify FMH.<sup>8</sup> The Kleihauer-Betke acid elution test is a subjective quantitation of hemoglobin F cells present in a maternal sample by microscopic blood smear review. This quantitation is then converted to a predicted volume of fetal RBCs in a standard maternal blood volume. This approach may result in underdosing or overdosing RhIG, as 300 mcg of RhIG is considered appropriate for 15 mL of fetal RBCs in maternal circulation,<sup>8</sup> but vial sizes and dosing standards vary by country. More objective flow cytometric measures can be used to quantify the concentration of D-positive RBCs of fetal origin in a maternal blood sample,<sup>48,49</sup> however, the use of this technique is limited due to

equipment and staffing requirements, as well as established national standards of care.<sup>50</sup> Accurate estimates of FMH are critical for appropriate dosing of RhIG as RhIG “failures” have been associated with conditions that increase the risk of FMH, such as assisted vaginal delivery, caesarian section, and postmaturity (>42 weeks gestational age).<sup>51</sup> Maternal obesity also increases the likelihood of under dosing of RhIG as maternal blood volume is likely greater than the standard 5000 mL maternal blood volume estimates typically used in the Kleihauer-Betke calculations. Significant adiposity may also decrease efficacy of RhIG, which is often administered intramuscularly (IM) and demonstrates poor absorption when administered subcutaneously. Intravenous dosing of RhIG should be considered when IM is not feasible or there are reasons to suspect it may have reduced efficacy.<sup>52,53</sup>

### Care of the sensitized pregnancy

For women who are alloimmunized, early recognition, fetal monitoring, and appropriate interventions may protect the fetus from complications of hydrops fetalis and ensure a safe, near-term delivery. As noted previously, in the absence of a history of affected pregnancies, antibody titers may be helpful to determine when an at-risk fetus requires additional monitoring. However, in women who have had a previously affected pregnancy, early interventions may be required. Prior to 18 weeks gestation, in mothers with previous pregnancies severely affected by HDFN, there are reports of successful treatments with a combination therapeutic plasma exchange and IVIG.<sup>54-59</sup> The intent is to inhibit the antibody enough to allow for the fetus to grow until fetal monitoring and intrauterine transfusions are technically possible.

Once a critical antibody titer threshold is met, or if the mother is alloimmunized against an antigen where titers have not been shown to be predictive, noninvasive fetal monitoring is performed beginning around 18 weeks gestation. Doppler ultrasonography of the fetal middle cerebral arteries (MCA) to measure peak systolic velocity (PSV) has been shown to predict moderate to severe fetal anemia.<sup>60</sup> This approach has replaced invasive, direct measurements of bilirubin from amniotic fluid.<sup>61,62</sup> If a fetus’ PSV is greater than 1.5 multiples of the median for gestational age, then direct measurement of fetal hematocrit via cordocentesis with the potential for immediate IUT is recommended. If the fetus is already at a gestation age compatible with life outside of the womb (typically >35 weeks), delivery may be recommended in lieu of IUT.<sup>38</sup> For affected pregnancies, definitive delivery around 37–38 weeks gestation is generally recommended. At the time of any IUT, the obstetric team should be prepared for urgent delivery of the fetus given potential risks of the transfusion procedure itself.

The blood units utilized for IUT are fresh, type O, D negative, irradiated, CMV negative/safe, sickle cell trait negative, and should lack other antigen(s) to which the mother is sensitized. RBC units are often concentrated to a hematocrit of 75–80%. Additional extended matching to the maternal phenotype has been shown to avoid further maternal sensitization at the time of IUT given the high rate of antibody formation in this population; however, finding multiply antigen negative blood can be difficult.<sup>63-65</sup> Calculations for IUT volume target a fetal hematocrit of 40–50%, but may target a lower post-transfusion hematocrit early in gestation (18–24 weeks) given an increased risk of complications.<sup>66</sup>

Long-term follow-up of infants with HDFN who received IUT has shown an incidence of neurodevelopmental impairment (NDI) of around 4–6%, with cerebral palsy occurring in 2.4% of infants.<sup>67,68</sup> However, milder developmental delays (<1 standard deviation)

have been detected in up to 14.4% of infants who received IUT, with hemoglobin at initial IUT correlating with later measures of IQ.<sup>69</sup> Severe neonatal morbidity, such as sepsis or intraventricular hemorrhage, and severity of HDFN as evidenced by the number of IUTs the infant received were predictive of more severe NDI.<sup>69</sup>

### Care of the affected newborn

#### Initial testing

The direct antiglobulin test (DAT) (see Chapter 12) is one of the cornerstones for the diagnosis of HDFN in a neonatal patient; however, significant practice variation exists in its use.<sup>70</sup> The DAT detects IgG antibodies on the surface of red cells where the number of IgG molecules bound to the erythrocyte surface determines the agglutination strength of the reaction. Using the spin antiglobulin test, the detection limit is 100–150 IgG molecules per red cell. When over 1000 are bound, the DAT is strongly positive (all cells are agglutinated).<sup>7</sup> In sensitized pregnancies, a positive postnatal DAT in the infant has been shown to be 90% sensitive for HDFN, but only 58% specific.<sup>71</sup> Furthermore, significant hemolysis can be observed in patients with a negative or weakly positive DAT. Only 23% of newborns found to be DAT positive have been reported to develop hyperbilirubinemia requiring treatment; however, in infants with clinically significant hemolysis, >80% have a positive DAT.<sup>5</sup> Thus, DAT alone is a poor predictor for identifying neonates who will require perinatal interventions for HDFN and hyperbilirubinemia, and additional clinical measures should be used. It should also be borne in mind that after antepartum treatment of D-negative women with prophylactic RhIG, neonates may demonstrate a positive DAT without signs of hemolysis.<sup>72</sup> Although obtaining a DAT on cord blood samples has been historically considered compulsory in infants of D-negative mothers, newer recommendations suggest that this should no longer be routine.<sup>32</sup> While neither required nor pathognomonic, as discussed previously, blood smear review may also be helpful.

#### Hyperbilirubinemia

Newborns should be screened for hyperbilirubinemia in the early neonatal period. This may be performed using transcutaneous measures of bilirubin. However, for infants who were affected by maternal antibodies during pregnancy, serologic testing and close monitoring of bilirubin levels are recommended to minimize the risk of long-term complications from HDFN.

Infants, even those who were not severely affected in pregnancy, may have early evidence of antibody mediated hemolysis soon after birth. Often within the first week of life, these infants can present with an elevated bilirubin and a normal or high reticulocyte count.<sup>73</sup> Hyperbilirubinemia may be exaggerated due to immature liver function. If inadequately treated, significant unconjugated hyperbilirubinemia can lead to bilirubin-induced neurotoxicity (BIND), which is damage to the brain from free bilirubin that crosses the blood-brain barrier. BIND occurs when total serum bilirubin is ≥30 mg/dL or ≥450 μmol/L, with higher peak levels conveying the greatest risk. Without treatment, BIND can lead to acute bilirubin encephalopathy (ABE), which progresses through three stages: early, intermediate, and advanced. In the early phase, infants may be less responsive, hypotonic, and have a high-pitched cry. In the intermediate phase, the infant may be lethargic with poor suck or irritable with strong suck. They may be difficult to console and exhibit hypertonic arching of the back and neck with stimulation. In the advanced stage, infants may have fevers, apnea, hypertension, inability to feed, and seizures. The condition may progress to a semicomatose or comatose

state. Ultimately, death from ABE can be due to respiratory failure or intractable seizures.<sup>74</sup> Chronic bilirubin encephalopathy, also referred to as kernicterus spectrum disorders, is permanent clinical sequelae due to bilirubin-induced neurotoxicity that manifests after the first year of life. The classic tetrad of kernicterus spectrum disorders includes auditory processing disturbances with or without sensorineural hearing loss, extrapyramidal neuromotor symptoms, oculomotor paresis presenting as an upward vertical gaze palsy, and dental enamel dysplasia.<sup>75</sup> Chronic bilirubin encephalopathy has an incidence of 0.4–2.7 cases per 100,000 births in high HDI countries. However, ABE continues to account for up to 15% of neonatal deaths in countries with low HDI.<sup>76</sup> The primary treatment strategies of phototherapy, IVIG, and exchange transfusion are aimed at preventing the neonatal bilirubin from reaching toxic levels.

### Phototherapy

Since its introduction in the late 1950s, the delivery and understanding of phototherapy have provided major improvements in the clinical treatment of HDFN. The efficacy of phototherapy depends on the following factors:<sup>77</sup>

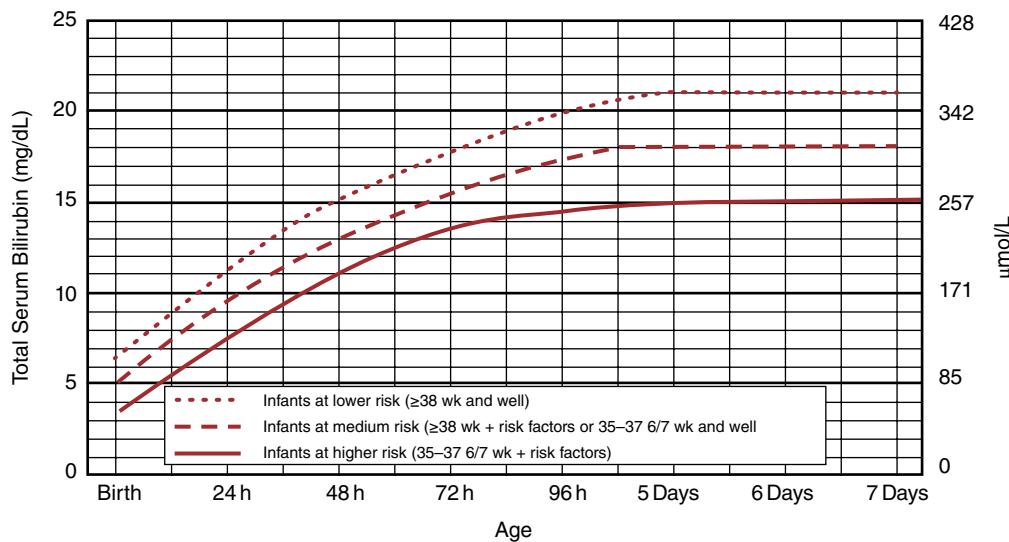

- Spectral qualities of the delivered light (wavelength range 400–520 nm, with peak emissions of 460 nm).
- Intensity of light (irradiance) delivered to the skin surface.
- Skin surface area receiving phototherapy.
- Distance from infant's skin to light source.
- Total serum bilirubin concentration at the start of phototherapy.
- The cause of jaundice.
- Duration of exposure.

Intensive phototherapy is often the first treatment to be initiated when infants present with hyperbilirubinemia due to HDFN and can significantly reduce the total serum bilirubin even in a short period of time. Phototherapy causes photooxidation of the serum bilirubin into water-soluble isomers that are more readily excreted. In addition, phototherapy is thought to decrease the risk of BIND as the conversion of a significant amount (25% or more) of circulating

bilirubin to more water-soluble isomers could theoretically reduce the transfer of bilirubin across the blood–brain barrier and into the brain.<sup>78</sup> Postnatal age and risk-stratified thresholds for initiation of phototherapy are presented in Figure 32.2.<sup>79</sup>

Modern phototherapy devices with high-intensity gallium nitride light-emitting diodes (LEDs) are small, efficient, and easy to use.<sup>77</sup> Compared to earlier versions of these instruments, the current technology can deliver considerably more total radiation to a neonate. The resulting “intensive phototherapy” has become an important alternative to exchange transfusion, even in the treatment of severe HDFN. Intensive phototherapy implies radiation in the blue-green spectrum (wavelengths 430–490 nm) of at least 30 µW/cm<sup>2</sup>/nm (measured at the infant's skin) delivered to as much of the infant's body surface area as possible.<sup>79</sup> Spectral power is the product of the irradiance and size of the irradiated area and is a key metric in phototherapy as high irradiance is of little help if only a small area of skin is exposed.

Phototherapy, when properly performed, is largely considered to be an innocuous procedure, although some concern has recently been raised about increased lethality in tiny, immature infants of <750 g birthweight, as well as future cancer risks in treated infants.<sup>80–82</sup> Additionally, the safety of pathogen inactivated blood products in infants receiving phototherapy has been questioned. Some pathogen inactivation systems work through exposing the blood product to a combination of UV light and a photosensitizing agent. These systems have been shown to improve transfusion safety; however, it is unclear how much of the photosensitizing agent is infused to patients as part of routine transfusions and whether that is enough to increase the risk of injury to infants receiving directed irradiance. Notably, modern phototherapy devices avoid the wavelengths of light that have the potential to cause injury. However, psoralen-treated blood products remain contraindicated in infants treated with phototherapy devices that emit a peak energy wavelength less than 425 nm or have a lower bound of emission bandwidth <375 nm.<sup>83</sup>

**Figure 32.2** The American Academy of Pediatrics (AAP) Guidelines for Phototherapy take into consideration the hours/days since birth as a surrogate for liver maturity along with patient risk factors for BIND to establish total serum bilirubin thresholds above which phototherapy should be initiated. Recommended thresholds are lower in infants <35 weeks' gestation.<sup>79</sup> The threshold to initiate therapies for hyperbilirubinemia may differ slightly between nations due to differences in national health care delivery systems, testing availability, and access to medical follow-up. Refer to local practice guidelines, if available. Image reproduced with permission from the American Academy of Pediatrics (2004).<sup>79</sup>

### High-dose intravenous immunoglobulin (HDIVIG)

Since the beginning of the 1990s, several studies have reported the effects of HDIVIG as an adjuvant to standard therapy for HDFN. Two systematic reviews have concluded that IVIG plus phototherapy reduced the risk of exchange transfusion when compared to phototherapy alone.<sup>84,85</sup> Thus, it may be considered for neonates with HDFN who are near exchange thresholds or in those who fail to respond to intensive phototherapy.<sup>79</sup> HDIVIG is administered as 0.5–1.0 g/kg over two hours and may be repeated. It has been argued that the results of several HDIVIG studies were confounded by the concurrent introduction of newer phototherapy devices with much higher irradiance.<sup>86</sup> Although this cannot be ruled out completely, Huizing *et al.*, in a study with a historical control cohort, found no effect of change of phototherapy devices, while confirming the salutary effect of HDIVIG in both D- and ABO-HDFN.<sup>87</sup> HDIVIG may be inadequate to prevent exchange transfusion in the setting of aggressive HDFN, as was seen in a Dutch cohort of patients with HDFN due to anti-D, the majority of whom required IUT.<sup>88</sup> It is not surprising that with such a high load of circulating D antibodies, a relatively moderate dose of IVIG would not be sufficient to block or reduce the effect. HDIVIG has not been shown to benefit neonates when given prophylactically,<sup>89</sup> rather it has the greatest potential to benefit a targeted population of neonates with HDFN who are close to the bilirubin threshold for exchange transfusion.<sup>90</sup>

It must be remembered that IVIG is a pooled plasma product, which, before the introduction of adequate pathogen inactivation, was involved in several cases of viral transmission. However, since 1994, there has been no transmission of bloodborne infections with pathogen-inactivated IVIG prepared from selected donors<sup>91</sup> (see also Chapter 23).

### Exchange transfusions

The criteria used to assess the need for exchange transfusion include total bilirubin level, trajectory of increase, hemoglobin level, and clinical symptoms. Traditional guidelines suggest exchange transfusion in the following circumstances.

#### Within 12 hours of birth if:

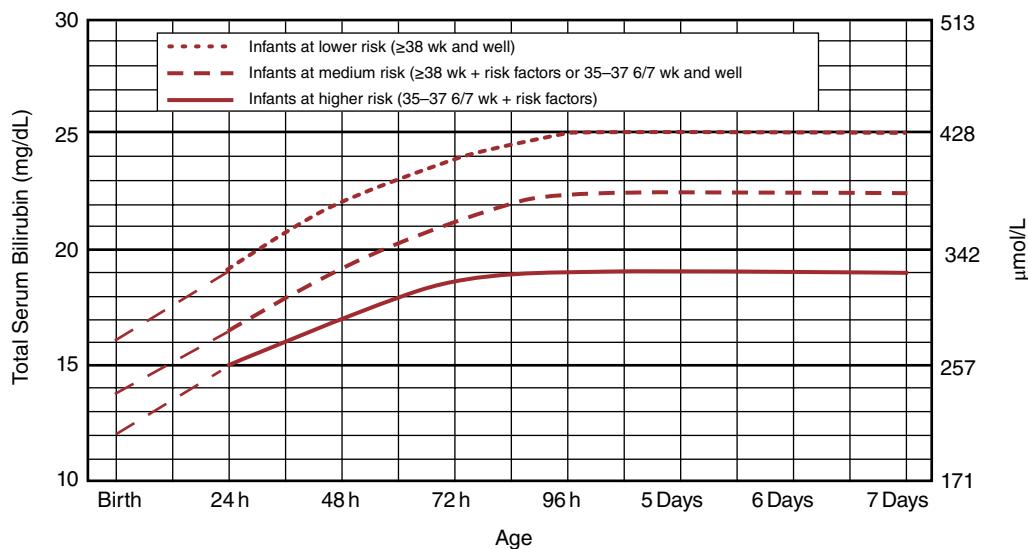

- cord blood bilirubin concentration exceeds 3–5 mg/dL (50–85 µmol/L) for preterm infants and 5–7 mg/dL (85–120 µmol/L) for term infants, or the rate of increase is >0.5 mg/dL/hour (8.5 µmol/L/hour); and
- severe anemia: hemoglobin <10 g/dL combined with hyperbilirubinemia.

#### After 24 hours of birth if:

- the total bilirubin concentration >20 mg/dL (342 µmol/L) or a bilirubin increase of >0.5 mg/dL/hour (8.5 µmol/L/hour), or hemoglobin <10 g/dL combined with hyperbilirubinemia

Today, the need to perform exchange transfusion has been much reduced through the combined use of intensive phototherapy and HDIVIG. In fact, these interventions often significantly decrease bilirubin levels over 2–6 hours needed to set up an exchange transfusion. Exchange transfusions are still considered indicated when intensive phototherapy, with or without IVIG, fails to adequately reduce bilirubin concentration or when the initial serum bilirubin places the infant at risk for bilirubin-induced neurologic damage. Factors potentiating bilirubin toxicity include immune-mediated hemolysis, acid–base disturbances, asphyxia, free heme groups, and other byproducts of hemolysis or drugs that displace bilirubin from albumin and other plasma-binding proteins.<sup>92</sup> Postnatal age and risk-stratified thresholds for initiation of red cell exchange are presented in Figure 32.3.<sup>79</sup>

Exchange transfusions supply the neonate with compatible red cells and fresh plasma, while incompatible red cells, bilirubin, and maternal antibodies in plasma are all removed. A standard exchange

**Figure 32.3** AAP guidelines for exchange transfusion. Similar to the guidelines for initiation of phototherapy, hours/days of age and patient specific risk factors are used to establish total serum bilirubin thresholds above which exchange transfusions may be indicated. Thresholds are lower in infants <35 weeks' gestation.<sup>79</sup> A lower threshold to initiate intensive therapy may be considered in infants with acidosis, septicemia, low serum albumin concentration, or an "ill" appearance. In the presence of one or more such risk factors, clinical judgment may suggest performing an exchange transfusion at TSB levels 50–100 µmol/L lower than those indicated by graph lines. Immediate exchange transfusion is recommended if the infant shows signs of acute bilirubin encephalopathy. Image reproduced with permission from the American Academy of Pediatrics (2004).<sup>79</sup>

transfusion of twice the infant's blood volume reduces incompatible fetal red cells by about 85%, while bilirubin and maternal antibody concentrations are reduced by 25–45%.<sup>23</sup> The amount of blood needed for an exchange transfusion is 170 mL/kg (200 mL/kg in preterm infants), with 25–50 mL added to compensate for dead space in the tubing and blood warmer. An exchange transfusion consists of hemoglobin S-negative red cells that are compatible with maternal antibodies and are reconstituted with fresh frozen group AB plasma to achieve a hematocrit of 45–60%, depending on the desired target hematocrit in the neonate. The blood should be CMV seronegative/safe (leukocyte reduced), irradiated, and preferably <5 days old. Platelet transfusion may be considered after an exchange transfusion if an infant's platelet count is reduced, which often occurs after multiple exchange transfusions.

Exchange transfusions are associated with a mortality of 2% and serious complications in 12% of patients. Because the frequency of exchange transfusions is decreasing and practitioners have fewer opportunities to attain and maintain the necessary procedural skills, the complication rate is unlikely to improve. It is important that maternity and neonatal services develop, maintain, and teach appropriate written guidelines for the use of exchange transfusion in HDFN and the performance of the procedure itself.

### Simple transfusions

While the clinical indications for exchange transfusion are becoming less common, the need for simple transfusion has increased.<sup>1</sup> Antibody mediated hemolysis due to HDFN may present or persist beyond two weeks of life. This may be exaggerated by the natural expansion of the infant's intravascular volume and progression toward physiologic nadir. For these infants, the bilirubin remains elevated, with a normal or high reticulocyte count. Hyporegenerative anemia has also been described in infants affected by HDFN. These infants may be older (>2 weeks old) and do not have signs of acute hemolysis. Instead, this hyporegenerative state is thought to be due to antibody mediated destruction of RBC precursors, low erythropoietin production, and bone marrow suppression due to IUT or early postnatal transfusions in a dose-dependent manner.<sup>73,93</sup> Antibody specificity and antigen density on early RBC precursors may underlie which infants have a greater likelihood of suffering from hyporegenerative anemia, such as those affected by anti-K1 or possibly anti-M, as discussed earlier.

Simple red cell transfusions are required to maintain an affected infant's hemoglobin through the early neonatal period, especially if infants receive treatment with phototherapy and HDIIVIG alone or together. In an observational cohort of almost 300 infants affected by HDFN, more than half of those who did not require IUT required simple red cell transfusion, most often in the first week of life. A higher reticulocyte count at birth and higher bilirubin were associated with the need for simple transfusion(s). In contrast, exchange transfusion reduced the need for simple transfusion.<sup>94</sup> For infants who received IUT, there may be a period where the infants' hemoglobin remains adequate due to the persistence of antigen negative transfused RBCs in circulation. However, close monitoring is warranted as up to 88% of these infants required transfusion as the previously transfused cells senesced. In this situation, the transfusion is needed typically during the first two weeks of life but can be delayed beyond three weeks of life.<sup>94</sup> Similar to infants who did not receive IUT, those who received an early exchange transfusion had a decreased likelihood of needing future simple transfusions; however, lower reticulocyte counts were associated with an increased likelihood of future anemia, highlighting the sustained effect of IUT on

erythropoiesis.<sup>94</sup> The likelihood of needing additional transfusions decreases as infants age; however, close clinical and laboratory monitoring is necessary through physiologic nadir and recovery.

### Breast milk

Several case reports have implicated breast milk as an ongoing source for maternal antibody exposure as evidenced by prolonged hemolysis and persistent antibody detection in affected neonates.<sup>95–97</sup> Elegant murine models of anti-KEL have demonstrated positive DATs in KEL positive pups who were only exposed to the antibody through breast feeding from sensitized mothers.<sup>98</sup> Several maternal IgG class antibodies have been detected in breast milk;<sup>99</sup> however, the direct link to enteric absorption has yet to be identified in humans. Currently, maternal RBC alloimmunization is not a contraindication for breast feeding, but further study is warranted.

### HDFN, anemia, transfusion, and NEC

Necrotizing enterocolitis (NEC), defined as ischemic necrosis of the intestines, is a common emergency in preterm and low birthweight infants. Several retrospective studies have associated NEC in term or near-term babies with HDFN. In one retrospective cohort study of infants between 30 and 38 weeks' gestational age, the incidence of NEC was significantly higher among infants with HDFN compared to those without HDFN (1.3% vs. 0.4%, relative risk 3.40, 95% CI 1.09–10.63).<sup>100</sup> Blood transfusions, a common intervention for infants with HDFN, have also been associated with the occurrence of NEC. Authors hypothesized that this was due to changes in intestinal perfusion, especially when infants are concurrently receiving enteral feeds; however, much of the data are retrospective and results are mixed.<sup>101</sup> In one prospective cohort study, exposure to severe anemia, and not blood transfusion, was associated with NEC.<sup>102</sup> HDIIVIG has also been associated with increased risk of NEC development.<sup>103</sup> Given the confounding interactions, additional studies are warranted to segregate the effects of HDFN itself, the anemia it causes, and the interventions used to treat HDFN including transfusions and IVIG. Given the late, hyporegenerative anemia that can occur in infants affected by HDFN, case reports have suggested that the administration of exogenous erythropoietin may minimize the need for transfusion support and avoid potential deleterious effects of RBCs.<sup>104,105</sup> This is currently an area of active research in the EPO-4-Rhesus Study (NCT03104426).

### Future therapies

Metalloporphyrins, which decrease bilirubin production through inhibition of heme oxygenase, may represent a novel mechanism to limit bilirubin accumulation. In preclinical models of BIND, minocycline has been shown to be neuroprotective, but this must be balanced against the known adverse effects on dentition and bone. Phenobarbital has also been shown to increase bilirubin clearance through activation of enzymes that enhance conjugation.<sup>76</sup> However, with all of these therapies, further research into efficacy and safety is needed.

### HDFN in low HDI nations

Although the mortality and morbidity of HDFN have been greatly reduced in countries with high HDI, HDFN still poses a serious challenge in countries with low HDI. In these countries, the introduction of maternal antibody screening for blood group antibodies and D blood type, routine prophylactic RhIG treatment, and development of affordable and effective phototherapy options should be encouraged. Filtered sunlight phototherapy (FSPT), which uses

sheets of film to remove most ultraviolet and infrared light from sunlight while transmitting effective levels of therapeutic blue light, has been shown to be as effective as electric phototherapy in low-resource settings.<sup>106</sup> Unfortunately, given reliance upon sunlight, delays in care may occur if infants present at night or on cloudy days; thus, lower bilirubin thresholds to initiate phototherapy may be warranted.<sup>107</sup> Testing of serum bilirubin may be limited in low HDI areas due to suboptimal laboratory services, as well as cost of the testing; however, recent studies have validated the use of transcutaneous measures of bilirubin for screening and intervention in these settings.<sup>108–110</sup> The adoption of novel technologies, such as LED phototherapy machines, has the potential to further improve outcomes.<sup>111,112</sup> Because HDIVIG is an expensive therapy, the use of other medications to reduce the postpartum formation of bilirubin could be of interest.<sup>113</sup>

## Conclusion

In immune-mediated HDFN, maternal IgG antibodies—usually related to the ABO, Rh, or Kell blood groups—cross the placental barrier, causing hemolysis of fetal red cells. Although HDFN can be fatal, advances in diagnosis, treatment, and prevention have made immune-mediated HDFN increasingly a preventable and treatable condition. Improvements in diagnostic modalities, including maternal blood typing and screening for antibodies, antepartum treatment, and routine prophylactic RhIG given to D-negative women at risk, have improved outcomes for affected pregnancies. Postpartum management includes treatment of hyperbilirubinemia and anemia. Hyperbilirubinemia is usually treated by means of intensive phototherapy, with HDIVIG serving an adjuvant role to further reduce hemolysis. In addition, anemia is corrected by simple transfusion of red cells. These approaches have reduced the indications for exchange transfusion to very severe HDFN or when

intensive phototherapy combined with HDIVIG fails to reduce hyperbilirubinemia to levels that are considered safe. Novel therapies that convey additional neuroprotection or work to inhibit bilirubin production require further study. Additional approaches for treatment and prevention of HDFN and neonatal hyperbilirubinemia are needed to improve neurodevelopmental outcomes, especially in low HDI areas.

## CHAPTER 33

# Obstetric transfusion practice

James Sikora & John D. Roback

Center for Transfusion and Cellular Therapies, Department of Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, GA, USA

## Introduction

Blood loss during childbirth of up to about 1000 mL is usually well tolerated because healthy mothers are in a state of physiological hypervolemia.<sup>1</sup> However, postpartum hemorrhage (PPH) of more than 1000 mL in 24 hours can cause significant morbidity and mortality. This amount of blood loss is not rare, occurring in about 5% of the deliveries in well-resourced countries and in up to 20% in under-resourced countries.<sup>1</sup> Furthermore, lesser blood loss can also cause significant problems in mothers with anemia, preeclampsia, or other obstetrical complications. Maternal blood loss is associated with nearly one-quarter of all maternal deaths globally and is the leading cause of maternal mortality in most low-income countries.<sup>2</sup> Obstetric hemorrhage and preeclampsia together account for 50% of maternal deaths in poor as well as well-resourced countries.<sup>2</sup> In addition to effects on the mother, blood loss during pregnancy and the concomitant reduction in oxygen-carrying capacity also pose threats to the fetus.

## Blood loss in pregnancy

### Obstetrical causes

Among the several factors that can contribute to maternal blood loss, parturition remains the most significant. For example, in a Dutch national survey on severe morbidity among 358,874 pregnancies from August 2004 through August 2006, major obstetric hemorrhage (a bleed during delivery that required transfusion of at least four units of red blood cells) occurred in 4.5 per 1000 births.<sup>3</sup> Thus, hemorrhage accounted for 70% of all severe obstetrical complications (which occurred at a rate of 7.1 per 1000 births) in this dataset. Table 33.1 shows the most frequent etiologies.<sup>3</sup> The risks of major obstetrical bleeding increased dramatically as pregnancies progressed from the early pregnancy phase (51 bleeds; 3.2% of total), through the antepartum period (135; 8.5%), and into postpartum phase (1480; 93%). In some cases, women experienced both antepartum and postpartum hemorrhages. In the latter two categories, bleeding was most commonly related to physical/structural issues with the placenta and/or uterus such as abruptio placentae and *placenta praevia* (antepartum) as well as retained placenta or uterine

atonia (postpartum). Only a small percentage of the hemorrhages were assigned to nonobstetrical causes, such as clotting disorders (see below). Nonetheless, given that we are focused on obstetrical transfusion practices in this chapter, we now turn our attention to conditions that can cause coagulopathies that complicate pregnancies, as well as transfusion therapies to address these problems.

### Hematological causes

Among the few maternal hematologic diseases that can cause blood loss, maternal thrombocytopenia of various causes and inherited bleeding disorders are of most significance.

#### Maternal thrombocytopenia

##### *Gestational thrombocytopenia, HELLP, and ITP*

A platelet count below  $150 \times 10^9/L$  is not infrequent during pregnancy. Once laboratory artifacts (such as EDTA agglutination) are ruled out, about 6% of third trimester pregnancies demonstrate thrombocytopenia of  $80\text{--}150 \times 10^9/L$ . Typically, this represents an incidental finding and is termed *gestational thrombocytopenia* (GT).<sup>5,6</sup> While GT is a diagnosis of exclusion, of unknown cause and significance, patients should be carefully monitored. If the blood film is normal and the mother has no history of immune thrombocytopenia (ITP) or antiphospholipid antibodies, no further testing is indicated. However, if the platelet count drops below  $70\text{--}80 \times 10^9/L$ , other causes of thrombocytopenia should be sought.<sup>7</sup> In particular, GT has been considered as subclinical idiopathic thrombocytopenic purpura (ITP) or as a precursor of HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome.<sup>8,9</sup> Women who develop GT may be at higher risk for postpartum HELLP syndrome.<sup>8</sup>

HELLP syndrome is a member of a class of microangiopathic hemolytic anemias referred to as *thrombotic microangiopathic anemias* (TMAs). HELLP is less common than GT, occurring in 0.2–0.8% of pregnancies.<sup>10,11</sup> Among these patients, 70–80% develop preeclampsia.<sup>12</sup> The peak incidence of HELLP is at 36 weeks of gestation, although 10% of cases can occur prior to the 27th week while one-third present up to seven days after a normal delivery not complicated by preeclampsia.<sup>13</sup> As with GT, platelet levels are reduced in HELLP, with a median of  $57 \times 10^9$  platelets/L as shown in a large survey of 442 affected patients

**Table 33.1** Primary Diagnosis in Major Obstetric Hemorrhage Defined as the Need for At Least four Units of Blood

Timing	Diagnosis <sup>†</sup>	n	(%)
Early pregnancy (n = 51)	Ectopic pregnancy	29	(56.9%)
	Spontaneous abortion	10	(19.6%)
	Termination of pregnancy	10	(19.6%)
	Miscellaneous <sup>‡</sup>	2	(3.9%)
Antepartum (n = 135)*	Abruptio placetae	61	(45.5%)

Source: Sibai (1990).<sup>36</sup>

(Table 33.2).<sup>10</sup> In addition to platelet counts being lower than those typically seen in GT, patients with HELLP also present with right-upper abdominal pain, nausea, and vomiting, which can suggest the diagnosis. Fortunately, severe bleeding rarely occurs despite low platelets because preeclampsia is associated with vasoconstriction. Nonetheless, if not treated, severe cases of HELLP can result in DIC, pulmonary edema, acute renal failure, abruptio placentae, and liver hematoma, with maternal mortality as high as 20%. The definitive therapy for HELLP is ending the pregnancy, which leads to resolution of the disease within 10 days. Thus, in mothers with HELLP, elective birth should be considered as soon as it is clinically feasible. Clinical judgement is required for scheduling childbirth. On the one hand, attention should be paid to the child's ability to survive premature birth. On the other hand, extending the pregnancy to unnecessary lengths may also be deleterious for the child; neonatal death in mothers with HELLP ranges from 10% to 60%, depending on intervention, while elective preterm deliveries can reduce the fetus' risk of death (as well as the mother's risk). While mild thrombocytopenia and schistocytes are observed in up to 50% of these neonates, these findings typically resolve without treatment.

ITP is a less common cause of pregnancy-associated thrombocytopenia than either GT or HELLP, with an estimated incidence of 1–5 cases per 10,000 pregnancies.<sup>14</sup> Often, the mother has a

history of ITP, although ITP can also present initially during pregnancy. In either case, the decrease in platelets is most pronounced during the third trimester.<sup>15,16</sup> Treatment is driven by maternal indications. During the pregnancy, corticosteroids are first-line therapies, with the goal of maintaining platelets above  $20 \times 10^9/\text{L}$  or higher in case of bleeding symptoms.<sup>16,17</sup> Intravenous immunoglobulin (IVIG) is often reserved as second-line treatment. IVIG may also be used in preparation for delivery and can be combined with platelet transfusions at that time. A platelet count  $>50 \times 10^9/\text{L}$  is considered safe for delivery. Specific aspects of delivery procedures should be based on obstetric indications, with the understanding that procedures should be avoided which increase the fetus' hemorrhagic risk.<sup>18</sup> Since ITP is not associated with severe maternal bleeding during delivery, by itself it is not an indication for caesarean section (CS).<sup>19</sup> Should CS be required, British guidelines recommend a platelet count  $>80 \times 10^9/\text{L}$  for this procedure and for epidural anesthesia.<sup>18</sup>

In pregnancies complicated by ITP, neonatal platelet counts of less than  $50 \times 10^9/\text{L}$  are seen in only a fraction of the cases, and related complications are fortunately rare. The risk for neonatal thrombocytopenia is 4.9% directly after birth but increases to 38% in the first two weeks after birth.<sup>20–22</sup> Platelet levels typically reach their nadir at four days after delivery (range of 1–7 days after parturition),<sup>14–16</sup> and thrombocytopenia can persist for months.<sup>23</sup> Predicting which children are most likely to experience significant thrombocytopenia is difficult. A platelet count less than  $50 \times 10^9/\text{L}$  is most likely when maternal ITP is refractory to corticosteroids, other immunosuppressive treatments, and splenectomy.<sup>15,16,24</sup> In contrast, if the mother is asymptomatic, severe fetal thrombocytopenia is close to the background rate of 1% in term newborns. Nonetheless, there is only a weak overall correlation between maternal platelet count and neonatal thrombocytopenia.<sup>16,17</sup> Furthermore, maternal treatments for ITP do not appear to affect neonatal platelet counts.<sup>5,10,25</sup> The occurrence of maternal ITP does not predict significant fetal complications. Intracranial hemorrhage (ICH) or other severe neonatal bleeding is not increased when the mother has ITP, with a rate of 0–1.5%.<sup>16,17,26,27</sup> Nevertheless, brain imaging of the child is recommended with platelet counts  $<50 \times 10^9/\text{L}$ .<sup>16</sup> Perinatal mortality associated with maternal ITP is about 0.6%.<sup>20</sup>

### TTP and HUS

TTP, which results from autoantibodies directed against the ADAMTS-13 protease that cleaves large molecular weight von Willebrand factor (vWF) multimers, can present in the second and third trimesters. TTP must be differentiated from other TMAs, especially HELLP, since TTP is not associated with preeclampsia and does not require termination of pregnancy. Rather, TTP in pregnancy can be effectively treated with plasma exchange as in nonpregnant patients. Accordingly, a history of TTP in remission is not a contraindication for pregnancy.<sup>28</sup>

HUS and TTP are often included in the same differential. In pregnant patients, however, there are key differences. HUS primarily affects children and young adults, whereas TTP can be seen in older women.<sup>18</sup> Furthermore, atypical HUS (aHUS), the most common form in pregnancy, typically presents from two days postdelivery onward (mean 26 days). While 5–10% of HUS cases occur in the antepartum period, TTP on the other hand most commonly presents prior to parturition. At presentation, 50% of females with aHUS have thrombocytopenia below  $100 \times 10^9/\text{L}$ .<sup>6</sup> aHUS is typically associated with complement dysregulation due to mutations

in one or more complement genes,<sup>18</sup> although 6–10% of aHUS cases are caused by acquired antibodies against complement factor H.

Early diagnosis of TTP or HUS is essential to start treatment because most fatal events occur in the first few days. Plasma exchange is the first-line effective therapy for TTP; plasma exchange is also effective in patients with aHUS due to antibodies against factor H.<sup>18,29</sup> For this reason, it is acceptable to start exchange treatments and then modify accordingly based on ADAMTS-13 levels (<10% of normal levels are associated with TTP) and/or low complement levels (in aHUS). If testing supports the diagnosis of aHUS, then plasma exchange should be discontinued and Eculizumab therapy initiated.<sup>30</sup> Platelet transfusions for thrombocytopenia in TTP and aHUS are only indicated in cases of severe bleeding and not for prophylaxis. If possible, delivery can be postponed until the patient's condition has stabilized or resolved.

## DIC

While DIC can be seen in severe TMAA, the occurrence of DIC in pregnancy is usually caused by primary obstetric (abruptio placentae) or septic pathology. While 20–40% of obstetric patients with critical illness have symptoms of DIC, the strict reliance on a DIC score to identify DIC in pregnancy (e.g., based on decreased platelet count, increased D-dimers, decreased fibrinogen, and prolonged prothrombin time) is not reliable primarily because D-dimers start to increase in the first trimester and are always increased after the 35th week. Nonetheless, it is appropriate to have a high index of suspicion for DIC in critically ill pregnant patients because fibrin deposition from DIC can contribute to multiple organ failure, depletion of platelets and coagulation factors, and severe bleeding. While the definitive treatment focuses on addressing the underlying etiology, supportive care may also be necessary. Platelet transfusions are recommended in bleeding thrombocytopenic patients (<50 × 10<sup>9</sup>/L), while plasma and cryoprecipitate should be provided in patients with low fibrinogen, coagulopathy, and bleeding.<sup>31</sup> Of note, in contrast to TTP and aHUS, HELLP is not associated with overt DIC, although 70% of these patients demonstrate reduced antithrombin III (ATIII) levels.<sup>32</sup>

## APS

Antiphospholipid antibody syndrome (APS) is an acquired condition of hypercoagulability, often associated with systemic lupus erythematosus (SLE). APS is characterized by arterial and venous thrombosis, gestational vascular complications, recurrent fetal loss, growth retardation, and prematurity. Patients with APS demonstrate antibodies against β2-GPI (Glycoprotein 1), anticardiolipin autoantibodies, and/or prolongation of plasma clotting time (lupus anticoagulant/LA).<sup>33</sup> Based on randomized studies, women with recurrent abortion that may be due to APS are treated with a combination of low-dose aspirin and low-molecular-weight heparin.<sup>26,33,34</sup> There is no risk for fetal bleeding, but the mother has a slightly increased risk for bleeding during delivery.

## Inherited bleeding disorders

There is a growing list of rare inherited thrombocytopenic disorders typically resulting from mutations in genes involved in megakaryocyte and platelet production. Many of these diseases also manifest with platelet dysfunction. It follows that women with these disorders are at particular risk of bleeding during pregnancy as are their children if they inherit the same mutations. A retrospective survey from the European Haematology Association

identified an inherited thrombocytopenia prevalence of 2–3/100,000, with most of the cases from Italian patients. In this survey, 339 pregnancies were complicated by 13 different forms of inherited thrombocytopenia (50% with MYH9-related diseases). Surprisingly, however, there was no dramatic increase in bleeding during pregnancy, although 5% were transfused with platelets and/or red cells, which is higher than in the general population. None of the 156 children who inherited their mother's disorder showed intrauterine bleeding, but the authors mentioned that such bleeding has been reported in the literature. Five newborns had petechiae, and two suffered cerebral hemorrhage.<sup>35</sup> Planned delivery and an individualized treatment plan should be considered for these mothers. Such a policy also applies to woman with inherited platelet function disorders such as Glanzmann thrombasthenia or Bernard Soulier syndrome, for which tranexamic acid with or without rVIIa is recommended.<sup>36</sup>

Mothers with von Willebrand disease (vWD) are at increased risk for postpartum hemorrhage and have up to fivefold higher risk of transfusions.<sup>37</sup> As bleeding in vWD or more rare inherited coagulation factor deficiencies can persist or reappear up to two weeks or longer after delivery, appropriate therapies (desmopressin, vWF concentrates, or specific clotting factor concentrates) are recommended for at least 3–5 days after delivery.<sup>38</sup>

## Chronic maternal anemia

Physiological anemia due to plasma volume expansion peaks around the 25th week of pregnancy. *Anemia in pregnancy* is defined by WHO as an Hb <6.8 mmol/L (11 g/dL), although significant fetal problems such as growth retardation are usually not noticed until Hb drops to 5.5–6.2 mmol/L (9–10 g/dL).<sup>39,40</sup>

In otherwise healthy pregnant women, anemia is most often caused by nutritional deficiencies. However, anemia can certainly complicate the pregnancies of mothers with hemolytic diseases, such as thalassemia, SCD, and paroxysmal nocturnal hemoglobinuria (PNH). In addition to anemia, pregnant women with PNH are also at increased risk for thrombosis requiring antithrombotic treatment. Randomized studies in pregnant women with SCD have shown that maintenance of a hematocrit above 33% with less than 35% sickle cells significantly reduced painful crises, although pregnancy outcomes were not improved.<sup>41</sup> Since patients with chronic hemolytic anemias are often high antibody responders, they usually receive phenotypically matched red blood cell transfusions (for C, E, and Kell).

## Transfusions in pregnancy

### Maternal transfusions

#### Major obstetric bleeding

Clotting problems that most often accompany preeclampsia, placental abruption, and amniotic fluid embolism increase the risks of bleeding in pregnancy and thus the need for transfusions. Among these groups, women with preeclampsia are hypovolemic before hemorrhage starts and require special attention. Urinary output should be carefully monitored as it is the best indicator of renal perfusion in a bleeding or preeclamptic woman and should be maintained at least 30 mL/hour.

Life-threatening massive bleeding after delivery is most commonly caused by uterine atony (Table 33.3). Treatment of PPH includes transfusion along with oxytocin, misoprostol, prostaglandin, vascular embolization, surgical interventions, and hysterectomy.

**Table 33.3** Risk Factors for Postpartum Hemorrhage

- Overdistended uterus (multiple pregnancy, large fetus, and polyhydramnios)
- Prolonged labor
- Induction of augmentation of labor
- Postpartum hemorrhage in previous pregnancy
- Chorioamnionitis
- High parity
- Coagulation disorders (e.g., HELLP syndrome or placental abruption)

### Hemorrhage protocols

To support transfusion needs, postpartum hemorrhage protocols have developed to more closely resemble massive transfusion protocols (MTP) such as those used for trauma.<sup>42</sup> These involve earlier transfusion interventions, without waiting for consumption and dilutional coagulopathies.

### California maternal quality care collaborative (CMQCC)

To help prepare for rapid bleeding events, specific guidance for all sections involved in obstetric emergencies is recommended. In addition to identifying risk categories and collecting data, the CMQCC established tiered protocols to follow in the event of obstetric hemorrhage. Established in 2006 as a partnership between Stanford University and the state of California to reduce maternal mortality in the state, the CMQCC achieved a reduction in maternal mortality of more than 50% while the rest of the United States observed an increase.<sup>43,44</sup> Well-planned protocols using online tool kits to address all aspects of obstetric hemorrhage helped achieve this outcome. Recognizing factors that include all teams involved in the hospital setting along with clear-cut roles to play in these events improves the outcomes in obstetric hemorrhage.<sup>44,45</sup> An example of an emergency management plan is shown in the figure that follows. More tools and resources are available at CMQCC.org.

#### CMQCC Obstetric Hemorrhage Emergency Management Plan: Table Chart Format Version 2.0

	Assessments	Meds/Procedures	Blood Bank
Stage 0	Every woman in labor/giving birth		
Stage 0 focuses on risk assessment and active management of the third stage.	<ul style="list-style-type: none"> <li>• Assess every woman for risk factors for hemorrhage</li> <li>• Measure cumulative quantitative blood loss on every birth</li> </ul>	<b>Active Management Third Stage:</b> <ul style="list-style-type: none"> <li>• Oxytocin IV infusion or 10u IM</li> <li>• Fundal Massage-vigorous, 15 seconds min.</li> </ul>	<ul style="list-style-type: none"> <li>• If Medium Risk: T &amp; Scr</li> <li>• If High Risk: T&amp;C 2 U</li> <li>• If Positive Antibody screen (prenatal or current, exclude low level anti-D from RhoGam):T&amp;C 2 U</li> </ul>
Stage 1	Blood loss: > 500mL vaginal or >1000 mL Cesarean, or VS changes (by >15% or HR ≥ 110, BP ≤ 85/45, O <sub>2</sub> sat < 95%)		
Stage 1 is short: activate hemorrhage protocol, initiate preparations and give Methergine IM.	<ul style="list-style-type: none"> <li>• Activate OB Hemorrhage Protocol and Checklist</li> <li>• Notify Charge nurse, OB/CNM, Anesthesia</li> <li>• VS, O<sub>2</sub> Sat q5'</li> <li>• Record cumulative blood loss q5-15'</li> <li>• Weigh bloody materials</li> <li>• Careful inspection with good exposure of vaginal walls, cervix, uterine cavity, placenta</li> </ul>	<ul style="list-style-type: none"> <li>• <b>IV Access:</b> at least 18 gauge</li> <li>• Increase IV fluid (LR) and Oxytocin rate and repeat fundal massage</li> <li>• <b>Methergine</b> 0.2 mg IM (if not hypertensive) May repeat if good response to first dose, BUT otherwise move on to second level uterotonic drug (see below)</li> <li>• Empty bladder: straight cath or place foley with urimeter</li> </ul>	<ul style="list-style-type: none"> <li>• T &amp; C 2 Unit PRBCs (if not already done)</li> </ul>
Stage 2	Continued bleeding with total blood loss under 1500 mL		
Stage 2 is focused on sequentially advancing through medications and procedures, mobilizing help and Blood Bank support, and keeping ahead with volume and blood products.	<ul style="list-style-type: none"> <li>• OB back to bedside (if not already there)</li> <li>• <b>Extra help:</b> second OB, Rapid Response Team (per hospital), assign roles</li> <li>• VS &amp; cumulative blood loss q 5-10 min</li> <li>• Weigh bloody materials</li> <li>• <b>Complete evaluation</b> of vaginal wall, cervix, placenta, uterine cavity</li> <li>• Send additional labs, including DIC panel</li> <li>• If in Postpartum: Move to L&amp;D/OR</li> <li>• Evaluate for special cases: -Uterine Inversion -Amn. Fluid Embolism</li> </ul>	<b>Second level Uterotonic Drugs:</b> <ul style="list-style-type: none"> <li>• Hemabate 250 mcg IM or</li> <li>• Misoprostol 800 mcg SL</li> </ul> <b>Second IV Access</b> (at least 18 gauge) Bimanual massage <b>Vaginal Birth:</b> (typical order) <ul style="list-style-type: none"> <li>• Move to OR</li> <li>• Repair any tears</li> <li>• D&amp;C: r/o retained placenta</li> <li>• Place intrauterine balloon</li> <li>• Selective Embolization (Interventional Radiology)</li> </ul> <b>Cesarean Birth:</b> (still intraop) (typical order) <ul style="list-style-type: none"> <li>• Inspect broad lig. posterior uterus and retained placenta</li> <li>• B-Lynch Suture</li> <li>• Place intrauterine balloon</li> </ul>	<ul style="list-style-type: none"> <li>• Notify Blood Bank of OB Hemorrhage</li> <li>• Bring 2 Unit PRBCs to bedside, transfuse per clinical signs—do not wait for lab values</li> <li>• Use blood warmer for transfusion</li> <li>• Consider thawing 2 FFP (takes 35 + min), use if transfusing &gt;2u PRBCs</li> <li>• Determine availability of additional RBCs and other Coag products</li> </ul>
Stage 3	Total blood loss over 1500 mL, or >2 units PRBCs given or VS unstable or suspicion of DIC		
Stage 3 is focused on the Massive Transfusion protocol and invasive surgical approaches for control of bleeding.	<ul style="list-style-type: none"> <li>• Mobilize team</li> <li>-Advanced GYN surgeon</li> <li>-Second Anesthesia Provider</li> <li>-OR staff</li> <li>-Adult Intensivist</li> <li>• <b>Repeat labs</b> including coags and ABGs</li> <li>• Central line</li> <li>• Social Worker/family support</li> </ul>	<ul style="list-style-type: none"> <li>• Activate Massive Hemorrhage Protocol</li> <li>• Laparotomy:               <ul style="list-style-type: none"> <li>-B-Lynch Suture</li> <li>-Uterine Artery ligation</li> <li>-Hysterectomy</li> </ul> </li> <li>• Patient support               <ul style="list-style-type: none"> <li>- Fluid warmer</li> <li>- Upper body warming device</li> <li>- Sequential compression stockings</li> </ul> </li> </ul>	<b>Transfuse Aggressively</b> Massive Hemorrhage Pack <ul style="list-style-type: none"> <li>• Near 1:1 PRBC:FFP</li> <li>• 1 PLT apheresis pack per 4–6 units PRBCs</li> </ul> <b>Unresponsive Coagulopathy:</b> After 8–10 units PRBCs and full coagulation factor replacement: may consult re rFactor VIIa risk/benefit

### **Massive transfusion protocol**

Extreme cases of obstetric hemorrhage may require transfusion support as robust as the MTP. The proactive transfusion of plasma and platelets in predefined ratios with red blood cells has been shown to reduce total blood use and mortality in trauma.<sup>46,47</sup> Although the evolution of the MTP has been dictated by military and trauma data, an increasing amount of research has been devoted to assessing whether MTP has a positive effect in the setting of obstetric hemorrhage. The use of cryoprecipitate or other fibrinogen products is an especially important component of MTP in obstetrics because hypofibrinogenemia develops early during major obstetric hemorrhage.<sup>38,48–52</sup> As is the case with the MTP in trauma, there are many differing opinions on the correct ratios of blood products to supply. Regardless of the ratios used, the importance of using the MTP as one possible tool to combat severe obstetric hemorrhage is supported by major societies in obstetrics and gynecology.<sup>45,52,53</sup>

### **Cell salvage**

Cell salvage involves the collection of shed blood to be transfused into a bleeding patient. While the use of cell salvage requires thorough planning and preparation and may not be feasible in an emergency obstetrical setting, it should be considered for high-risk patients and those that do not accept allogeneic blood. Current filtration systems in use have removed the risk of causing amniotic fluid embolism. Additionally, limiting the use of cell salvage during cesarean section deliveries has reduced fears of introducing infections.<sup>45,54–58</sup> It is important to remember that fetal blood can be transfused to the mother during cell salvage; if necessary, Rh immunoglobulin can be administered to prevent alloimmunization.

### **Laboratory testing**

Although transfusion ratios are predetermined in MTP, coagulation testing is also encouraged in order to guide customization of blood product usage when necessary.<sup>38</sup> Laboratory evaluation of coagulation indices is an important part of guiding the use of blood products or pharmacologic therapy. As the coagulation status of a patient changes with resuscitation, more frequent laboratory information is needed. Thromboelastography (TEG [Haemonetics, Braintree, MA, USA]) and thromboelastometry (ROTEM [Tem International, Munich, Germany]) have emerged as technologies to monitor coagulation parameters in such situations. Furthermore, the results compare favorably to traditional testing despite usually having a faster turnaround time.<sup>45,59,60</sup>

### **Pharmacologic therapies**

Because the most common cause of PPH is uterine atony, drugs used to increase tone (oxytocin) are first-line therapy. Additionally, pharmacologics that aid coagulation may also be used to control bleeding.

### **Antifibrinolytics**

After uterine atony, one of the main causes of PPH is the degradation of fibrin. The use of antifibrinolytics like tranexamic acid (TXA) to prevent fibrin breakdown and aid in hemorrhage control has been used in cardiac surgery and trauma successfully for years.<sup>45,61,62</sup> More recently, large studies have focused on TXA for use in PPH.<sup>63–68</sup> The World Maternal Antifibrinolytic (WOMAN) trial found in 2017 that 1 g of intravenous TXA given within three hours significantly reduced mortality associated with PPH. The WOMAN trial found that a small window existed for intervention with TXA, as a delay of 15 minutes could lead to a decrease in the

benefits seen by as much as 10%. Furthermore, at three hours there was no benefit observed with administering TXA. Much of the initial hesitation with use of TXA in PPH came from the concern of causing emboli or renal dysfunction; however, the investigators found no increase in such complications with the dose studied.<sup>69</sup> Even though the majority of subjects included in this study were from developing countries, the evidence was strong enough for the WHO, ACOG, and CMQCC to update the OB guidelines to include TXA as a second-line drug for PPH.<sup>70,71</sup>

### **Fibrinogen**

Fibrinogen is the precursor to fibrin, which is important in management of hemorrhage. Although there are differences in the recommended level of fibrinogen for optimal treatment of PPH (200 mg/dL internationally or 125 mg/dL in the United States),<sup>72</sup> the need to maintain adequate levels for hemostasis is universal. As the guidance for adequate levels in PPH vary worldwide, so does the product primarily used to replace fibrinogen. In North America, cryoprecipitate is the product of choice for replacing fibrinogen, while purified fibrinogen concentrates (FC) are used in other countries. In the United States and Canada, FC is only approved for the treatment of congenital afibrinogenemia, although off-label use in acquired hypofibrinogenemia does occur. The advantages of FC over cryoprecipitate include pathogen inactivation, precise dosing, and immediate availability (does not need to be thawed prior to use). However, recent studies investigating the use of FC versus placebo in PPH showed no difference in the groups when used as preemptive treatment. Importantly, the studies found no increase in thromboembolic events associated with FC administration. The largest of the studies did however uncover findings to suggest that replacing fibrinogen at levels greater than 200 mg/dL in obstetric hemorrhage does not improve outcomes.<sup>73–76</sup>

### **Coagulation factor replacements**

Targeted coagulation factor replacement has been successful in treating and preventing hemorrhage in specific patients and situations. Four-factor prothrombin complex concentrates (PCC) contain proteins C and S in addition to factors II, VII, IX. In the United States, this product is FDA approved for reversal of coagulation deficiency caused by vitamin K antagonist therapy (warfarin) when Vitamin K administration is not timely enough to replenish cofactor levels (active bleeding or urgent surgery/invasive procedure).<sup>77</sup> Currently, evidence is lacking for the use of PCC in PPH.<sup>73</sup> Recombinant factor VIIa (rFVIIa) is FDA approved in the United States for hemophilia A/B that is complicated by inhibitors, acquired hemophilia, and Glanzmann's thrombasthenia.<sup>78</sup> Instances of thromboembolic events urge the careful use of rFVIIa.<sup>79–81</sup> The use of rFVIIa is considered a last choice in PPH when all other interventions have failed.

### **Postpartum anemia**

The need for transfusion to treat anemia is reduced in the postpartum period as compared to preparturition. At 3–6 weeks after delivery, healthy women with a postpartum median Hb level of 6.5 mmol/L (10.5 g/dL; range 7–15 g/dL) demonstrated no relationship between the Hb level and the quality of life.<sup>82</sup> Similar findings were seen in women who experienced lower Hb nadirs (3–4.9 mmol/L; 4.8–7.9 g/dL) at 12–24 hours after PPH. When these patients were randomized to receive transfusion of two RBC units ( $n = 259$ ), or not ( $n = 262$ ), physical fatigue was slightly better in the transfused group at 3–7 days postpartum, but the quality of life and physical complications were no different up to six weeks

after delivery.<sup>83</sup> These data suggest that Hb concentration of 4–5 mmol/L (7.0–8.0 g/dL), or lower (3 mmol/L; 5.0 g/dL), is usually well tolerated if isovolemia is maintained. Furthermore, even in the case of PPH, transfusion is usually only required for symptomatic anemia. There are no good studies of pregnant women with lower Hb concentrations; however, studies on Jehovah's Witness patients and others who declined blood transfusion found that morbidity and mortality rates start to accelerate below the level of 5.0 g/dL.<sup>84,85</sup>

### **Platelet transfusions during pregnancy and for delivery**

Platelet transfusion may be required under several different obstetrical situations. In otherwise uncomplicated pregnancies, most obstetrical guidelines recommend considering platelet transfusion prior to vaginal delivery when the mother's platelet count is below  $50 \times 10^9/\text{L}$ .<sup>18,86</sup> If local anesthesia is needed, most guidelines advise a platelet count of 50 or  $80 \times 10^9/\text{L}$ .

The situation becomes more complicated if the patient is suffering from thrombotic disorders. Platelet transfusions should be considered for patients who are thrombocytopenic secondary to TMAAs, ITP, or DIC; TTP, however, is an exception since it is considered a relative (but not absolute) contraindication for platelet transfusions. In these thrombocytopenic conditions, characterized by enhanced platelet phagocytosis or consumption, platelet transfusions are typically used therapeutically when the patient is bleeding rather than prophylactically. Because of different pathophysiology and bleeding history, an individual treatment plan for every pregnant patient with thrombocytopenia is required.<sup>87</sup>

### **Blood products used and special precautions**

#### *Red cell transfusions*

In Western countries, women are routinely screened early in pregnancy for RhD expression as well as for red cell alloantibodies. The objective is to identify potential causes or risks for hemolytic disease of the fetus and newborn (HDN), which can significantly complicate pregnancy. Women who are RhD-negative are candidates for RhIg administration, while those with preexisting red cell alloantibodies are brought to the attention of their obstetricians for evaluation and closer management. Of note, in addition to anti-RhD antibodies, antibodies against Rhc and Kel1 can also cause severe HDFN.<sup>88</sup> In more than 40% of cases, mothers with these latter antibodies had received prior transfusions indicating the significance of transfusion exposure.<sup>89</sup> Many national guidelines recommend the use of Kel1-negative (often also Rhc-compatible) donors for woman up to the age of 45–50 years, but this practice is not yet uniform.

#### *Platelet transfusions*

Although platelet units contain minimal amounts of red cells, that quantity is still sufficient to immunize RhD-negative recipients against the RhD antigen. Thus, when blood inventory challenges necessitate that RhD-negative women of childbearing potential receive RhD-positive platelet units, prophylaxis with RhIg is indicated.<sup>90</sup>

#### *Immunoglobulin*

To prevent HDN due to anti-RhD antibodies, all RhD-negative mothers should receive RhIg between the 28th and 34th weeks of gestation. Furthermore, these RhD-negative mothers should also

receive additional RhIg within 72 hours after delivery if the child is confirmed to be RhD-positive.<sup>91</sup> This approach reduces the incidence of RhD HDN in RhD-negative mothers to less than 1%. Nevertheless, HDN due to RhD antibodies remains the most frequent cause of severe HDN. This typically occurs due to medical, laboratory, or clerical errors, for example if RhIg is given in a dose that is too low to prevent alloimmunization following a large fetomaternal hemorrhage.<sup>92,93</sup>

In recent years, tests have been developed to perform fetal RhD typing on the maternal plasma; a negative RhD result means the mother will not be exposed to RhIg treatment unnecessarily.<sup>94</sup> This approach can also be used to type for other red cell antigens, including C, c, E, and Kel1.

High-dose intravenously immunoglobulin (IVIg) is another immunoglobulin preparation that may be administered during pregnancy. For example, IVIg may be used to increase the maternal platelet count in ITP and to reduce severe fetal bleeding in fetal or neonatal thrombocytopenia (FNAIT).

#### *Special safety aspects of transfusion products*

Blood products have been shown to transmit infectious agents that may harm the fetus, including CMV and parvo-B19. For this reason, there has been considerable debate over the years regarding the safest RBC and platelet products for pregnant CMV-seronegative women who require transfusion. Data show that units from donors who are CMV-seronegative have a similar safety profile to leukoreduced units from CMV-untested donors.<sup>95,96</sup> While the question of superiority of one method over the other has not been resolved, a large prospective observational trial showed that the transfusion of leukoreduced RBC and platelet units obtained from CMV-seronegative donors (the “belt and suspenders” approach) completely prevented CMV transmission to seronegative pregnant women.<sup>97</sup> While some countries test for parvovirus B19, this is not a widely available approach to providing B19-safe blood for transfusion.

#### *Low-income countries*

The blood transfusion services in some low-income countries have difficulty providing the quality or quantity of blood products taken for granted in the United States and other developed countries. This issue can have significant ramifications for pregnant women when considering that approximately 25% of maternal deaths can be traced to inadequate access to blood transfusion.<sup>98</sup> Furthermore, pregnant women in low-income countries are more likely to have underlying anemias due to malaria, iron and folic acid deficiency, SCD, and infectious diseases, suggesting that a relatively small hemorrhage can be deadly. To address these challenges, bed nets, nutritional supplements, antihelmintics, presumptive treatment of malaria, folic acid, and ferrous medication should be utilized as part of antenatal care to mitigate causes of anemia.<sup>99</sup>

Prevention of postpartum hemorrhage is another critical component of obstetrical care. While effective approaches include the use of oxytocic drugs, early cord clamping, and active efforts to deliver the placenta, actual practices differ between countries.<sup>100</sup>

It is also important to note that in some countries emergent blood donation by relatives is a common source of blood for maternal transfusion. However, the transmission of hepatitis and HIV is a serious risk with this practice and has been ascribed as the cause for 8–16 million hepatitis B, 2.3–4.7 million hepatitis C, and 80,000–160,000 HIV infections annually.<sup>101</sup>

## Fetal transfusions

### Alloimmune hemolytic disease

The state of the art for fetal transfusions has progressed significantly since 1963 when Liley transfused red cells into the fetal intraperitoneal cavity under X-ray guidance.<sup>102</sup> Survival rates for the procedure were approximately 50%,<sup>103</sup> and those fetuses had variable red cell uptake into the circulation that was negatively affected by conditions such as severe hydrops. Success improved significantly with the introduction of real-time ultrasound in the 1980s, which allowed transfusion directly into the umbilical vein of fetuses as young as 16 weeks.<sup>104</sup> The most frequent indication for fetal transfusion is anemia secondary to maternal alloimmunization to red cell alloantigens; other causes of fetal anemia that can be treated by in utero transfusion include parvovirus B19 infection,<sup>105,106</sup> severe fetomaternal hemorrhage,<sup>107</sup> placental chorioangiomas,<sup>108</sup> and homozygous α-thalassemia.<sup>109</sup>

Under ultrasound guidance, a 20–22 gauge needle is used to both aspirate blood for diagnosis and deliver red cells, platelets, or drugs into the fetal circulation. The umbilical vein is the preferred target for several reasons when the placenta is inserted anteriorly: the vein has a larger diameter than the umbilical arteries; because of its location, missing or overshooting the vein is most likely to leak blood into the amniotic cavity rather than Wharton's jelly, while the opposite is true when targeting the artery that can produce arterial spasm and fetal bradycardia; and flow of the transfused blood can be monitored by ultrasound during the transfusion. Typically, the mother is premedicated to reduce anxiety and sedate the fetus; muscle relaxants such as atracurium or pancuronium are also used to produce fetal paralysis that reduces the chances of needle displacement.<sup>110</sup>

After the needle is inserted, and prior to transfusion, 1–2 mL fetal blood is aspirated to quantify hemoglobin, hematocrit, and mean corpuscular volume. These values are used to calculate transfusion volume based on pretransfusion fetal hematocrit, estimated fetal placental blood volume, and hematocrit of the donor blood.<sup>111</sup>

Blood components to be transfused are extensively processed beforehand. Units are typically group O, RhD-negative, lack antigens against which the mother has produced alloantibodies, and crossmatch-compatible with maternal serum. To reduce the risks of CMV transmission, units are leukoreduced and at many centers also selected from the CMV seronegative inventory to further mitigate risk. To prevent transfusion-associated graft-versus-host disease, the components are also irradiated. At the time of this edition, the use of pathogen-reduced products in this population is being widely studied with a consensus still pending. Prior to transfusion, the unit is centrifuged, the supernatant removed (containing plasma, anticoagulant, and preservation solution), and 0.9% saline is added to a final packed red cell concentration of 80%.<sup>112</sup> The blood is transfused at 5–10 mL per minute while ultrasound is used for continuous monitoring of blood flow and the fetal heart rate.<sup>111</sup>

In the setting of alloimmune fetal anemia, due to maternal anti-RhD antibodies for example, the goal of fetal transfusion is not only to replace the volume of destroyed red cells but also to suppress ongoing production of incompatible fetal red cells. To this end, a second transfusion is given 1–2 weeks later, and additional transfusions are performed every 3–4 weeks afterward until the fetus can be safely delivered. It is important that prior to each transfusion the maternal antibody screen is repeated and the units to be transfused are crossmatched against the newest maternal sample. More than 70% of women with HDN requiring intrauterine transfusions

develop multiple erythrocyte antibodies,<sup>112</sup> most often caused by ongoing exposure to fetal red cells.<sup>112</sup>

The outcomes of fetal transfusion have improved significantly over the last half century. For example, at Leiden University Medical Centre, 593 ultrasound-guided intravascular transfusions of fetuses between 17 and 35 gestational weeks between 1988 and 1999 resulted in an 86% overall survival rate;<sup>88</sup> survival further improved to 98% between 1999 and 2009.<sup>113</sup> Although techniques have doubtless improved over this time, better pretransfusion management has also led to fewer mothers presenting with fetuses suffering from severe irreversible hydrops.<sup>88</sup> A follow-up study of 291 infants at a median age of eight years after fetal transfusion showed neurodevelopmental impairment in 4.8%, which is not statistically significant different from the general population. Hydrops and prematurity were identified as risk factors for the children with impairment.<sup>114</sup>

After birth, additional transfusion management including exchange transfusions or top-up transfusions may be required despite efforts to reduce the need for transfusion through IVIg administration.<sup>115,116</sup>

### Fetal or neonatal alloimmune thrombocytopenia

Immune-mediated thrombocytopenias, including fetal/neonatal alloimmune thrombocytopenia (FNAIT) or ITP, are identified in 0.3% of newborns.<sup>117–119</sup> Red blood cell alloimmunization can also cause thrombocytopenia in 10–30% of severely hydropic fetuses presumably through inhibition of thrombopoiesis due to expanded erythropoiesis.<sup>120</sup> With the exception of FNAIT, in utero bleeding such as intracerebral hemorrhage (ICH) is rare in these conditions and intrauterine platelet transfusions are not indicated.<sup>16,17,19,26</sup>

In contrast, FNAIT carries a significant risk for ICH. About 20% of fetuses affected by FNAIT will develop ICH, which can occur as early as the 20th week of gestation.<sup>121</sup> FNAIT is caused by maternal alloantibodies against polymorphic antigens on fetal platelets. In Caucasians, anti-HPA-1a antibodies cause 85% of FNAIT cases despite the fact that only about 2% of mothers are capable of producing these antibodies (HPA-1a negative).<sup>122</sup> Most of the remaining cases of FNAIT are caused by HPA-5b, HPA-3a, and HPA-15 antibodies,<sup>123</sup> although in some cases no antibodies can be detected suggesting that the target platelet antigen has not yet been discovered.<sup>124</sup> When considered from the perspective of pregnant women alloimmunized to platelet antigens, thrombocytopenia occurs in up to 85% of fetuses who express the cognate antigen. Despite frequent thrombocytopenia, the development of ICH is variable in FNAIT and appears to correlate with ICH in previous pregnancies; the risk ranges from 7%, typically when there was a sibling without ICH, to 80% when a sibling had ICH.<sup>125</sup>

While parental HPA genotypes can be used to predict the risk of FNAIT in a child, such screening is not routine. Accordingly, FNAIT is usually only diagnosed when a child presents with thrombocytopenia and/or ICH. While this index child must be managed reactively, the diagnosis of FNAIT allows physicians to manage the risks of FNAIT in later siblings. Parental genotyping can be used to assess the risk that a subsequent fetus may suffer FNAIT. A homozygous father will invariably pass the gene for the offending antigen to the fetus; a heterozygous father has a 50–50 chance of transmitting that gene, indicating the need for fetal genotyping.

If the fetus is determined to be at risk for FNAIT, antenatal management protocols are directed at preventing ICH. Unfortunately, the utility of quantifying maternal anti-HPA antibodies is unclear in this regard, although studies suggest it may predict the severity of

fetal thrombocytopenia.<sup>126–128</sup> The most direct way to assess the risk of ICH is by quantifying fetal thrombocytopenia through fetal blood sampling (FBS) beginning as early as 20 weeks of gestation.<sup>129,130</sup> However, the cumulative risk of fetal loss by repetitive FBS is approximately 6% per pregnancy,<sup>131,132</sup> while the cumulative risk for emergency delivery due to FBS is 13–17%.<sup>133,134</sup>

Given these significant risks, antenatal management is gradually transitioning from routine use of repetitive FBS, to a less invasive approach (fewer FBS procedures combined with IVIG and intrauterine platelet transfusions before delivery), to a completely noninvasive approach (IVIG only). Many centers have adopted this last approach and initiate weekly high-dose maternal IVIG when the fetus is judged to be at risk for FNAIT. As compared to FBS-guided treatment protocols, empiric IVIg administration without FBS guidance has been shown to be a cost-effective strategy.<sup>135</sup> In some cases, corticosteroids are administered as well.

Weekly maternal administration of IVIg (1.0 g/kg maternal weight) has been shown to increase platelet counts in fetuses with FNAIT. While an increase in platelet counts is only seen in 30% and 85% of cases, even fetal nonresponders whose platelet count remains depressed show reduced risks of ICH.<sup>134,136,137</sup> The mechanisms of IVIg action in FNAIT remain unclear, with several leading candidates. First, IVIg may downregulate maternal B cells including those producing anti-HPA antibodies. Second, IVIg may increase maternal catabolism of IgG as well as dilute out anti-HPA antibodies, essentially reducing the maternal titer of the offending antibody. Third, IVIG may block the placenta receptor that shuttles maternal antibodies, including anti-HPA antibodies, across the placenta. Fourth, in the fetus, IVIg may block Fc receptors on macrophages and prolong the lifespan of fetal platelets coated with anti-HPA antibodies. Fifth, IVIg may downregulate endothelial activation by platelet antibodies that crossreact with endothelial cells, accounting for the reduction in ICH when no impact on platelet count is observed.<sup>138</sup> In a mouse model of FNAIT, maternal IVIG administration demonstrated many of these hypothesized mechanisms as well as reduced bleeding and increased fetal survival.<sup>139</sup>

### Fetal transfusions for other indications

Parvovirus B19 infection during pregnancy can produce fetal anemia and thrombocytopenia by causing maturation arrest in hematopoietic stem and precursor cells. Parvo B19V is a frequent cause of nonimmune hydrops fetalis, and 46% of these hydropic fetuses have platelet counts below  $50 \times 10^9/L$ , which can further decrease after transfusion of red blood cells.<sup>140</sup> Intrauterine transfusions are indicated in Parvovirus B19 infected fetuses, although a single red cell transfusion is usually sufficient.<sup>106</sup>

Massive fetomaternal (transplacental) hemorrhage is a rare and serious complication of pregnancy that can produce severe fetal anemia, hydrops, and death. Reduced fetal movement may be the presenting condition, and the diagnosis can be confirmed by

increased flow in the middle cerebral artery measured by ultrasound<sup>141</sup> and fetal red cells in the maternal circulation in the Kleihauer-Betke test.<sup>135</sup> In the preterm period, fetal red cell transfusion is a realistic option.

After the introduction of laser coagulation of placental anastomosis as treatment for severe twin-to-twin transfusion syndrome (TTTS), TAPS (twin anemia–polycythemia sequence) is described as a new syndrome.<sup>142</sup> After laser coagulation, very small residual anastomosis may lead to chronic anemia and polycythemia in one of the twins.<sup>143</sup> Robyr *et al.* described 13 cases of TAPS (13% of their group of TTTS cases).<sup>144</sup> In 12 of the 13 cases, 1–5 fetal red cell transfusions were performed. Slaghekke described that, when the Solomon laser technique was used, the incidence of TAPS decreased from 16% to 3%.<sup>145</sup>

Very rare indications for fetal transfusions are placental chorioangioma and alpha-thalassemia.

### Conclusion

Postpartum hemorrhage is a serious risk factor in obstetrics. Most maternal mortality can be prevented using oxytocics, embolization of uterine vessels, and blood transfusion. In some cases, fetal transfusion of red blood cells and/or platelets is required.

### Acknowledgment

We would like to recognize the authors of the previous edition for the contributions they made to the present chapter.

Physiologically speaking, infants and children are not simply “small adults” when considering causes and treatments of anemia, thrombocytopenia, and coagulopathy. Several factors such as gestational age, congenital diseases, immature liver, maternal factors, and transplacental antibody transfer must all be considered when evaluating and treating neonates with anemia, thrombocytopenia, bleeding, or coagulopathy. Bleeding tendencies and diseases prevalent in childhood must be understood for optimal transfusion support. Additionally, special consideration must be given to the product(s) transfused to infants and children, whether the transfusion be for prophylactic reasons or otherwise. These considerations include ABO compatibility, total blood volume, immaturity, immunosuppression, immunodeficiencies, and blood donor exposure. This chapter first briefly reviews the etiology of anemia, thrombocytopenia, and coagulopathy in infants and children, and then provides a general overview of transfusion support.

## Red blood cell transfusion

### Pathophysiology of anemia in infants

Anemia in infants may be due to prematurity, blood loss, decreased RBC production (including rare instances of bone marrow failure), or increased RBC destruction (hemolytic disease of the fetus and newborn, mediated by maternal RBC alloantibodies, is covered in Chapter 32).

Anemia noted at birth in preterm infants is typically a result of incomplete iron transfer from the mother to the fetus via the placenta, in combination with incomplete erythropoietic activity of the fetal marrow.<sup>1</sup> After birth, this anemia is significantly exacerbated by phlebotomy associated blood loss; it has been estimated that this blood loss in preterm infants may approach as much as 11–22 mL/kg per week.<sup>2,3</sup> During the first weeks of life, all infants experience a decline in the number of circulating RBCs caused by physiologic factors. In healthy term infants, the nadir blood hemoglobin value rarely decreases to less than 9 g/dL (mean = 11–12 g/dL) at an age of approximately 10–12 weeks. Because this postnatal decrease in the hemoglobin level is universal and is well tolerated by term infants, it is referred to as “physiologic anemia” of infancy. Among preterm infants, this decline occurs at an

earlier age and is more pronounced in severity.<sup>4</sup> Mean hemoglobin concentration decreases to approximately 8 g/dL in infants of 1.0–1.5 kg birth weight and to 7 g/dL in infants weighing less than 1.0 kg. Anemia of infancy occurs as the production of hemoglobin F (with high oxygen affinity) transitions to the production of adult hemoglobin, hemoglobin A, with lower oxygen affinity; simultaneously there is a transient reduction in erythropoietin production.<sup>5</sup> This physiologic anemia improves when receptors in the kidneys and liver sense the hypoxia, leading to increased erythropoietin production.

As compared to infants born at term, preterm infants have a relatively diminished erythropoietin response to anemia.<sup>6</sup> However, since erythroid progenitor cells of preterm infants are responsive to erythropoietin in vitro, inadequate erythropoietin production is likely more of a factor than marrow unresponsiveness.<sup>7</sup> The use of erythropoietic-stimulating agents has been extensively studied in preterm infants over the past few decades. Whereas erythropoietin has been shown to stimulate erythropoiesis, conflicting data exist regarding the impact on neurologic outcomes. Ohls *et al.* demonstrated that erythropoietin improved neurologic outcome at 18–22 months in preterm infants and decreased transfusion burden.<sup>8,9</sup> In contrast, a multicenter randomized controlled trial (Preterm Erythropoietin Neuroprotection Trial [PENUT]), published in 2020, found no decrease in severe neurodevelopmental impairment or death by two years of age in infants treated with erythropoietin.<sup>10</sup> However, a subanalysis found that the infants randomized to erythropoietin required a lower volume of transfused red blood cells after 10 days of life.<sup>11</sup>

Another variable to consider in anemic preterm infants is the relative deficiency of micronutrients such as iron, folate, and other vitamins required for erythropoiesis,<sup>1</sup> in combination with shortened endogenous RBC survival compared to adults.<sup>5</sup> A 2012 review found that infants who receive iron supplementation have a slightly higher hemoglobin level, improved iron stores, and a lower risk of developing iron deficiency anemia compared with those who are not supplemented.<sup>12</sup>

Multiple additional strategies have been studied in preterm infants to decrease anemia and thus RBC transfusion burden, including delayed cord clamping, decreased phlebotomy blood loss, and pharmacologic interventions.<sup>5</sup> Delayed cord clamping ( $\geq 30$  seconds) has

been shown in a systematic review and meta-analysis of preterm infants to decrease mortality, increase peak Hct, and decrease the need for RBC transfusion.<sup>13</sup> As such, the American College of Obstetricians and Gynecologists (ACOG) recommends that cord clamping in vigorous term and preterm infants should be delayed until 30–60 seconds after birth.<sup>14</sup> Simple and novel strategies are also in use to decrease therapeutic phlebotomy loss.<sup>2</sup>

### **Red blood cell transfusion in infants**

Red blood cell transfusions in term and preterm infants are administered to increase oxygen-carrying capacity, and studies involving near infrared spectroscopy (NIRS) have confirmed increased cerebral-mesenteric oxygenation following transfusion.<sup>15,16</sup> Transfusions are more common in extremely low birth weight infants (ELBW, <1000 g) than in most other patient populations, with approximately 90% of such infants requiring some sort of transfusion support.<sup>17,18</sup> Among very low birth weight infants (VLBW, <1500 g), approximately 40–50% require transfusion. Despite the prevalence of anemia in these low birth weight populations, optimal transfusion protocols remain unclear.<sup>19–21</sup>

To help address this issue, two large randomized control trials investigating restrictive versus liberal transfusion thresholds in premature infants have recently been completed. A multicenter study (transfusion of prematures [TOP]) evaluated the effects of liberal (Hct 32–38% in critical and 29–35% in noncritical infants) versus conservative transfusion thresholds (Hct 25–32% in critical and 21–29% in noncritical infants) in 1824 randomized infants <1000 g and <29 weeks, with primary outcomes of death or neurodevelopmental impairment at 22–26 months corrected age.<sup>22</sup> A similar number of infants (423 or 50.1%) in the higher-threshold group died or survived with neurodevelopmental impairment, compared with 422 (49.8%) in the lower-threshold group. The neurodevelopmental data from TOP, with no evidence of a difference at 22–26 months corrected age in infants randomized to liberal versus conservative transfusion thresholds, are similar to those from the recently published ETTNO trial (the Effect of Transfusion Thresholds on Neurocognitive Outcomes of extremely low birth weight infants). ETTNO included 1013 infants in Europe with birth weight <1000 g and reported similar primary outcomes of death or major neurodevelopmental impairment at 24 months corrected age regardless of liberal (Hct 28–41%) or restrictive (Hct 21–34%) transfusion strategy assignment.<sup>23</sup> The results of TOP and ETTNO contrast with those from a prior smaller study (Premature Infants in Need of Transfusion [PINT]).<sup>24,25</sup> PINT included 456 preterm infants under 1000 g and reported a potential cognitive benefit in the liberal transfusion group. One important consideration for both the TOP and ETTNO studies is that neonates were not randomized to the most restrictive Hct values until they were older than 21 days of life. Prior to the TOP and ETTNO results being published, general Hct thresholds for preterm infants were developed using a compilation of existing British, American, Australian, and Canadian practice guidelines;<sup>26</sup> more detailed Hct thresholds by postnatal age have also been published.<sup>21</sup>

In term infants, red blood cell transfusions are most likely to be administered during surgery or while receiving extracorporeal membrane oxygenation (ECMO). In infants facing major surgery, definitive studies are not available to establish the optimal hematocrit. However, it seems reasonable to maintain the hematocrit >30% for major surgery because of the limited ability of the neonate's heart, lungs, and vasculature to compensate for anemia. Additional

factors include the inferior off-loading of oxygen to tissues by the infant's own red cells because of the diminished interaction between fetal hemoglobin and 2,3-DPG plus the developmental impairment of neonatal pulmonary, renal, hepatic, and neurologic function. The amount of anticipated blood loss must be strongly considered in preoperative transfusion decisions. With a likelihood of large blood loss, some physicians might prefer the preoperative hematocrit to be relatively high.

Some studies have documented RBC transfusion volumes as high as 30–40 mL/kg/day in infants and children on ECMO, but it is not clear that these transfusions increase tissue oxygenation.<sup>27</sup> Further, red blood cell and platelet transfusion volume in infants receiving ECMO have been shown to correlate with in-hospital mortality, although this correlation could be confounded by disease severity.<sup>28</sup> One facility that changed their Hct threshold from 40% to 35% for infants receiving ECMO did not find a detrimental impact on patient outcomes.

In infants with severe respiratory disease, such as those requiring high volumes of oxygen with ventilator support, it has historically been customary to maintain the hematocrit at approximately 35–40%—particularly when blood is being drawn frequently for testing. This practice is based on the belief that transfused donor RBCs, containing adult hemoglobin (with increased O<sub>2</sub> availability for a given PaO<sub>2</sub>), will provide optimal oxygen delivery throughout the period of diminished pulmonary function. Consistent with this rationale for ensuring optimal oxygen delivery in neonates with pulmonary failure, a hematocrit near 40% may be maintained in infants with congenital heart disease that is severe enough to cause either cyanosis or congestive heart failure. Following similar logic, it seems reasonable to maintain the hematocrit above 30–35% for moderate cardiopulmonary disease. Overall, however, data on transfusion support for term infants are quite limited, and additional studies would be beneficial to help inform practice.

### **Special considerations regarding RBC transfusion in preterm infants**

Red blood cell transfusion burden has been associated with multiple comorbidities in preterm infants, including necrotizing enterocolitis (NEC), bronchopulmonary dysplasia (BPD), retinopathy of prematurity (ROP), or death.<sup>17,29</sup> This is not without controversy, however, as a large meta-analysis failed to find any such relationship<sup>30</sup> and most recently the TOP trial reported similar secondary outcomes in the higher and lower hemoglobin threshold groups.<sup>24</sup> NEC is among the best studied of these complications, with many studies describing a temporal association between RBC transfusion and NEC<sup>31–38</sup> and with one meta-analysis identifying RBC transfusion as a significant risk factor for NEC.<sup>39</sup> However, other studies, including a prospective study and another meta-analysis, failed to find such an association,<sup>40,41</sup> and a recent GRADE review<sup>42</sup> has questioned the generalizability of previous study results. A multicenter birth cohort study of very low birth weight infants (<1500 g) identified the severity of anemia prior to RBC transfusion, specifically hemoglobin ≤8 g/dL per week, as being an independent risk factor for NEC.<sup>43</sup> These findings are consistent with an animal study.<sup>44</sup> Further, a subgroup analysis of a case-crossover study found that infants with anemia were at greater risk of NEC than infants who were not anemic.<sup>45</sup>

Beyond NEC, one study found early RBC transfusion (in the first 10 days of life) to be an independent risk factor for severe ROP

in preterm infants, independent of gestational age;<sup>46</sup> another found mechanical ventilation and transfusion burden to be associated with ROP.<sup>47</sup> It has been hypothesized that the increase in hemoglobin A (and the decrease in hemoglobin F) associated with RBC transfusion increases oxygen to the retina and plays a contributory role in ROP development.<sup>48</sup> Early anemia and RBC transfusion have also been associated with BPD in some studies.<sup>49</sup>

### Pathophysiology of anemia in children

Anemia in children is most frequently a result of decreased RBC production or ineffective erythropoiesis, secondary to antineoplastic chemotherapy, iron deficiency, chronic kidney disease,<sup>50</sup> thalassemia, and other causes. Blood loss, through trauma or surgery, may also lead to anemia in children. Less frequently, antibody or nonantibody-mediated RBC destruction are the causes of anemia.

### Red blood cell transfusion in children

Transfusions in children are broadly given for the same reasons as in infants, to increase oxygen-carrying capacity. Historically, studies of RBC transfusion thresholds in the pediatric population have lagged behind those in adults. A landmark study published in 2007, the Transfusion Strategies for Patients in Pediatric Intensive Care Units (TRIPICU) study,<sup>51</sup> randomized children in the ICU to receive RBCs at a restrictive (Hgb 7 g/dL) or liberal (>9.5 g/dL) threshold. The restrictive arm was found to have similar rates of new or progressive multisystem organ dysfunction. Thus, the TRIPICU investigators concluded that in stable critically ill children, a hemoglobin threshold of 7 g/dL for red-cell transfusion can decrease transfusion requirements without increasing adverse outcomes. This study, other published guidelines,<sup>52,53</sup> and the recommendations described below support the general pediatric transfusion thresholds shown in Table 34.1.

The Pediatric Critical Care Transfusion and Anemia EXpertise Initiative (TAXI) was formed through the Pediatric Critical Care Blood Research Network (BloodNet) and the Pediatric Acute Lung Injury and Investigators (PALISI) Network to develop evidence-based guidelines for transfusions in children. In 2018, after evaluating the existing evidence, this initiative published a series of guidelines for transfusion in children.<sup>54</sup> General good practice statements included evaluating laboratory values in the setting of the patient's condition and checking hemoglobin values prior to each additional RBC transfusion when feasible. Additional recommendations were separated by types of patient populations and conditions as follows:

- For critically ill children that do not otherwise meet the conditions described below,<sup>55</sup> the TAXI group recommended RBC transfu-

sion if the hemoglobin concentration is <5 g/dL. If the patients were hemodynamically stable, the group recommended not administering an RBC transfusion if the hemoglobin is ≥7 g/dL. The group determined that there was insufficient evidence to make a recommendation when the hemoglobin was between 5 and 7 g/dL.

- For critically ill children with respiratory failure,<sup>56</sup> the group recommended RBC transfusion if the hemoglobin is <5 g/dL. However, if the children with respiratory failure did not have severe acute hypoxemia or other qualifications, the TAXI group recommended not administering RBC transfusions when the hemoglobin is ≥7 g/dL. The appropriateness of transfusions at hemoglobin concentrations between 5 and 7 g/dL was left up to clinical judgement.
- For critically ill children with nonhemorrhagic shock,<sup>57</sup> the group could not recommend a specific RBC transfusion threshold. However, they made a weak recommendation not to administer RBCs for a hemoglobin ≥7 g/dL in children with severe sepsis.
- For critically ill children with non-life-threatening bleeding,<sup>58</sup> TAXI recommended that RBC transfusion should be given for a hemoglobin <5 g/dL and should be considered for a hemoglobin between 5 and 7 g/dL. They also recommended an RBC:plasma:platelet ratio between 2:1:1 and 1:1:1 for critically ill children with hemorrhagic shock.
- For critically ill children with acute brain injury,<sup>59</sup> the group recommended RBC transfusion be considered for hemoglobin values between 7 and 10 g/dL.
- For children with cardiac disease,<sup>60</sup> the TAXI group recommendations were broken down based on patient subgroups. For all such patients, the components contributing to oxygen delivery should be optimized before initiation of RBC transfusion except in cases of hemorrhagic shock. In children undergoing cardiac surgery (repair or palliation) or heart transplants, the group recommended considering not just the hemoglobin but also the overall clinical context. In infants and children with congenital heart disease, TAXI recommended investigating and treating preoperative anemia. In hemodynamically stable children with CHD and adequate oxygenation (for their cardiac lesion) and normal end organ function who are awaiting cardiac surgery, they recommended that the risk/benefit ratio be carefully considered before RBC transfusion was given. The group also commented that there is no evidence that a hemoglobin >10 g/dL is beneficial in children with ventricular dysfunction or in children with a normal heart and idiopathic or acquired pulmonary hypertension. For children with uncorrected heart disease, they recommended maintaining a hemoglobin of 7–9 g/dL. For stable children undergoing biventricular repairs, TAXI recommended not transfusing if the hemoglobin is >7.0 g/dL. For infants and children undergoing staged palliative procedures with stable hemodynamics, the group recommended avoiding transfusions solely based upon hemoglobin if the hemoglobin is >9 g/dL. In all cases, the TAXI recommendations strongly supported the use of intra- and postoperative blood conservation measures.
- For children with sickle cell disease who are critically ill or at risk of critical illness,<sup>61</sup> the group recommended RBC transfusion to a goal of 10 g/dL prior to a surgical procedure requiring general anesthesia. For children with acute chest syndrome who are critically ill and deteriorating, TAXI recommended an exchange transfusion over a simple transfusion when possible; otherwise a

**Table 34.1** Pediatric RBC Transfusion Thresholds

Situation	RBC Transfusion Threshold (Hgb)	Comment
Stable child	<5 g/dL	Always consider transfusion
	5–7 g/dL	Clinical judgement
	>7 g/dL	No transfusion except for some situations (including bleeding, heart disease, and others)
Unstable child	<7 g/dL	Always consider transfusion
	>7 g/dL	Clinical judgment

simple transfusion was recommended. For children with stroke, the group recommended exchange transfusion if possible but did not recommend an optimal postexchange hemoglobin or percent S level.

- For children with cancer or those undergoing hematopoietic stem cell transplantation who are critically ill or at risk of critical illness,<sup>61</sup> the group recommended that a hemoglobin of 7–8 g/dL be considered a threshold for transfusion.
- For critically ill children on extracorporeal membrane oxygenation (ECMO),<sup>62</sup> TAXI recommended reporting hemoglobin concentration rather than hematocrit for transfusion algorithms, that blood sparing measures be adopted, and that physiologic metrics and biomarkers of oxygen delivery be taken into consideration. The group determined that there was insufficient evidence to recommend a specific transfusion threshold. Instead, RBC transfusions should be based on evidence of inadequate cardiorespiratory support or decreased oxygen delivery.

Outside of the critical illness setting, prophylactic RBC transfusions are administered to children with cancer, sickle cell disease, and thalassemia major. The Children's Oncology group updated their Supportive Care Guidelines in 2020,<sup>63</sup> though no specific recommendations were included for RBC transfusion thresholds. The American Society of Hematology published transfusion support guidelines for sickle cell disease in 2020;<sup>64</sup> those guidelines recommend automated RBC exchange transfusion over simple transfusion or manual exchange transfusion when feasible for chronic transfusion therapy (conditional recommendation, low certainty evidence). For children with thalassemia major, there is limited practice guidance and thus a broad range of RBC transfusion practices in the United States, with hemoglobin thresholds ranging from 8 to >10 g/dL in one survey.<sup>65</sup>

Existing studies of RBC transfusion (and other transfusion support) for pediatric trauma resuscitation have been summarized by Kamyszek *et al.*<sup>66</sup> and by Maw *et al.*<sup>67</sup> In brief, optimal transfusion thresholds and RBC:plasma:platelet ratios are not well established for pediatric trauma patients. Furthermore, unlike the situation in adults, pediatric massive transfusion protocols in and of themselves have not improved outcomes in critically ill children. Tranexamic acid is increasingly being utilized in pediatric trauma cases and has been shown to decrease mortality in children under 18 years old in the combat setting.<sup>68</sup> However, at least one study has reported an increased risk of seizures associated with its use.<sup>69</sup>

### Red blood cell product selection for infants and children

Beyond matching for ABO and Rh compatibility, storage solution and storage duration are variables to consider in RBC selection for infants and children. While Chapter 14 describes the history of storage and additive solution development, an entire chapter could be written on the history on optimization of storage solutions for transfusion of infants and children. The short summary is that most pediatric centers in the United States now utilize RBCs stored in additive solutions, and these products are presumed safe for “small-volume” (<10–15 mL/kg) RBC transfusions.<sup>70–72</sup> The amount of potassium infused during an RBC transfusion into small infants has been the subject of much debate over the years, with the consensus being that the actual amount of extracellular

(plasma) potassium infused during “small-volume” transfusions is relatively minimal. For example, an infant weighing 1 kg given a 15 mL/kg transfusion of RBCs at an Hct of 55–60% stored for 42 days in additive solution receives approximately 0.3 mEq total of potassium; these doses have been shown to be safe in infants.<sup>71</sup> Historically some centers used RBCs stored in CPDA-1, given the higher Hct of these units. However, CPDA-1 units contain more plasma and as such may at least theoretically be associated with more transfusion reactions. Further, due to a low demand nationwide, it has become more difficult for blood centers to maintain adequate production of CPDA-1 units.

From the perspective of component modification, irradiation is used to prevent transfusion associated graft versus host disease in at-risk pediatric patients. Given that infants may have undiagnosed immunodeficiencies,<sup>73</sup> some institutions irradiate all cellular products transfused to neonates and infants.<sup>74</sup> Other institutions selectively irradiate products transfused to neonates weighing less than 1200 g. However, the 2020 Guidelines on Irradiation from the British Society for Haematology Guidelines Transfusion Task Force state that routine irradiation is not required for cellular products transfused to preterm or term infants unless those infants received intrauterine transfusions.<sup>75</sup>

There are several specific subgroups of patients where irradiation is noncontroversial. Neonates or children with known or suspected cellular immunodeficiencies, undergoing bone marrow transplantation, and/or receiving directed donor products, require irradiated cellular blood products.<sup>74,76</sup> Children with certain malignancies (including Hodgkin disease) require irradiated cellular blood products, and those receiving intensive chemotherapy often receive irradiated cellular blood products as well. The impact of the post-irradiation storage period on outcomes in infants and children has not been studied in detail,<sup>77</sup> though metabolomic changes are evident in the RBC unit.<sup>78</sup> The British Society Guidelines recommend that RBCs be transfused within 24 hours of irradiation if the fetal/neonatal recipient is at risk for hyperkalemia (e.g., for large-volume transfusion, exchange transfusion, or intrauterine transfusion).<sup>75</sup>

A more common component modification, leukoreduction, is effective at decreasing HLA alloimmunization, febrile transfusion reactions, and transmission of viruses harbored in WBCs.<sup>79</sup> Thus, leukoreduced cellular products are typically recommended for transfusion to infants and children.<sup>63</sup> Leukoreduced products are also considered to be “CMV reduced risk.”<sup>80–85</sup> A birth cohort study of very low birth weight infants investigated the effectiveness of the so-called “belt and suspenders” approach of preventing transfusion transmitted CMV infection. In this study, leukoreduced components obtained from CMV-seronegative donors were found to be extremely effective at preventing CMV transmission through transfusion; almost all documented cases of postnatal CMV infection were attributable to virus in maternal breast milk.<sup>86</sup>

Historically, pediatric clinicians have been attentive to the storage time of units prior to transfusion. To address the importance of this variable, two randomized studies have evaluated the impact of storage duration on outcomes in infants and children, both with similar conclusions. The Age of Red Blood Cells in Premature Infants (ARIPI) study found no difference in the primary end point (a composite end point of major morbidities) in premature infants <1250 g transfused with fresher (<7-day-old) or standard issue (mean 14.6-day-old) RBCs. The ARIPI study sites used a relatively

liberal transfusion threshold, however (mean pretransfusion Hb 8.7–10.7 g/dL). Thus, it is unclear whether these results can be extrapolated to premature infants transfused at more conservative transfusion thresholds or to RBCs stored for up to 28 days post-irradiation. A biotin-labeled allogeneic RBC study in infants found that the slope of 24-hour post-transfusion recovery did not decrease with increasing storage duration, suggesting that the survival of transfused RBCs in circulation was not affected by storage duration.<sup>87</sup> The Age of Transfused Blood in Critically Ill children (ABC-PICU) study also found no difference in new or progressive multiorgan dysfunction (including mortality) in children in the ICU receiving fresh (median 5-day-old) versus standard issue (median 18-day-old) RBCs.<sup>88</sup>

Of note, nontransferrin bound iron has been shown to increase by three hours following RBC transfusion in preterm infants<sup>89</sup> and to remain increased for up to 24 hours.<sup>90</sup> Inflammatory cytokines (IL-1 $\beta$ , IL-8, TNF-alpha, and MCP-1) and measures of endothelial activation (increased macrophage inhibitory factor and soluble intracellular adhesion markers) have also been shown to increase in such infants post-transfusion.<sup>91–93</sup> A 2017 study demonstrated that very low birth weight infants are more likely to show increased levels of nontransferrin bound iron after RBC transfusion than are healthy adult volunteers. For example, when transfused with RBCs stored for 20 or more days, nontransferrin bound iron increased in preterm infants but not in adults. The adult transfusion volunteers did not experience an increase in nontransferrin bound iron until RBCs had been stored 35–42 days prior to transfusion.<sup>94</sup> Regardless of storage duration, these very low birth weight infants also had increased levels of serum iron, bilirubin, and MCP-1 post-RBC transfusion. Thus, very low birth weight infants seem to have a unique inability (compared to term infants, children, or adults) to respond to iron release from macrophages following consumption of transfused RBCs, presumably due to impaired hepcidin responses and low transferrin.<sup>95,96</sup> The long-term consequences of these findings remain under investigation.

## Platelet transfusion

### Pathophysiology of thrombocytopenia in infants

Platelet counts in developing fetuses are typically higher than 150,000/ $\mu$ L by the end of the first trimester,<sup>97,98</sup> and most healthy newborns have counts above this level at term.<sup>99</sup> However, 1–5% of all neonates are affected by thrombocytopenia, with platelet counts lower than 150,000/ $\mu$ L, although the prevalence varies by study.<sup>100–102</sup> Preterm infants and those born small for gestational age are more likely to be affected by thrombocytopenia than term infants,<sup>101</sup> with up to 25% of all neonates admitted to neonatal intensive care units (NICUs) having mild, moderate, or severe thrombocytopenia at some point during their hospital stay. Babies in the NICU with extremely low birth weights are quite likely to have low platelet counts, with 73% of infants weighing under 1000 g reported to have platelet counts lower than 150,000/ $\mu$ L.<sup>101</sup>

Neonatal thrombocytopenia can be caused by decreased platelet production, increased platelet destruction, or a combination of these. The pathophysiology of neonatal thrombocytopenia noted at or soon after birth may also be due in part to maternal hypertension, placental insufficiency, and/or perinatal hypoxemia;<sup>103</sup> such conditions are more likely to be present in preterm than term infants. Perinatal infections such as Group B Streptococcus or *Escherichia*

*coli* may also be associated with early neonatal thrombocytopenia as may congenital infections such as toxoplasmosis, rubella, CMV, or HSV.<sup>103</sup> Thrombocytopenia that develops after the first few days of life may be due to postnatally acquired sepsis, disseminated intravascular coagulopathy (DIC), or necrotizing enterocolitis (NEC).<sup>102</sup>

Unique to neonates, transplacental transfer of maternal alloantibodies may contribute to thrombocytopenia in otherwise “well-appearing” infants.<sup>104</sup> Maternal antibodies against human leukocyte antigens (HLA) as well as human platelet-specific glycoprotein antigens (HPA) are capable of crossing the placenta, binding to the platelets of fetuses, and producing neonatal alloimmune thrombocytopenic purpura (NAITP).<sup>105,106</sup> Antibodies against HPA-1a are the most well-known causes of NAITP in Caucasians, with women lacking the HPA-1a antigen and expressing the HLA DRB3\*0101 being at particularly high risk of developing these antibodies during pregnancy with HPA-1a expressing fetuses.<sup>106</sup> Antibodies against HPA-5b, HPA-15a, or other HPA proteins may also lead to NAITP.<sup>107</sup> Rarely, maternal autoantibodies such as those found in mothers with ITP or other autoimmune diseases like SLE may also lead to neonatal thrombocytopenia.<sup>108</sup> Thus, it is prudent to check the maternal history and the maternal platelet count in instances of unexpected neonatal thrombocytopenia.

Platelet dysfunction may also contribute to bleeding in infants and children, with etiologies including those that are congenital (such as in Glanzmann's thrombasthenia or Bernard Soulier) or medication-induced. For example, medications given to mothers prior to delivery, including Ketorolac,<sup>109</sup> can potentially impact neonatal platelet function. Medications used in NICUs, including indomethacin and nitric oxide, may also impact platelet function.

### Platelet transfusion in infants

Historically, neonatal platelet transfusion guidelines have been based largely on consensus.<sup>110,111</sup> A randomized trial of premature infants (<1500 g) in their first week of life, completed more than 25 years ago, demonstrated that a liberal pretransfusion threshold of 150,000/ $\mu$ L was not associated with fewer bleeding episodes than a more conservative transfusion threshold of 50,000/ $\mu$ L.<sup>112</sup> With those data in mind, some institutions have historically prophylactically transfused stable term and preterm infants at platelet counts of 25,000 and 30,000/ $\mu$ L, respectively,<sup>113</sup> whereas others have transfused stable infants at platelet counts of 50,000/ $\mu$ L. Table 34.2 lists potential guidelines for neonatal platelet transfusions.

In 2019, the landmark Platelets for Neonatal Transfusion-Study 2 (PlaNeT-2),<sup>114</sup> a randomized trial comparing preterm infants (median gestation age 26.6 weeks and median birth weight 740 g) receiving prophylactic platelet transfusions to maintain counts

**Table 34.2** Neonatal Platelet Transfusion Thresholds

Situation	Platelet Transfusion Threshold
Clinically stable term neonate	20,000–25,000/ $\mu$ L
Clinically stable preterm neonate	25,000–50,000/ $\mu$ L*
Clinically unstable neonate or bleeding neonate	50,000–100,000/ $\mu$ L
Need for invasive procedure	50,000/ $\mu$ L
NAITP	30,000–50,000/ $\mu$ L#
ECMO	50,000–100,000/ $\mu$ L#

\*Two studies found worse outcomes at higher thresholds

#Transfusion threshold dependent on past and present bleeding

above 25,000 or above 50,000/ $\mu\text{L}$ , reported a lower mortality and less intracranial bleeding in the restrictive arm. A subanalysis reported that these outcomes occurred in infants at both lower or higher baseline risk, with the authors suggesting that a threshold of 25,000/ $\mu\text{L}$  could be safely adopted in all preterm infants.<sup>115</sup>

A retrospective study of newborns <32 weeks of gestational age born in two different cities showed no difference in intracranial hemorrhage rates between neonates transfused with restrictive (transfusion for platelet count less than 50,000/ $\mu\text{L}$  in bleeding or sick neonates), compared to liberal (transfusion according to institutional guidelines) criteria.<sup>116</sup> Another study of preterm, low birth weight infants (<1500 g) demonstrated that more restrictive transfusion thresholds (transfusion for platelet count less than 50,000/ $\mu\text{L}$  in sick infants or less than 25,000/ $\mu\text{L}$  in stable infants) were associated with no greater bleeding than more liberal thresholds.<sup>117</sup> Furthermore, a 2009 study showed there is no clear relationship between platelet count and major intracranial hemorrhage; more than 91% of neonates with platelet counts under 20,000/ $\mu\text{L}$  demonstrating no bleeding.<sup>118</sup>

Two neonatal subpopulations worthy of additional discussion include those on ECMO and those with NAITP. Babies on ECMO are at risk of bleeding due in part to thrombocytopenia secondary to consumption, platelet dysfunction, and heparinization of the circuit. Thus, platelet transfusion thresholds between 50,000 and 100,000/ $\mu\text{L}$  are typically utilized in these babies, dependent on bleeding status.<sup>119,120</sup> Neonates with NAITP are also at high risk of bleeding. Babies with NAITP and a documented intracranial bleed should be maintained at platelet counts above 50,000/ $\mu\text{L}$  for at least the first week of life. Neonates with NAITP and no bleeding are typically maintained at platelet counts above 30,000/ $\mu\text{L}$  and often higher for the first week of life. Random donor ("off the shelf") platelets may be transfused for babies with NAITP and will typically increase the neonate's platelet count at least transiently.<sup>104,121,122</sup> Platelets lacking HPA-1a, HPA-5b, or other offending antigens may be requested from blood donor centers for neonates thought to have NAITP mediated by these respective antibodies, though emergent transfusions should never be withheld while antigen-negative platelets are being located. Maternal platelets are another therapeutic option, yet they may be difficult to obtain and they *must* be washed to remove offending antibodies and irradiated prior to transfusion.<sup>105</sup> IVIG may be given to affected neonates in an attempt to increase the platelet circulatory half-life; it is also administered during pregnancy to women carrying fetuses at risk for NAITP, with dose and schedule determined by risk stratification.<sup>122–124</sup>

### **Pathophysiology of thrombocytopenia in children**

Thrombocytopenia in children is typically caused by decreased production, increased destruction, or sequestration of platelets. Dilutional thrombocytopenia can also occur in situations of massive transfusion.

Hypoproliferative thrombocytopenia occurs in children treated with chemotherapy or radiation, with most platelet transfusions in childhood given in these patient populations. A subset of antiepileptic drugs, along with drugs in other categories, may decrease platelet production in children. Myelodysplasia, marrow infiltrative processes, and aplastic anemia also lead to decreased platelet production. Lastly, hereditary bone marrow failure syndromes and other congenital disorders such as Wiscott Aldrich Syndrome can lead to impaired platelet production.

The most common cause of destructive thrombocytopenia in children is idiopathic thrombocytopenic purpura (ITP). Most

children who present for medical care with acute ITP have isolated thrombocytopenia with platelet counts lower than 20,000/ $\mu\text{L}$  and may have the abrupt onset of bruising and bleeding. Platelet count alone has not been shown to predict bleeding severity in ITP.<sup>125</sup> Intracranial hemorrhage is a rare but life-threatening complication of acute ITP,<sup>126</sup> occurring in less than 1% of cases. A 2009 study of 40 children with ITP and intracranial hemorrhage showed that 90% had a platelet count lower than 20,000/ $\mu\text{L}$ , 33% had head trauma, and 22% had hematuria.<sup>127</sup>

Other destructive causes of thrombocytopenia in children include chronic ITP, autoimmune diseases, heparin induced thrombocytopenia, HIV, post-transplant thrombocytopenia, post-transfusion purpura, and neoplasm-associated immune thrombocytopenia. Nonimmune causes of destructive thrombocytopenias in children include hemophagocytic syndromes, Kasabach–Merritt syndrome, DIC, infectious etiologies, congenital heart disease, type 2B vWD, and platelet-type vWD. Thrombotic microangiopathies including HUS, TTP, and drug or bone marrow transplant-associated microangiopathy also occur in children.

Mild thrombocytopenia may occur in children with hypersplenism or splenic sequestration, although platelet counts rarely drop below 50,000/ $\mu\text{L}$  in these patients. Thrombocytopenia may also be associated with liver disease. Rarely, laboratory artifacts may lead to "spurious" thrombocytopenia (e.g., platelet counts reported to be low by automated counters, but not truly low); the main causes of such incorrect platelet counts include EDTA-dependent antibodies, cold agglutinins, and certain medications.

### **Platelet transfusion in children**

As with transfusions in infants or adults, platelet transfusions in children may be given: (1) in the setting of an acute hemorrhage or (2) as prophylaxis to decrease bleeding in at-risk patients. Thresholds for both situations continue to be debated, however. Young children with treatment-associated hypoproliferative thrombocytopenia may be at higher risk for bleeding than adults,<sup>128,129</sup> with factors in addition to low platelet counts likely contributing to this risk. These factors may include chemotherapy intensity as well as functional differences in interactions between the vascular endothelium and platelets.<sup>128</sup>

### **Platelet transfusion in children with active bleeding**

Platelet transfusion should be considered in any pediatric patient with thrombocytopenia and active bleeding, with transfusion thresholds being situation dependent (Table 34.3). Patients with

**Table 34.3** Pediatric Platelet Transfusion Threshold

Situation	Platelet Transfusion Threshold
Bleeding patient	Situation dependent
Bleeding on ECMO or during surgery	50,000–100,000/ $\mu\text{L}$
Prophylaxis for hypoproliferative thrombocytopenia	10,000/ $\mu\text{L}$
Prophylaxis for line placement	20,000/ $\mu\text{L}$
Prophylaxis for lumbar puncture	50,000/ $\mu\text{L}$ #
Prophylaxis for major surgery	50,000/ $\mu\text{L}$ %
Platelet dysfunction with bleeding or in need of invasive procedure	Not applicable

#May consider applying a higher threshold when circulating blasts are present

%May consider applying a higher threshold for CNS surgery

congenital platelet disorders and active bleeding may also benefit from platelet transfusions in addition to adjunctive therapies, regardless of platelet count.

Children with hypoproliferative thrombocytopenia from chemotherapy or radiation, those undergoing bone marrow transplantation, those on ECMO, or those undergoing surgery who are bleeding may also benefit from platelet transfusions. Children with ITP and acute, life-threatening bleeding should receive 1–2 doses of platelets (with a dose defined as 5–10 mL/kg) in addition to 0.8–1 g/kg of IVIG and 30 mg/kg of methylprednisolone.<sup>130–132</sup> Repeat platelet dosing may be needed due to rapid antibody-mediated removal post-transfusion. Rarely, emergent splenectomy is also considered in this setting. Though platelet transfusion thresholds are not applicable and alloimmunization may result, platelet transfusions may be effective at controlling bleeding in children with Glanzmann's thrombasthenia, Bernard Soulier, and other congenital causes of severe platelet dysfunction.<sup>133,134</sup> However, other treatments including topical therapies, antifibrinolytics, desmopressin, or recombinant Factor VIIa may also be used in some of these disorders.

### **Prophylactic platelet transfusion in children**

The 2015 AABB guidelines recommend that adult patients with hypoproliferative thrombocytopenia be transfused at a platelet count of 10,000/µL to prevent spontaneous bleeding<sup>135</sup> consistent with the 2018 American Society of Clinical Oncology guidelines for adults and children<sup>136</sup> and consistent with the 2020 Children's Oncology Group's Supportive Care Guidelines.<sup>63</sup> Despite these guidelines, some degree of equipoise exists regarding platelet transfusion thresholds for children with hypoproliferative thrombocytopenia.<sup>137,138</sup> A single institution study evaluating transfusion practice over 10 years showed the median platelet count for which pediatric oncology patients with hypoproliferative thrombocytopenia were transfused was 16,000/µL.<sup>139</sup> A 2013 survey of Children's Oncology Group Stem Cell Transplant Directors showed that 69% of institutions transfused nontransplant oncology patients for platelet counts below 10,000/µL, with 27% of institutions transfusing these patients for platelet counts below 15,000/µL.<sup>138</sup> This survey also found that transfusion thresholds for stem cell transplant patients were higher: 47% of institutions prophylactically transfused their transplant patients for platelet counts below 10,000/µL and 44% of institutions prophylactically transfused for platelet counts below 20,000/µL.<sup>138</sup>

Of the multiple large transfusion studies performed to date on patients with hypoproliferative thrombocytopenia, only one (Optimal Platelet Dose Strategy to Prevent Bleeding in Thrombocytopenia Patients [PLADO]) has included a separate pediatric analysis.<sup>140</sup> PLADO enrolled 200 pediatric patients from 0 to 18 years of age<sup>128</sup> and was designed to evaluate the relationship between platelet transfusion dose and bleeding. PLADO showed that platelet dose did not predict bleeding in pediatric patients. Of note, the children in the study had a higher risk of World Health Organization grade 2 or greater bleeding than the adults. Additionally, the children in this study had more days of grade 2 or higher bleeding than adults, with a median of three days (compared to one day in adults). Bleeding was most pronounced in the pediatric patients undergoing stem cell transplantation. Taken in combination, these results emphasize that factors beyond platelet counts impact bleeding risk.

Children with sickle cell disease undergoing stem cell transplantation are at risk of CNS bleeding<sup>141,142</sup> given vascular issues, prior CVAs, and transplant-associated hypertension. The prophylactic platelet transfusion threshold for this patient population has thus been set higher than that of other pediatric transplant patients;<sup>141,143</sup> many centers now use a transfusion threshold of 30,000/µL.<sup>144</sup>

Adult guidelines for platelet transfusion that are reasonable to translate to pediatric patients include transfusion for platelet counts less than 20,000/µL prior to central line placement and for platelet counts less than 50,000/µL prior to non-CNS surgeries.<sup>145</sup> The 2015 AABB guidelines recommend transfusing platelets for adult patient with platelet counts less than 50,000/µL prior to lumbar puncture; extrapolating these guidelines to lumbar punctures in children *without circulating blasts* is reasonable. It must be noted, however, that traumatic lumbar punctures in children with circulating blasts have been shown to decrease event-free survival from 7 to 17%.<sup>146–148</sup> Two studies have identified a platelet count under 100,000/µL as a risk factor for a traumatic lumbar puncture in pediatric leukemia patients.<sup>149,150</sup> As such, the optimal prelumbar puncture platelet count for pediatric patients with circulating blasts remains unclear.<sup>151</sup>

Prophylactic transfusions of functional platelets in the peri-surgery or peri-partum period may be indicated in patients with congenital or acquired platelet function defects; adjunctive therapies are often necessary as well. Careful care coordination and treatment planning between multiple specialties is necessary in these cases, to minimize the likelihood of operative or delayed postoperative bleeding. Conditions in which platelet transfusions should generally be avoided include those associated with consumptive coagulopathies such as TTP and HUS.

### **Platelet product selection for infants and children**

Platelets chosen for transfusion to infants and children in the United States may be from apheresis or whole blood donors, with many centers preferentially utilizing apheresis platelets. ABO compatible or identical platelets are ideally selected for transfusion into pediatric patients, in order to (1) minimize the passive transfer of incompatible plasma,<sup>152,153</sup> (2) minimize the destruction of platelets expressing incompatible antigens,<sup>154</sup> and (3) minimize transfusion reaction rates (including febrile and allergic reactions).<sup>155</sup> An additional consideration in neonates is the need for chosen platelets to be compatible with maternally derived isoantibodies that may be transiently present in the neonate's circulation. The same irradiation and leukoreduction indications reviewed in the RBC section also apply to platelets; HLA-matched or crossmatched platelets must always be irradiated. Pathogen reduction of platelets also inactivates T-cells, and thus pathogen-reduced platelets do not require irradiation. Of note, no increased rates of transfusion reactions have been reported in children transfused with pathogen-reduced platelets, though increased platelet utilization has been described.<sup>156</sup> However, a paucity of data currently exists regarding outcomes of preterm neonates transfused with pathogen-reduced platelets. Transfusion of Rh(D) positive platelet products into Rh(D) negative female children should be avoided when possible. Although the likelihood of an Rh(D) negative patient forming an anti-D after exposure to low amounts of residual RBCs in an Rh(D) positive apheresis platelet unit is extremely small,<sup>157–160</sup> prophylaxis with RhIg is appropriate in female children.<sup>136</sup> A 300 µg dose of RhIg can suppress immunization to 15 mL of packed RBCs.<sup>161</sup>

5–10 mL/kg of platelets are typically infused as a single “dose,” with a maximum dose regardless of weight typically being 1 apheresis unit or 1 “pool” of whole-blood-derived platelets (from 4 to 8 donors). Some centers provide fractions of apheresis platelet units in a weight-based fashion (e.g., 5–10 mL/kg to infants,  $\frac{1}{4}$  apheresis unit to children <15 kg,  $\frac{1}{2}$  apheresis unit to children between 15 and 30 kg, and a whole apheresis unit to children >30 kg), and others provide platelets derived from a single whole blood unit for every 10 kg of body weight. Small volumes of platelets are often transferred prior to transfusion from parent platelet units into syringes, with these aliquots retaining acceptable in vitro characteristics for up to six hours after transfer.<sup>162–164</sup> Volume reduction is not typically recommended, given the loss and/or activation of platelets that occurs during this modification.<sup>165</sup> Transfusion rates vary based on recipient condition, but each dose must be fully infused within four hours of being released from the blood bank. Post-transfusion platelet increases are dependent in part on the platelet count of the transfused unit, the recipient’s condition, the degree of donor/recipient ABO matching, and whether the unit was pathogen-reduced or not.

### Transfusion reactions in the pediatric population

In addition to infectious complications of transfusion, other noninfectious hazards of transfusion should also be considered.<sup>79</sup> Allergic transfusion reactions are relatively common in children compared with adults, and platelets are the most common component to cause such reactions. A 2015 study at a single institution found that 6.2/1000 pediatric transfusions were associated with a reported transfusions reaction compared to 2.4/1000 adult transfusions, with platelets being the most likely blood product to result in a transfusion reaction. 2.7/1000 pediatric transfusions (vs. 1.1/1000 adult transfusions) were associated with an allergic transfusion reaction, while 1.9/1000 pediatric transfusions (vs. 0.47/1000 adult transfusions) were associated with a febrile nonhemolytic transfusion reaction.<sup>166</sup> Another study evaluated composite data from multiple pediatric and adult US hospitals over a seven-year study period and reported an incidence of allergic transfusion reactions in children to be 3.23/1000, compared to 0.72/1000 in adults.<sup>167</sup> A final study reviewed the charts of pediatric patients at a single institution being transfused with platelets and found that 116/805 platelet transfusions were associated with a potential acute transfusion reaction; however, only 4 of these 116 potential reactions were reported to the hospital transfusion service.<sup>168</sup> In combination, these studies suggest that transfusion reaction rates in pediatric patients are likely higher than previously appreciated, with additional studies being warranted.

### Plasma transfusion

#### Development of the coagulation system

Quantitative and qualitative differences in coagulation factors, coagulation inhibitors, and fibrinolytic proteins exist in neonates compared to older children and adults. At one day of age, vitamin-K-dependent coagulation factors (II, VII, IX, and X) and the contact factors (XII, XI, high-molecular-weight-kininogen, and

prekallikrein) are 30% or more below the levels typically seen in adults.<sup>169,170</sup> By six months of age, levels of these coagulation factors in both premature and full-term infants are within normal adult ranges. On the other hand, levels of fibrinogen, FV, FVIII, and FXIII, and vWF are above 70% of adult values on the first day of life in both premature and full-term infants. Fibrinogen levels are lower in premature infants than in full-term infants. Inhibitors of coagulation (AT, protein C, and protein S) are also lower in infants than adults. In the fibrinolytic system, plasminogen levels are lower in infants than adults and significantly lower in preterm than term infants.<sup>171</sup>

Taken together, these alterations in factor concentrations affect the functioning of the coagulation system as well as standard laboratory coagulation tests. The activated partial thromboplastin time (aPTT) is most prolonged in premature and full-term infants on Day 1 of life as compared to adults, being 1.4–2.4 times and 1.2–1.5 times longer, respectively.<sup>171</sup> This prolongation has been attributed to the quantitative and qualitative deficiencies of contact factors. In premature and full-term infants, aPTT values normalize to adult values by six and three months of age, respectively. The prothrombin time (PT) is less prolonged in neonates, ranging from being not significantly different from adult values to being 1.15–1.3 times longer, depending on the study.<sup>171</sup> All diagnoses and treatment decisions must be made within the context of these age-dependent ranges.<sup>172</sup>

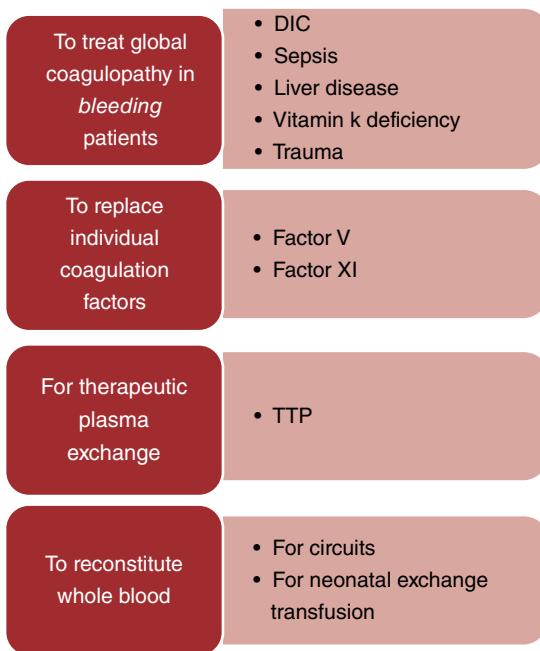

#### Plasma transfusion in infants and children

Plasma is one of the most inappropriately utilized blood products in pediatric transfusion. A 2014 study of multiple NICUs in Italy reported that 60% of 609 plasma transfusions given to neonates were noncompliant with published recommendations.<sup>174</sup> Other studies and surveys have also shown relatively high rates of plasma transfusion to nonbleeding infants and children despite limited evidence of efficacy.<sup>174–178</sup> The magnitude of this problem becomes apparent when one considers that 2.85% of children admitted to hospitals are transfused with plasma, based on a 2012 study of three million admissions of infants and children.<sup>173</sup>

Drawing on experience, past publications,<sup>76,179</sup> and adult guidelines,<sup>180</sup> Figure 34.1 lists acceptable plasma transfusion indications in infants and children. Generally, plasma may be used in infants and children to (1) treat global coagulopathy, (2) replace individual coagulation factors, (3) treat diseases such as TTP requiring therapeutic plasma exchange, and (4) to reconstitute whole blood for neonatal exchange transfusions. Other reasons for plasma transfusion are rarely supportable.

#### Plasma to treat global coagulopathy

Causes of coagulopathy in infants and children include DIC, liver disease, trauma, and dilutional effects. With the understanding that treatment of the underlying cause of DIC is essential, plasma may be transfused to mitigate DIC-associated bleeding. Plasma is also indicated for liver failure with active bleeding and prior to invasive procedures, though the hemostasis observed after FFP infusion is typically quite transient. Although vitamin K is the first-line therapy for neonates with congenital or acquired vitamin K deficiency, plasma or prothrombin complex concentrates are also indicated in cases of life-threatening bleeding in such patients.<sup>171,181,182</sup> Trauma-associated coagulopathy has been demonstrated in children

**Figure 34.1** Considerations for Plasma Transfusion in Infants and Children. Source: Based on Roback *et al.*<sup>180</sup>

independent of dilutional effects and is associated with adverse outcomes.<sup>183</sup> Pediatric massive transfusion protocols typically treat trauma and dilutional coagulopathy by providing plasma, cryoprecipitate, and platelets for resuscitation, in addition to RBCs, as described earlier in this chapter.<sup>67</sup> Infants with hypoxic ischemic encephalopathy treated with therapeutic hypothermia can also benefit from plasma transfusion to treat their well-described coagulopathy.<sup>184</sup> In contrast to the above clinical scenarios, empiric infusion of plasma is not recommended to correct an elevated INR in the absence of bleeding.<sup>185,186</sup>

#### Plasma to replace individual coagulation factors

Plasma is indicated for replacement of coagulation factors in situations where specific factor concentrates are not available.<sup>185</sup> If a child has a suspected congenital bleeding deficiency but the etiology is not apparent, initial therapy with 10–15 mL/kg of plasma is reasonable while awaiting definitive factor testing.<sup>171</sup> Plasma remains the treatment of choice in the United States for the replacement of Factors V and XI,<sup>182,187,188</sup> though two Factor XI concentrates are available outside the United States.<sup>189,190</sup> Reviewed in more detail in Chapters 37, the administration of recombinant or virally inactivated plasma-derived Factors VII, VIII, IX, XIII, vWF, and fibrinogen have replaced the use for plasma or cryoprecipitate in patients congenitally deficient in these factors.

#### Plasma as a replacement fluid for therapeutic plasma exchange

Plasma is typically used as a replacement fluid in therapeutic plasma exchange procedures for children with acquired TTP.<sup>191,192</sup>

The act of removing the patient's plasma reduces levels of IgG autoantibodies against ADAMTS13, while the plasma components used for replacement replenish the ADAMTS13 cleaving enzyme.

#### Plasma to reconstitute whole blood (for circuits or neonatal exchange transfusions)

Transfusion support of pediatric cardiothoracic surgery patients is complex, with dual risks of thrombosis and bleeding. RBCs, fresh whole blood, plasma in combination with RBCs, or nonblood products are used to prime cardiothoracic surgery circuits.<sup>193</sup> Studies show conflicting data with regard to which components in a prime result in less bleeding, fewer transfusion requirements, and better outcomes.<sup>194–197</sup>

Similarly, the priming and maintenance of ECMO circuits, which are used to treat a number of pediatric conditions nonresponsive to traditional ventilatory support,<sup>119</sup> are also complicated with some institutions combining albumin, RBCs, and/or other additives for this purpose.<sup>74</sup> Plasma can be transfused to children on ECMO for bleeding and/or elevated INR.<sup>120,198</sup> A protocol that includes Factor Xa monitoring, thromboelastography, and antithrombin monitoring, in addition to traditional coagulation testing, has been shown to decrease bleeding and transfusion requirements, while increasing circuit life in pediatric ECMO patients.<sup>199</sup>

Neonatal exchange transfusions are typically performed using group O RBCs (lacking offending cognate minor antigens), reconstituted with AB plasma to an Hct of 50–55%. The primary indication for exchange transfusion in neonates, reviewed in detail in Chapter 33, is hemolytic disease of the fetus and newborn with antibody-mediated hemolysis and hyperbilirubinemia.<sup>200</sup>

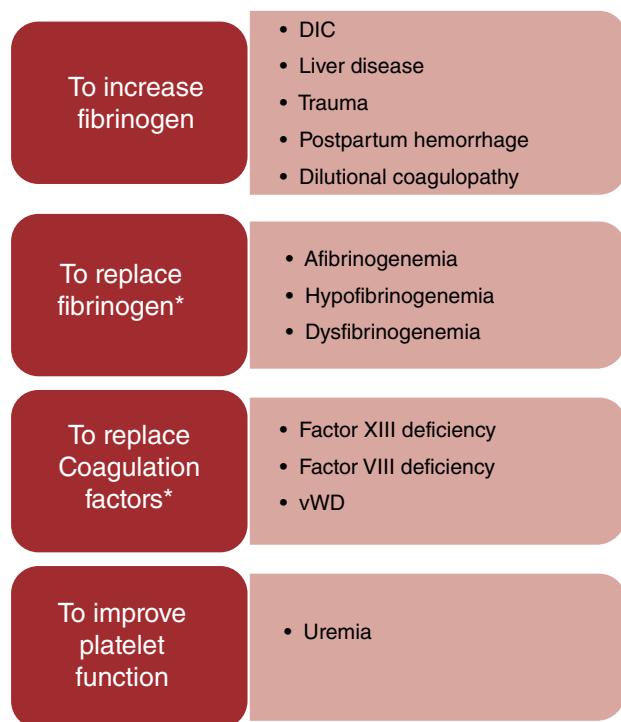

#### Plasma product selection for infants and children

FFP is the proper name for plasma frozen to  $-18^{\circ}\text{C}$  within 6–8 hours of phlebotomy, while PF24 is used to denote plasma frozen within 24 hours of phlebotomy. These products can be used interchangeably, unless single Factor V or VIII replacement is needed.<sup>201,202</sup> Thawed plasma is a term used to describe FFP or PF24 stored at  $1\text{--}6^{\circ}\text{C}$  for up to four days since these products show degradation of coagulation factors over time. This product may be useful in situations such as traumas, in which plasma is rapidly needed;<sup>203</sup> however, few pediatric studies have been completed involving thawed plasma. Plasma cryoprecipitate reduced (also known as cryo-poor plasma) is utilized in some centers as a second-line product and in others as a product equivalent to FFP or PF24 for TTP plasmapheresis.

Plasma chosen for transfusion should ideally be ABO compatible, though Rh(D) matching is not required. Plasma is considered an acellular product and thus irradiation is not necessary. 10–15 mL/kg of plasma typically raises coagulation factors by approximately 30%.

#### Cryoprecipitate transfusion

Cryoprecipitate is made from the cold insoluble high-molecular-weight proteins removed from thawed plasma, including fibrinogen, Factor VIII, Factor XIII, vWF, and fibronectin. Each individual bag of cryoprecipitate must include 80 IU of Factor VIII and 150 mg of fibrinogen, typically in 5–20 mL of plasma.<sup>201</sup> Many blood manufacturers prepool 2–10 individual bags of cryoprecipitate for transfusion convenience.

**Figure 34.2** Considerations for Cryoprecipitate Transfusion in Infants and Children

**Figure 34.3** Platelet, Plasma, and Cryoprecipitate Dosing for Infants and Children. Source: Based on Poterjoy & Josephson<sup>177</sup> and Fasano & Luban.<sup>204</sup>

Cryoprecipitate may be used to increase fibrinogen levels in infants and children with hypofibrinogenemia and hemorrhage due to liver disease or DIC<sup>204</sup> (Figure 34.2). Cryoprecipitate may also be used to increase fibrinogen levels in older adolescents/young women with postpartum hemorrhage<sup>205</sup> and to replenish fibrinogen levels in pediatric trauma patients, a subset of whom have been reported to have trauma-associated hypofibrinogenemia independent of dilutional coagulopathy.<sup>185</sup> In addition, cryoprecipitate can be

used in combination with FFP to replace fibrinogen plus coagulation factors in instances of dilutional coagulopathy. Cryoprecipitate has also been used as a second-line therapy to treat uremia associated bleeding.<sup>206</sup>

While cryoprecipitate has historically been used to treat bleeding or for prophylaxis in patients with hemophilia, vWD, Factor XIII deficiency, or congenital afibrinogenemia, hypofibrinogenemia, or dysfibrinogenemia, these diseases are now largely treated with recombinant

or human-derived concentrates.<sup>207</sup> Nonetheless, cryoprecipitate remains a second-line therapy should such concentrates be unavailable.

Transfusion thresholds for fibrinogen have not been extensively studied in children, though extrapolation of adult guidelines would suggest that fibrinogen levels should be maintained above 80–100 mg/dL.<sup>181,208</sup> Recent adult studies suggest that fibrinogen levels above 150 mg/dL may be more ideal,<sup>205,209</sup> depending on the transfusion indication.

In children, 1 unit of cryoprecipitate per 5–10 kg of body weight is estimated to raise the fibrinogen level by 60–100 mg/dL (Figure 34.3);<sup>177,204</sup> this equates to approximately 2–3 mL of cryoprecipitate per kg.<sup>181,210</sup> The half-life of fibrinogen (3–5 days), along with the indication for transfusion, will determine the recommended frequency of cryoprecipitate transfusion. Cryoprecipitate is considered an acellular product and thus does not require irradiation for recipients at risk for transfusion associated graft-versus-host disease. Potential adverse effects of cryoprecipitate transfusion include the risk of thrombosis.

## CHAPTER 35

# Thrombocytopenia and platelet transfusion

Michael F. Murphy, Simon J. Stanworth, & Lise J Estcourt

NHS Blood and Transplant, Department of Haematology, Oxford University Hospitals and University of Oxford, Oxford, UK

Thrombocytopenia is caused by disorders impairing platelet production, causing platelet destruction, or leading to platelet sequestration. In addition, there are both congenital and acquired disorders of platelet function. These latter conditions may lead to the functional equivalent of thrombocytopenia despite the presence of a normal platelet count. Platelet transfusion represents an important therapeutic option for most of these disorders. However, under certain circumstances, platelet transfusion is contraindicated. Therefore, correct diagnosis of the underlying etiology of thrombocytopenia is important.

Methods for the preparation of platelet products for transfusion include platelet pools derived from multiple whole blood donations and apheresis units from individual donors. These components may be further manipulated depending on the requirements of the recipient. Platelet refractoriness represents a significant problem that develops in some patients who require repeated platelet transfusions. While refractoriness is most frequently due to nonimmune platelet consumption, immune responses to platelet antigens also occur. HLA alloimmunization is the most important immune cause, and it is managed by the provision of HLA-matched or crossmatched platelets. The development of platelet substitutes and the administration of thrombopoiesis-stimulating agents represent alternatives to platelet transfusion that are in various stages of clinical development and may ultimately reduce the need for donor-derived platelets.

### Thrombocytopenia

*Thrombocytopenia* refers to any reduction in platelet number below the lower limit of the normal range, which is about  $150 \times 10^9/L$  in most laboratories. In the absence of other factors, however, the risk of bleeding is considered to be relatively modest until the platelet count is less than  $50 \times 10^9/L$ , and it is not considered to be severe until the platelet count is less than  $25 \times 10^9/L$ .<sup>1</sup> However, congenital or acquired abnormalities in platelet function may be associated with bleeding even when the platelet count is in the normal range.<sup>2,3</sup> A systematic diagnostic approach facilitates the correct diagnosis and appropriate management of thrombocytopenia and platelet dysfunction. Careful assessment of the medical history is imperative, including a review of concomitant medications. The peripheral

blood smear should be reviewed for morphologic abnormalities in any of the three lineages (myeloid, erythroid, and megakaryocytic), which may provide important insights into the underlying diagnosis, be it congenital or acquired. The causes of thrombocytopenia are summarized in Table 35.1.

### Impaired platelet production

Disorders of platelet production may be congenital or acquired. Congenital disorders are relatively rare, whereas acquired disorders are much more commonly encountered in clinical practice. In the absence of an apparent etiology, distinguishing decreased platelet production from increased platelet destruction or from splenic sequestration can be challenging. Decreased platelet production is generally characterized by normal platelet size on the peripheral blood smear and a normal mean platelet volume (MPV). In addition, the reticulated platelet count as measured by flow cytometry is low.<sup>4</sup> A bone marrow aspirate and biopsy may be required in order to determine the underlying disorder associated with thrombocytopenia.

Hematologic and nonhematologic malignancies, and myelofibrosis, are associated with replacement of the marrow space and a reduction in blood cell production and pancytopenia. However, sometimes reduction in the platelet count is the first indication of one of these abnormalities. Platelet transfusions may be used appropriately for supportive care as needed while the cause of the underlying disorder is identified.

### Platelet sequestration

About one-third of the platelet mass is normally sequestered in the spleen.<sup>5</sup> Splenomegaly from any cause tends to further increase splenic platelet pooling. Hematologic malignancies including the myeloproliferative disorders may result in marked splenomegaly. In particular, myelofibrosis may be associated with thrombocytopenia.<sup>6</sup> Portal hypertension from liver disease may also be associated with marked splenomegaly leading to thrombocytopenia or even pancytopenia. The thrombocytopenia associated with splenic sequestration alone is generally moderate and is not associated with bleeding. However, concomitant conditions, such as the coagulopathy of liver disease or dysfibrinogenemia, can exacerbate the tendency to bleed in this setting.<sup>7</sup> Individuals with alcoholic cirrhosis

**Table 35.1** Causes of Thrombocytopenia

<b>Impaired Production</b>
Selective megakaryocyte depression:
Rare congenital defects
Drugs, chemicals, and viruses
As part of general bone marrow failure:
Cytotoxic drugs and chemicals
Radiation
Megaloblastic anemia
Leukemia
Infection
Myelodysplastic syndromes
Myeloma
Myelofibrosis
Solid tumors
Aplastic anemia
<b>Excessive Destruction or Increased Consumption</b>
Immune
Autoimmune: ITP
Drug induced (e.g., GP IIb/IIIa inhibitors, penicillins, and thiazides)
Secondary immune (SLE, CLL, viruses, drugs, e.g., heparin and bivalirudin)
Neonatal alloimmune thrombocytopenia
Posttransfusion purpura
Disseminated intravascular coagulation
Thrombotic thrombocytopenic purpura
<b>Sequestration</b>
Splenomegaly
Hypersplenism
<b>Dilutional</b>
Massive transfusion

and portal hypertension who continue to consume alcohol may also have exacerbated thrombocytopenia resulting from suppression of platelet production.<sup>8</sup>

### Congenital platelet disorders

Hereditary disorders may affect platelet number, platelet function, or both. Some congenital disorders leading to severe thrombocytopenia or markedly abnormal platelet function are identified early in life, but others are identified only after excessive bleeding is encountered in adulthood at the time of trauma or surgery.<sup>9</sup> Although platelet transfusion is effective in the treatment of bleeding in congenital platelet disorders, it can lead to the production of platelet antibodies and thus should be reserved for serious bleeding episodes.  $\epsilon$ -Aminocaproic acid (EACA) or desmopressin (DDAVP) may be useful for minor bleeding or for perioperative management of minor procedures, depending on the severity of the underlying disorder. In the absence of any bleeding, patients should be counseled to avoid aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) and to take appropriate prophylactic measures before procedures (e.g., use of EACA before minor dental procedures).<sup>9,10</sup>

### Acquired platelet disorders

Thrombocytopenia may be the primary manifestation of several different hematologic disorders. These include immune thrombocytopenic purpura (ITP) and the microangiopathic hemolytic anemias.

#### Immune thrombocytopenic purpura

ITP, covered in more detail in Chapter 36, is an acquired immune-mediated disorder characterized by isolated thrombocytopenia in the absence of any obvious underlying cause.<sup>11,12</sup> In particular, red cell morphology is normal, and large platelets are often seen. In

children, this condition is typically acute, is associated with an antecedent viral illness, and resolves spontaneously. However, in adults it often follows a chronic course and there are usually no precipitating factors. Signs and symptoms vary widely; some patients have little or no bleeding, whereas others can experience life-threatening hemorrhage.<sup>11</sup>

The standard initial treatment in adults is with corticosteroids (1 mg/kg/day). Individuals with bleeding, at high risk for bleeding, who require a surgical procedure, or who are unresponsive to steroids may benefit from additional treatment with intravenous immunoglobulin at a dose of either 1 g/kg/day for one or two days or 0.4 g/kg/day for up to five days.<sup>11</sup> In cases of severe or life-threatening bleeding, platelet transfusion is indicated. Although the survival of transfused platelets is greatly reduced, they are likely to have some beneficial effect on active bleeding.<sup>11</sup>

### Microangiopathic hemolytic anemia

Several different conditions can cause a similar appearance on the blood smear: thrombocytopenia and the presence of red cell fragmentation (schistocytes).<sup>13</sup> However, clinical distinction between TTP/HUS and disseminated intravascular coagulation (DIC) is critical. In addition, malignant hypertension and valvular hemolysis may result in a similarly appearing smear.

TTP represents a medical emergency. It is a rare condition that has been characterized by a pentad of clinical findings:

- microangiopathic hemolytic anemia (MAHA),
- thrombocytopenia,
- neurological deficits,
- fever, and
- renal abnormalities.

However, its onset is insidious and the classic pentad is rarely present at diagnosis.<sup>14</sup> The pathophysiology of this disorder has become elucidated as resulting from reduction or inhibition in function of the von Willebrand factor (vWF)-cleaving protease ADAMTS13.<sup>14</sup> Decreased ADAMTS13 activity leads to an accumulation of ultralarge von Willebrand factor multimers, which bind to platelets and induce aggregation. Microthrombi cause tissue ischemia and organ dysfunction (commonly involving the brain, heart, and kidneys), which may result in long-term as well as early complications.<sup>15</sup> Early diagnosis and treatment are essential, and TTP is now often diagnosed and treated when MAHA and thrombocytopenia are present, without the other findings in the pentad, in the absence of any other known cause.<sup>14</sup> Coagulation tests are almost always normal.

Platelets are activated in TTP, leading to a hypercoagulable state. Therefore, transfusion with platelets should be reserved for individuals with thrombocytopenia and life-threatening hemorrhage. The therapy of choice is plasma exchange.<sup>14</sup> Steroids are useful to suppress the autoantibodies inhibiting ADAMTS13 activity in severe ADAMTS13 deficiency.<sup>14</sup> Relapsing and refractory TTP, a less common presentation of this disease, has been treated successfully with the CD20 monoclonal antibody rituximab.<sup>14</sup> Caplacizumab, a humanized single-variable-domain antibody against vWF, prevents interaction with the platelet glycoprotein Ib-IX-V receptor and has been shown to speed the resolution of acute TTP.<sup>16</sup> A recent study found that the treatment of acquired TTP with caplacizumab, but without plasma exchange, increased platelet counts and improved surrogate parameters of organ damage in select patients.<sup>17</sup>

HUS is characterized by the triad of thrombocytopenia, MAHA, and acute renal failure.<sup>18,19</sup> The most common form of HUS is

associated with diarrheal illness with Shiga-toxin-producing bacteria such as *Escherichia coli* H:0157.<sup>19</sup> Supportive care is usually all that is required because spontaneous recovery is the rule. Atypical HUS (aHUS), a term applied to any HUS not caused by Shiga toxin, has been associated with a variety of precipitating events including infections, drugs, autoimmune conditions, and pregnancy. Until the beginning of the 2010s, plasma exchange was considered the gold standard for aHUS. Eculizumab has now been shown to be highly effective in aHUS, with up to 95% of patients becoming disease free.<sup>20</sup>

DIC is most commonly associated with infection or malignancy, although it can also be observed in the setting of vascular lesions such as hemangiomas and intravascular dissections. In contrast to TTP and HUS, the consumptive coagulopathy that occurs is not exacerbated by the administration of platelets and other blood components.<sup>21</sup> Although primary therapy should address the underlying condition, transfusions of platelets and other blood components may be safely administered to treat bleeding.

### Malignancy

Thrombocytopenia is also a side effect of the cytotoxic chemotherapy administered for many different hematologic and nonhematologic malignancies. However, in addition, several hematologic malignancies are associated with inherent impairment in platelet function. Both the myelodysplastic and myeloproliferative syndromes are potentially associated with impaired platelet function out of proportion to any reduction in platelet number that is present.<sup>22</sup> Platelet transfusions are sometimes indicated in the bleeding patient despite apparently acceptable platelet numbers but are not indicated to treat stable thrombocytopenia in nonbleeding patients.<sup>23</sup> It should also be noted, however, that myeloproliferative syndromes are also associated in some situations with platelet activation and thrombosis. Because of the latter, agents such as EACA and tranexamic acid should be used cautiously in these disorders and reserved for situations with symptomatic bleeding due to reduced platelet function or severe thrombocytopenia.

### Uremia

Several nonmalignant acquired conditions are associated with platelet dysfunction. Of these, uremia is most commonly encountered in clinical practice. Treatment of uremia with dialysis restores platelet function toward normal. For the patient with acute bleeding in the setting of uremia, several therapies have potential benefit.<sup>24</sup> DDAVP releases additional vWF from endothelial stores and is reasonably safe and effective in this setting. Administration of cryoprecipitate facilitates the same end. For less acute bleeding, high doses of conjugated estrogens and correction of anemia may be effective.

### Dialysis

Although dialysis improves platelet function in uremia, it is also associated with the development of thrombocytopenia. In particular, continuous venovenous dialysis or hemofiltration has been associated with a reduction in platelet number in some patients. It is important to distinguish thrombocytopenia caused by the dialysis procedure from heparin-induced thrombocytopenia (see below) because patients are often treated with this anticoagulant in the intensive care setting.

### Cardiac interventions and abnormal vascular surfaces

Cardiac procedures, use of ventricular assist devices, and cardiopulmonary bypass may all be associated with thrombocytopenia and/or defects in platelet function.<sup>25,26</sup> A predisposition to bleeding is

exacerbated by the concomitant use of antiplatelet agents. There is increasing recognition of the role of point-of-care viscoelastic and functional platelet testing, and these along with the use of antifibrinolytics may reduce the need for transfusion.<sup>27</sup> As in the dialysis setting, the distinction of heparin-induced thrombocytopenia from other causes is critical. Platelet transfusion is indicated if simple platelet consumption is suspected, whereas it is relatively contraindicated when heparin-associated thrombocytopenia is present.

### Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia is a special type of immune-mediated thrombocytopenia. It is a prothrombotic drug reaction caused by antibodies to platelet factor 4 (PF4)/heparin complexes that activate platelets.<sup>28</sup>

Although perhaps more commonly associated with unfractionated heparin, this syndrome is also associated with the use of low-molecular-weight heparins. The diagnosis is suggested when the platelet count decreases by 50%, or to less than  $100 \times 10^9/L$ , in a patient receiving one of these drugs. Diagnosis requires a high clinical likelihood of the condition (e.g., 4Ts scoring system) plus the presence of platelet-activating antibodies.<sup>29</sup>

When heparin-induced thrombocytopenia is suspected, treatment consists of immediate discontinuation of any heparin-containing product and institution of a nonheparin anticoagulant such as argatroban, bivalirudin, danaparoid, fondaparinux, or a direct oral anticoagulant.<sup>30</sup> Use of warfarin alone is contraindicated because it decreases protein C levels and can lead to catastrophic thrombosis. Platelet transfusion is contraindicated even in patients with low counts on anticoagulation except in the circumstance of life-threatening bleeding.

### Other medications and supplements

A number of medications, herbal remedies, and nutritional substances result in disorders of platelet function or number.<sup>31,32</sup> Aspirin and NSAIDs are among the most commonly used over-the-counter medications. In the case of aspirin, irreversible acetylation of cyclooxygenase in the platelet results in loss of function for the remainder of the 5–7-day lifespan of the platelet. Conversely, NSAIDs are reversible inhibitors. This distinction is important in the bleeding patient. If a patient with life-threatening bleeding has consumed aspirin during the past several days, platelet transfusion may be indicated. However, in the case of NSAIDs, once at least 4–5 half-lives have elapsed (the half-life of ibuprofen is 1.8–2 hours and that of acetaminophen is 1–4 hours), there is generally little utility in platelet transfusion unless a concomitant condition is present.

Immune-mediated thrombocytopenia (see Chapter 36) has been associated with the use of many different drugs. Most notably, quinine, quinidine, sulfonamides, sulfonamide derivatives such as furosemide, and vancomycin have been associated with autoantibody formation.<sup>33,34</sup> Although platelet transfusion may be necessary in patients with active bleeding, treatment consists primarily of discontinuation of the agent and observation. If necessary, treatment with intravenous immunoglobulin or corticosteroids may be initiated to hasten the recovery of the platelet count.

Many other commonly encountered classes of drugs are associated with qualitative or quantitative changes in platelets. These include traditional anticonvulsants such as valproic acid, which has also been associated with immune-mediated thrombocytopenia, and more recently approved agents such as gabapentin.<sup>35,36</sup> Simple discontinuation of these agents is generally all that is required in order to facilitate the resolution of the defects.

### Posttransfusion purpura

PTP is a rare but serious complication of blood transfusion, characterized by the sudden onset of severe thrombocytopenia (platelet count often  $<10 \times 10^9/L$ ) usually within 5–10 days of a blood transfusion.<sup>37</sup> It usually affects HPA-1a-negative women who have been previously alloimmunized by pregnancy. The transfusion precipitating PTP causes a secondary immune response, boosting the HPA-1a antibodies, although the mechanism of destruction of the patient's own HPA-1a-negative platelets remains uncertain. On average, 10 cases per year of PTP were reported to the UK hemovigilance scheme (SHOT) prior to the introduction of universal leukoreduction of blood components in 1999.<sup>38</sup> Since then, PTP has been rarely reported.<sup>39</sup>

Although the thrombocytopenia usually resolves spontaneously within a few weeks, there is a relatively high rate of bleeding associated with PTP so that treatment should be considered. Platelet transfusions are usually ineffective in raising the platelet count.<sup>40,41</sup> Administration of IVIg (0.4 g/kg for five days or the equivalent) has been shown to have some efficacy in this setting.<sup>42</sup>

### Neonatal alloimmune thrombocytopenia

About 2% of women have platelets of the HPA-1b/1b phenotype. When they become pregnant with an HPA-1a-positive fetus, about 10% develop HPA-1a antibodies. These antibodies cross the placenta and can lead to fetal/neonatal thrombocytopenia even during the first pregnancy. This is unlike the situation with RhD-negative mothers in which sensitization is caused by the first RhD-positive fetus, but the RhD antibodies do not cause adverse effects until the following RhD-positive pregnancies. Neonatal alloimmune thrombocytopenia (NAIT) is most commonly manifest as skin and other minor bleeding after birth. However, it may cause intracranial hemorrhage either at the time of delivery or in utero usually after 30 weeks of gestation. The precise incidence of intracranial hemorrhage is unknown, but conservative estimates suggest that it is around 1 in 20,000 live births.<sup>43</sup> For the management of an affected neonate, if the platelet count is  $<30 \times 10^9/L$  or if there are signs of bleeding with a low count, it is recommended that the neonate be transfused with donor platelets that are ideally both HPA-1a and -5b-negative as these will be compatible with the maternal HPA alloantibody in ≥95% of cases.<sup>44</sup> If HPA-1a-negative and HPA-5b-negative platelets are not immediately available and there is an urgent clinical need for transfusion, then random, ABO- and RhD-compatible donor platelets should be used.<sup>44</sup> Washed maternal platelets are a less readily available alternative. The results of laboratory investigations should not delay immediate platelet transfusion as full investigation may be time-consuming and the risk of intracranial hemorrhage is highest in the first 48 hours postdelivery. In a typical case, the platelet count should recover to normal within a week, although a more protracted recovery can occur. Intravenous immunoglobulin is not recommended as first-line treatment as it is only effective in about 75% of cases and there is a delay of 24–48 hours before a satisfactory count is achieved.

For the antenatal management of women with a history of NAIT in a previous pregnancy, referral to specialists in fetal medicine and hematology is required. Treatment during the subsequent pregnancy involves the administration of immunoglobulin and steroids; the timing of the initiation of treatment and the doses depend on the history of hemorrhage and fetal/neonatal thrombocytopenia in previous pregnancies.<sup>44,45</sup>

### Platelet transfusion

#### Platelet components

In the United States, whole-blood-derived platelet units (also called random-donor units) are prepared as platelet-rich plasma (see Chapter 17).<sup>46,47</sup> Outside of the United States, the buffy coat method is often used for platelet preparation.<sup>48</sup> In this case, after centrifugation analogous to that used to separate plasma from the red cell pellet, the buffy coat layer atop the red cells is harvested. Both platelet preparation methods involve the pooling of 4–6 units and result in a similar quality product. Each unit contains at least  $5.5 \times 10^{10}$  platelets.<sup>49</sup> Apheresis platelets (often called single donor platelets) are harvested from an individual through use of an apheresis device.<sup>50</sup> A six-unit random-donor pool or an apheresis unit contains around  $3 \times 10^{11}$  platelets, and this platelet dose generally leads to a platelet increment of  $30–60 \times 10^9/L$  in the platelet-naive patient when measured one hour after administration. Although the different platelet products may be considered interchangeable in terms of efficacy and safety,<sup>51</sup> the use of whole-blood-derived platelets in some settings may be preferred to the use of apheresis platelets in the absence of special circumstances such as the need for HLA matching.<sup>52</sup>

Platelet storage and processing are described in detail in Chapter 17.

#### Platelet administration

Platelets contain ABO antigens on their surface. Transfusion of ABO-mismatched platelets, however, is not associated with a major reaction. Nonetheless, there are data to indicate that naturally occurring anti-A or anti-B in the recipient may lead to the destruction of group A or B mismatched platelets and to poorer platelet increments.<sup>53,54</sup> When the supply allows, ABO-matched platelets should be transfused.

In contrast to ABO, Rh blood group antigens are not expressed on the surface of the platelet. However, red cells with these antigens are invariably contained in platelet products, albeit to a much lower extent in modern platelet products. Therefore, the transfusion of platelets from RhD-positive donors to RhD-negative recipients can lead to RhD alloimmunization. Because of immune suppression, this is uncommonly encountered in patients with hematologic malignancies receiving RhD-mismatched platelets. However, it is recommended to administer RhD-negative platelets to RhD-negative recipients whenever available and to administer intravenous Rh immunoglobulin to female children and females of childbearing age who have hypoproliferative thrombocytopenia. A dose of 1500 IU will cover multiple platelet exposures.

Specific platelet transfusion products, such as for patients with acute leukemia, may be needed e.g., leukocyte-reduced, irradiated platelet products (see other Chapters including 28, 42, 48, and 50). Because of the potential reduction in the number of platelets, washing of platelets should be reserved for individuals with severe allergic reactions that cannot otherwise be overcome by appropriate medications.

Although acetaminophen 650–1000 mg and diphenhydramine 25–50 mg are frequently administered before platelet transfusion as primary prophylaxis against febrile and allergic reactions, few data exist to support this as routine practice.<sup>55,56</sup> However, once an allergic reaction has been observed (hives, wheezing, or dyspnea), diphenhydramine is the drug of choice to prevent additional reactions in the future. If a moderate allergic reaction recurs in an adult despite the administration of these premedications, hydrocortisone 100 mg IV is often effective. Recurrence of severe allergic reactions

despite premedication is an indication for the use of washed platelets. Platelet concentrates must be administered to adults through a blood filter. This is generally a standard blood set with an infusion time of about 30 minutes.

Platelet transfusion is not without risk. Data from the UK hemovigilance system, Serious Hazards of Transfusion (SHOT), indicates that platelets are the most commonly implicated component in reported reactions and adverse events.<sup>57</sup> Aside from the development of platelet refractoriness and allergic reactions that can be observed with any blood component, platelets are the component most commonly associated with the transmission of bacterial infection (Chapter 46).<sup>58</sup> In the past, it has been estimated that about 1 in 5000 platelet units were contaminated with bacteria. Newer methods for bacterial testing have reduced the incidence of bacteremia associated with platelet transfusion. Nonetheless, there should be a heightened sense of awareness for the possibility of bacterial transmission in those receiving platelet transfusions, particularly if individuals are neutropenic and become febrile during or shortly after a platelet transfusion.

### **Prophylactic platelet transfusions**

*Prophylactic transfusion* refers to the maintenance of the platelet count above a certain threshold in patients who are neither bleeding nor actively consuming platelets because of immune destruction or infection. In patients with acute myeloid leukemia who have received 25 platelet transfusions, the mean one-hour platelet increment is reduced by about one-third, and the 18–24-hour platelet increment is reduced by more than half in comparison to that observed after the first platelet transfusion.<sup>59</sup> Therefore, reduction in the number of unnecessary platelet transfusions is of significant benefit, including cost and supply implications. As an example, around 300,000 units for platelet transfusion are issued by UK Blood Services each year, for an estimated annual cost of over \$90 million (\$300/unit, excluding storage, administration, and patient monitoring costs in hospital).

Several of the questions raised regarding prophylactic platelet transfusions in patients with reversible bone marrow failure are addressed below.

### **Should prophylactic platelet transfusions be given?**

A number of trials have addressed this first key question, as to whether a policy of prophylaxis has benefit for patients. These trials have compared prophylactic versus therapeutic platelet transfusion strategies.<sup>60</sup> The early studies used outdated methods of platelet component production and patient supportive care. More recently two larger randomized controlled trials have addressed the question of whether prophylactic platelet transfusions should be used.<sup>61,62</sup> Both showed that prophylactic platelet transfusions reduced the risk of bleeding. However, this effect was less marked in the prespecified subgroup of patients receiving autologous hematopoietic stem cell transplants (HSCTs).<sup>63</sup> When considering these results as a number needed to treat (NTT), five patients receiving intensive chemotherapy or an allogeneic stem cell transplant would need to receive prophylactic platelet transfusions over a 30-day period to prevent one patient from having clinically significant bleeding (WHO grade 2 or above) (95% CI, 3–18), whereas for autologous HSCT patients 43 patients would need to receive prophylactic platelet transfusions to prevent one patient from bleeding.<sup>63</sup> One further observation from both studies was that bleeding continued to be frequently observed in patients despite a policy of prophylaxis.

### **What platelet transfusion threshold should be used?**

The largest groups of trials of platelet transfusions have evaluated different platelet transfusion thresholds in patients with hematological malignancies. Two trials compared a threshold of  $20 \times 10^9/\text{L}$  versus  $10 \times 10^9/\text{L}$ ,<sup>64,65</sup> and other trials different thresholds. A meta-analysis of all four studies (658 patients) showed no increase in the proportion of patients who bled and also showed a significant reduction in the number of platelet transfusions given when using lower thresholds.<sup>66</sup> However, this meta-analysis may not be sufficiently powered to detect an increased bleeding risk in the  $10 \times 10^9/\text{L}$  threshold arm of less than 50%. There has been a suggestion that platelet transfusion thresholds should be lowered, but automated hematology analyzers are not yet accurate enough in counting very low platelet numbers.<sup>67</sup> No randomized studies in adult patients have assessed the use of other transfusion metrics, such as platelet mass, absolute immature platelet number, or immature platelet fraction.

For patients with chronic bone marrow failure, there is little evidence on which to base practice. A retrospective study considered platelet transfusion in outpatients with stable chronic severe aplastic anemia.<sup>68</sup> Prophylactic platelets were given if the count was  $5 \times 10^9/\text{L}$  or less, or if the patient was unwell with fever (temperature  $>38^\circ\text{C}$ ) or recent hemorrhage when the count was  $10 \times 10^9/\text{L}$  or less. Patients with significant bleeding or prior to minor surgery received platelets at counts  $>10 \times 10^9/\text{L}$ . In total, 55,239 patient days were reviewed with 18,706 days when the platelet count was  $10 \times 10^9/\text{L}$  or less. All deaths from hemorrhage were associated with alloimmunization or withdrawal from treatment. Three nonlethal major bleeding episodes occurred. The authors concluded that this restrictive policy, with a median transfusion interval of seven days, was feasible, safe, and economical.

Both national and international guidelines vary in their advice for platelet transfusion in stable nonbleeding patients with bone marrow failure resulting in chronic thrombocytopenia. Recommendations include a threshold of  $<10 \times 10^9/\text{L}$ , as used in patients with reversible bone marrow failure;<sup>69</sup> a threshold of  $5 \times 10^9/\text{L}$  or less;<sup>70,71</sup> or no prophylaxis.<sup>24,72,73</sup> National recommendations for adult intensive care patients are not based on randomized trials.<sup>74</sup>

A number of trials have tested different thresholds in groups of patients outside hematological malignancies. Two RCTs have assessed whether prophylactic platelet transfusions are beneficial in dengue hemorrhagic fever.<sup>75,76</sup> Platelet transfusion did not prevent progression to severe bleeding, nor did it appear to shorten time to cessation of bleeding. It was also associated with an increased risk of severe side effects. Other studies have shown no correlation between the platelet count and risk of bleeding;<sup>77,78</sup> therefore, the use of platelet transfusions in dengue fever should not be based solely on a platelet count.

Platelet transfusion thresholds in neonates are varied.<sup>79</sup> The Platelets for Neonatal Thrombocytopenia (PlaNeT-2) study compared platelet count thresholds that were relevant to neonatal practice, and which are typically much higher than found in adult patients with hematological malignancies. This trial recruited 660 babies and reported an overall benefit of a prophylactic platelet transfusion threshold of  $25 \times 10^9/\text{L}$  compared with  $50 \times 10^9/\text{L}$  for major hemorrhage and/or death in preterm neonates (7% absolute-risk reduction).<sup>80</sup> This unexpected result should reinforce the recommendations for more restrictive practices in neonatal intensive care units. Additional analyses found that these harmful effects occurred in neonates with both high and low baseline risks of death or hemorrhage, supporting the generalizability of the main trial

findings to all groups of preterm babies.<sup>81</sup> However, a limitation of the study was the lack of mechanistic studies to understand why platelets might cause harm. Hypotheses include the use of adult platelet donations into a neonatal hemostatic system or the effects of platelets through immunomodulatory pathways.<sup>82</sup>

### What platelet transfusion dose should be used?

Multiple randomized trials have compared different platelet transfusion doses in patients with hematological malignancies.<sup>83</sup> Four studies have assessed clinically significant bleeding as an outcome measure (usually defined as WHO grade 2 or above), including the largest trial to date (PLADO).<sup>84</sup> There was no evidence of a difference in the risk of bleeding between low-dose ( $1.1 \times 10^{11}/m^2$ ) and standard-dose transfusions ( $2.2 \times 10^{11}/m^2$ ) and between standard-dose and high-dose platelet transfusions ( $4.4 \times 10^{11}/m^2$ ). Low-dose transfusions decreased the total amount of platelets that patients received but at the expense of a higher number of transfusion episodes. The UK dose for platelet transfusions is that at least 75% of units contain  $>2.4 \times 10^{11}$  platelets per adult dose and should continue to be used as standard. Increasing the platelet dose from a standard-dose ( $2.2 \times 10^{11}/m^2$ ) to a high-dose ( $4.4 \times 10^{11}/m^2$ ) transfusion regimen does not increase the transfusion interval (a median of five days for both regimens). Again, as mentioned earlier, it should be noted that despite different policies of platelet transfusion by dose, patients continued to experience significant rates of bleeding. The lack of a dose-effect response perhaps continues to argue for a limited role of platelet transfusions to impact clinical bleeding in thrombocytopenic patients with hematological malignancies. With this in mind, new clinical studies are ongoing to assess the role of alternatives to platelet transfusion, for example tranexamic acid.<sup>85</sup>

### Additional risk factors for bleeding

Numerous clinical factors have been associated with an increased risk of bleeding (Table 35.1). However, the majority of these postulated risk factors are based on low-level evidence, such as expert opinion or retrospective analysis of patient databases. Currently, the platelet transfusion threshold is commonly raised to  $20 \times 10^9/L$  when patients have an infection or fever. While inflammation has been shown to be associated with an increased risk of bleeding in mice,<sup>86</sup> studies have differed on whether fever increases the risk of bleeding in humans.<sup>87</sup> Further studies are required to identify clearly which factors should prompt an increase in the transfusion threshold, and what this threshold should be.

### Preprocedure platelet transfusions

#### Bone marrow aspirates and trephines

According to the UK confidential registry of complications after bone marrow aspirates and trephines, the risk of significant bleeding is very low (less than 1:1000), and the majority of patients had bleeding when they did not have a significant thrombocytopenia.<sup>88–92</sup>

#### Central venous catheters

Twenty observational studies have reported bleeding outcomes in thrombocytopenic patients after insertion of central venous catheters (CVCs).<sup>93–112</sup> At least 1450 procedures were performed when the platelet count was  $\leq 50 \times 10^9/L$ . Only one case of severe bleeding (Hb drop  $>15$  g/L) was reported throughout all of these studies.<sup>110</sup> Three of these studies looked at risk factors associated with bleeding. The two studies that did not perform the CVC procedure with ultrasound guidance found that the number of attempts, site of insertion (jugular

vs. subclavian), and failed guidewire insertion significantly increased the risk of bleeding on multivariable analysis,<sup>93,99</sup> whereas the third study that used ultrasound guidance did not.<sup>111</sup> Systematic reviews of complications of CVC placement have found that ultrasound guidance significantly reduced failure and complication rates.<sup>113,114</sup> A small study in thrombocytopenic patients that compared ultrasound-guided versus landmark insertion techniques reiterated this finding.<sup>109</sup> The Zeidler study<sup>111</sup> looked at risk of bleeding according to platelet count thresholds with multivariable analysis. The risk of bleeding only increased when the platelet count was less than  $20 \times 10^9/L$  (OR, 2.88; 95% CI, 1.23–6.75;  $p = 0.015$ ); this analysis controlled for sex, type of leukemia, insertion site, and use of prophylactic platelet transfusions. All CVCs in this study were un tunneled and inserted by experienced individuals.<sup>111</sup> In the large Haas study, no patient with thrombocytopenia experienced bleeding that could not be treated with simple pressure at the site of the tunneled CVC; their platelet count threshold for insertion was  $25 \times 10^9/L$ .<sup>101</sup>

A small RCT (57 participants) comparing three transfusion policies in patients with liver disease showed that a restrictive transfusion policy reduced costs with no increase in the risk of bleeding or other harms.<sup>115</sup>

One additional prospective study assessed peripherally inserted central catheters (PICCs) without prophylactic platelet transfusions. Of the 50 patients who had a line inserted with a platelet count less than  $20 \times 10^9/L$ , only one bleeding episode occurred (minor oozing).<sup>116</sup>

One prospective nonrandomized study has assessed the risk of bleeding after traction removal of tunneled cuffed CVCs in patients with abnormal platelet counts or international normalized ratio (INR).<sup>117</sup> Fourteen of the 179 patients enrolled in the study had a time to hemostasis of over five minutes, and only one of these patients had a platelet count  $<100 \times 10^9/L$ .

### Lumbar punctures and epidural anesthesia

Reviews of the literature have been performed of the risk of spinal hematoma following lumbar puncture or neuraxial anesthesia.<sup>118,119</sup> New small studies have contributed to the more recent review. Resulting recommendations suggest that lumbar punctures can be performed safely when the platelet count is  $>40 \times 10^9/L$ , and that epidural anesthesia can be performed safely when the platelet count is  $>80 \times 10^9/L$ .<sup>119</sup> Platelet transfusions should be administered to raise the platelet count above these thresholds if it is below these levels.

### Liver biopsy

Percutaneous liver biopsies are considered safe when the platelet count is at least  $50–60 \times 10^9/L$ .<sup>120</sup> 2740 percutaneous liver biopsies were conducted in the HALT-C trial;<sup>121</sup> only 16 patients (0.6%) had a serious adverse event due to bleeding after the biopsy. A single center retrospective study has shown no increase in harm using a lower threshold of  $25 \times 10^9/L$ , none of the 21 participants who had a platelet count  $<50 \times 10^9/L$  had bleeding that required an intervention, and only 2/21 had any bleeding.<sup>122</sup> Transjugular liver biopsy has been shown to be safe in patients with low platelet counts, and with more modern techniques it can produce comparable histological samples to percutaneous liver biopsies.<sup>123–125</sup>

### Renal biopsy

Uncontrolled hypertension, high serum creatinine, anemia, older age, and female sex have all been shown to be risk factors for bleeding post renal biopsy as well as a prolonged bleeding time.<sup>126–129</sup> There have been no systematic studies that have assessed the effect

of acutely lowering blood pressure prior to renal biopsy.<sup>127</sup> Dialysis may improve the bleeding tendency in patients with uremia. DDAVP can be used successfully to prevent bleeding before invasive procedures.<sup>24,130–132</sup> Conjugated estrogens are a long-acting alternative to DDAVP because they shorten the bleeding time with a more sustained effect.<sup>24,133</sup> Correcting anemia will also decrease the bleeding time.<sup>24</sup> Transjugular renal biopsy has been used in patients in whom percutaneous renal biopsy has failed or been contraindicated, and has produced a similar diagnostic yield and safety profile.<sup>134</sup> Given the possibility that patients with kidney disease will go on to transplant, it is recommended that platelet transfusions be avoided if possible because of the risk of alloimmunization.<sup>135</sup>

### Dental extraction

One recent small RCT (36 patients) has shown a low rate of bleeding complications with no blood products transfused, in patients with liver disease.<sup>136</sup> Patients were randomized to desmopressin, platelet or plasma transfusions, or both. There was no evidence of a difference in minor or major bleeding. Two observational studies also found that local hemostatic measures (e.g., gauze soaked in tranexamic acid) were sufficient to stop bleeding post dental extraction without the need for platelet transfusions.<sup>137,138</sup>

### Surgery

There remains a lack of evidence to guide the prophylactic use of platelet transfusions before major surgery.<sup>139</sup> Guidelines from around the world suggest a threshold of  $50 \times 10^9/L$  before major surgery,<sup>24,140,141</sup> and a threshold of  $100 \times 10^9/L$  prior to neurosurgery or ophthalmic surgery involving the posterior segment of the eye, because of the critical sites involved.<sup>24,140,141</sup> A platelet count increment after any platelet transfusion is desirable, but it may be limited by the circumstances of the conduct of the procedure.

### Therapeutic platelet transfusions

The predominant usage of platelet transfusions is to prevent bleeding (up to 67%),<sup>142</sup> but therapeutic platelet transfusions are also needed to treat active bleeding from thrombocytopenia and/or

platelet dysfunction in a wide range of clinical scenarios. Although most clinical research of the use of platelet transfusions has been in the area of prophylactic transfusions in patients with hematologic malignancies, the management of the actively bleeding patient with severe thrombocytopenia and/or platelet dysfunction has received less attention and is arguably more challenging. The clinical scenario is often complex, and management depends on the nature and site of the bleeding, the severity of the thrombocytopenia, the presence or absence of other disorders of hemostasis, and the presence or absence of anemia, as well as the clinical condition of the patient.

Consensus guidelines have generally recommended a threshold for therapeutic platelet transfusions of at least  $50 \times 10^9/L$  if a patient is actively bleeding (Table 35.2). However, there are few definitive studies to substantiate these platelet transfusion triggers, and the level of evidence to support the recommendations is poor.

### Platelet refractoriness

*Platelet refractoriness* is defined as the repeated failure to achieve satisfactory responses to platelet transfusions; this topic has been comprehensively reviewed.<sup>143</sup> The effectiveness of platelet transfusions can be assessed clinically in a bleeding patient by monitoring cessation of bleeding or not. However, where platelet transfusions have been given prophylactically, the response is assessed by measuring the posttransfusion platelet count increment. Various formulas have been devised to refine this assessment of the response to platelet transfusion.<sup>144</sup>

- 1 The percentage platelet recovery ( $R$ ) is calculated from the platelet increment  $\times 10^9/L$  (PI), the blood volume (BV) in liters, and the platelet dose transfused  $\times 10^9$  (PD):

$$R (\%) = PI \times BV \times PD^{-1} \times 100$$

The corrected count increment  $\times 10^9/L$  (CCI) is calculated from the platelet increment (PI), the body surface area of the patient in square meters (BSA), and the dose of platelets transfused  $\times 10^{11}$  (PD):

**Table 35.2** Platelet Thresholds for Therapeutic Transfusion during Active Bleeding

Clinical Indication	Treatment Trigger ( $\times 10^9/L$ )	Level of Evidence*
Major bleeding and thrombocytopenia or massive hemorrhage	50–75	Grade C, level IV
Massive transfusion and multiple trauma or TBI	75–100	Grade C, level IV
Surgery	50–100	Grade B, level III, to Grade C, level IV
DIC	50	Grade C, level IV
DIC in neonates	100	Grade C, level IV
Intracerebral bleeding	100	Grade C, level IV
Platelet function defects	No threshold	Grade C, level IV

\* Levels of evidence originate from the US Agency for Healthcare Research and Quality ([www.ahrq.gov](http://www.ahrq.gov)):

#### Statements of evidence

Ia: Evidence obtained from meta-analysis of randomized controlled trials.

Ib: Evidence obtained from at least one randomized controlled trial.

IIa: Evidence obtained from at least one well-designed controlled study without randomization.

IIb: Evidence obtained from at least one other type of well-designed quasi-experimental study.

III: Evidence obtained from well-designed nonexperimental descriptive studies, such as comparative studies, correlation studies, and case studies.

IV: Evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities.

#### Grades of recommendations

A: Requires at least one randomized controlled trial as part of a body of literature of overall good quality and consistency addressing the specific recommendation. (Evidence levels Ia and Ib.)

B: Requires the availability of well-conducted clinical studies but no randomized clinical trials on the topic of recommendation. (Evidence levels IIa, IIb, and III.)

C: Requires evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities. It indicates an absence of directly applicable clinical studies of good quality. (Evidence level IV.)

TBI: traumatic brain injury; DIC: disseminated intravascular coagulation.

$$\text{CCI} = \text{PI} \times \text{BSA} \times \text{PD}^{-1}$$

A platelet recovery of about 67% in a stable patient is considered an appropriate response, but the minimum platelet recovery to define a successful transfusion is considered to be >30% at 1-hour post transfusion and >20% at 20–24 hours. When using CCI, thresholds for successful transfusions are  $>7.5 \times 10^9/\text{L}$  at 1 hour and  $>4.5 \times 10^9/\text{L}$  at 20–24 hours. In practice, a 24-hour platelet increment of  $<5 \times 10^9/\text{L}$  following a platelet transfusion on two or more occasions is a good indicator of refractoriness to random-donor platelets.

It is sometimes stated that the absence of a response one hour after transfusion indicates refractoriness from immunologic causes, and lack of a response at a later time following transfusion is caused by underlying clinical problems, but this rule is an unreliable way of determining the cause of platelet refractoriness.

There are many causes of platelet refractoriness, and they can be subdivided into immune and nonimmune. The main immune cause is HLA alloimmunization, which occurs predominantly in females with a history of pregnancy or in patients who have received multiple transfusions. Other immune causes include HPA alloimmunization, ABO incompatibility with high-titer ABO antibodies in the recipient, platelet autoantibodies, and drug-related platelet antibodies. On the other hand, a lack of response to platelet transfusion may be the result of an underlying acute illness, such as infection, or it may result from a more chronic condition, such as splenomegaly. Fever, sepsis, DIC, hemorrhage, and conditions associated with marrow transplantation such as veno-occlusive disease and graft-versus-host disease all contribute to platelet refractoriness.

The incidence of HLA alloimmunization varies with the type of blood components transfused, the patient's underlying condition, and the previous history of pregnancy and transfusion. For example, HLA alloimmunization is more frequent in patients with aplastic anemia than in patients with acute leukemia. The Trial to Reduce Alloimmunisation to Platelets found that in patients with acute myeloblastic leukemia receiving nonleukocyte-reduced blood components the incidence of HLA alloimmunization was 33% in those who had never been pregnant and 62% in those who had been pregnant; in patients receiving leukocyte-reduced blood components, it was 9% and 32%, respectively.<sup>145</sup> The incidence of alloimmune platelet refractoriness caused by HLA antibodies has declined due to the implementation of leukocyte reduction of blood components and more aggressive treatment for patients with hematological malignancies and other cancers.

The role of platelet-specific (or HPA) antibodies in platelet refractoriness is less clear. HPA antibodies have been detected at a frequency of 8%<sup>145</sup> to 20–25%<sup>146</sup> in various studies of multitransfused hematology patients and are usually found in combination with HLA antibodies. Most commonly, HPA alloimmunization is directed toward antigens with phenotypic frequencies below 30%.<sup>147</sup> Some studies have suggested that there is no clear correlation between HPA antibodies and poor responses to platelet transfusions,<sup>148,149</sup> but others have found that matching for platelet-specific antigens in patients refractory to HLA-matched platelets may be beneficial.<sup>150</sup>

While immune causes are often prioritized during the investigation of platelet refractoriness, the observed reduction in platelet survival is most commonly due to nonimmune clinical factors, including DIC, splenomegaly, and intravenous antibiotics (especially antifungal drugs such as amphotericin B).<sup>59,151,152</sup> Fever has

also been implicated in causing poor responses to platelet transfusions, although whether this is a reflection of sepsis, associated DIC, or antibiotic therapy rather than the temperature itself is unclear.<sup>59,153</sup>

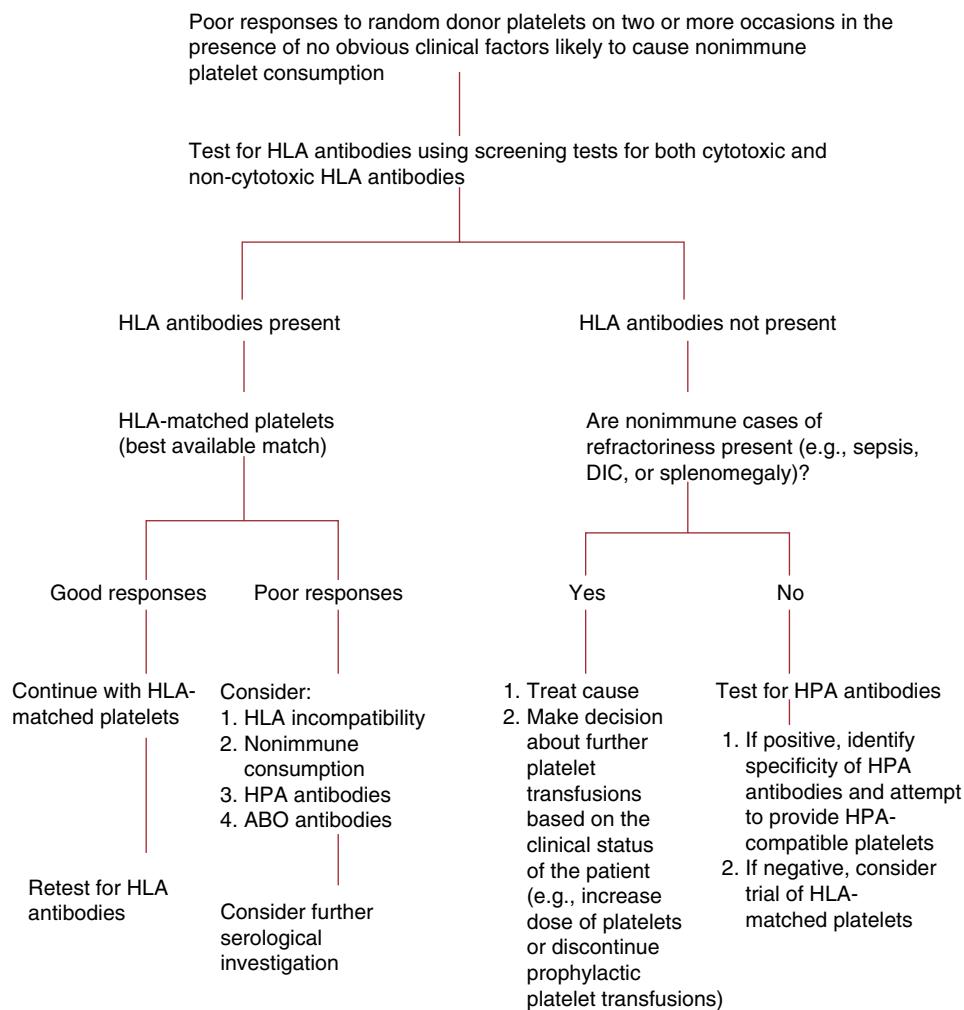

The appropriate investigation and management of platelet refractoriness require consideration of information from a clinical assessment of the patient as well as laboratory investigations (Figure 35.1). The first step is a clinical evaluation for possible nonimmune clinical causes. Any significant clinical factors such as infection should be treated if possible, and prophylactic platelet transfusions from random donors continued as standard care. If poor responses to platelet transfusions persist, the patient should be tested for HLA antibodies, and, if present, platelet transfusions selected for the HLA-A and HLA-B antigens of the patient should be used.<sup>154</sup>

HLA matching of platelets uses databases of HLA-typed platelet donors who can then be asked to donate by apheresis. This requires logistic coordination and may result in a time lag before the product is available. There are a number of ways to select HLA-matched platelet transfusions. Traditionally, recipient and donor are matched for HLA-A and HLA-B antigens as the most important antibodies in causing platelet refractoriness are directed against these antigens.<sup>154</sup> Refinements to HLA matching have been made, including grading of the quality of HLA match and its revision to include "permissive" mismatches,<sup>155,156</sup> the identification of the specificity of HLA antibodies and the issue of HLA-matched platelets based on their specificity,<sup>155</sup> and more recently the use of software tools such as *HLA matchmaker* to predict HLA compatibility by identifying immunogenic epitopes in antibody-accessible regions of HLA molecules.<sup>157,158</sup> A systematic review found that HLA-matched platelet transfusions improved one-hour posttransfusion platelet increments but did not consistently improve the 24-hour increments, and failed to demonstrate any reduction in mortality or bleeding as the studies were inadequately powered for these outcomes.<sup>159</sup>

HPA antibodies are rare in the absence of HLA antibodies and do not always cause platelet refractoriness. It is not necessary to test for HPA antibodies during the initial serological investigation of platelet refractoriness.

The use of HLA-matched platelet transfusions is also justified if there has not been time to carry out serological testing, particularly when platelet refractoriness is associated with bleeding. However, HLA-matched platelet transfusions are not indicated when full serological testing has failed to detect HLA antibodies. In this case, further consideration should be given to the identification of nonimmune clinical factors, and if they still appear to be absent, testing for HPA antibodies should be undertaken.

Responses to HLA-matched platelet transfusions should be carefully monitored, ideally with posttransfusion platelet counts both 1 and 20–24 hours post transfusion. If there are improved responses, HLA-matched platelet transfusions should continue to be used for further transfusions. If there are poor responses to HLA-matched platelet transfusions, the reasons should be sought, including residual HLA incompatibility, which is most likely to occur in patients with unusual HLA types with few well-matched donors, nonimmune platelet consumption, and HPA and ABO incompatibility. Further serological investigations including testing for HPA antibodies may be useful to differentiate between these possibilities. Depending on the results of these investigations, the appropriate management could be the use of ABO-identical or HPA-matched platelet concentrates if the specificity of the HPA antibodies can be identified.

**Figure 35.1** Algorithm for the investigation and management of patients refractory to platelet transfusions. Source: Modified from Phekoo *et al.* (1997).<sup>154</sup>

Platelet crossmatching of the patient's plasma against the lymphocytes and platelets of donors of HLA-matched platelet transfusions that have failed to produce satisfactory responses may be very helpful in identifying the cause of the poor responses.<sup>160</sup> Platelet crossmatching can also be used as an alternative approach to the management of refractory patients with HLA-matched platelet transfusions.<sup>161–163</sup> Typically, the patient's plasma is tested against platelet samples of ABO-compatible apheresis platelet donors. Donor platelets lacking reactivity are considered to be *crossmatch compatible*, and the associated platelet concentrates selected for transfusion in preference to those from random donors. An advantage of platelet crossmatching is its timeliness when the HLA types of platelet refractory patients are not yet known. A disadvantage is the need to carry out testing each time a platelet transfusion is required.

The management of patients with HLA and/or HPA alloimmunization with no compatible donors may be very difficult. There is no evidence that alloimmunized patients benefit from prophylactic transfusions of incompatible platelets that do not produce an increase in the platelet count, and prophylactic platelet support should be discontinued. If bleeding occurs, platelet transfusions from random donors or the best-matched donors, despite being incompatible, may reduce the severity of hemorrhage, although large doses of platelets may be required. Other management

approaches for severe alloimmune refractoriness, such as the use of high-dose intravenous immunoglobulin, splenectomy, and plasma exchange, have not been shown to be effective.<sup>73</sup>

The management of patients with nonimmune platelet consumption is similarly problematic. Treatment of the underlying illness is indicated. Common practice is to continue with daily platelet transfusions as prophylactic platelet support, but it is not known whether this approach is effective, or whether platelet transfusions should be discontinued or the dose of platelets increased. Intravenous immunoglobulin is ineffective in this scenario. However, EACA and tranexamic acid may be useful in reducing bleeding in patients with severe thrombocytopenia (although tranexamic acid is not available in the United States). Even at relatively low doses of 1 g every six hours, EACA appears to be effective in this setting.

### Platelet substitutes and storage technologies

The possibility of providing various forms of platelet substitutes has been proposed for many years, but currently there are no alternatives in clinical use.<sup>164,165</sup>

More research has been performed on different storage methods to increase shelf-life or hemostatic activity.<sup>166</sup> Pilot studies have shown that cryopreserved platelets are safe, and further work is being performed to assess their effectiveness.<sup>167</sup>

### Thrombopoietin receptor agonists

Thrombopoietin is the primary regulator of megakaryocyte progenitor expansion and differentiation.<sup>168</sup> Its cloning in the mid-1990s led to the development of thrombopoietic drugs, and there was initial success in reducing the duration of thrombocytopenia with its use in cancer patients. However, trials were discontinued because healthy volunteers developed severe thrombocytopenia as a result of an immune response to the drug where antibodies crossreacted with endogenous thrombopoietin. Focus shifted to the development of small-molecule peptide (romiplostim; Nplate marketed by Amgen) and nonpeptide thrombopoietin mimetics (eltrombopag; Promacta marketed by GlaxoSmithKline), and these have proved successful in the treatment of autoimmune thrombocytopenia. Several trials have assessed the use of thrombopoietin mimetics in patients with liver disease prior to procedures. Eltrombopag has been shown to reduce the requirement for platelet transfusions; however, the study was stopped early due to an increased risk of thrombosis.<sup>169</sup> More recent studies using lusotrombopag and avatrombopag have also shown decreased platelet use but without any evidence of an increased risk of thrombosis.<sup>170</sup> Thrombopoietin mimetics probably slightly decrease the risk of bleeding in patients with myelodysplastic syndrome,<sup>171</sup> but the evidence is much more limited for patients with other cancers.<sup>172,173</sup>

### Summary

A variety of diverse congenital and acquired conditions are associated with thrombocytopenia or its functional equivalent. Congenital causes are rare, but acquired causes are relatively common. In particular, thrombocytopenia or platelet dysfunction associated with the administration of chemotherapy or with surgical procedures is a leading indication for platelet transfusion. The availability of a variety of platelet products for transfusion facilitates the supportive care of individuals receiving chemotherapy and the treatment of bleeding individuals with thrombocytopenia or its functional equivalent. Leukocyte-reduced whole-blood-derived platelets and apheresis platelets are associated with similar rates of infection and alloimmunization, and they can be used interchangeably in most settings. A prophylactic platelet transfusion threshold of  $10 \times 10^9/L$  is generally acceptable for afebrile patients receiving cancer chemotherapy. Maintenance of a higher platelet count is indicated in a number of situations, including the settings of sepsis, DIC, hemorrhage, trauma, and surgery. Febrile and allergic reactions to platelet

transfusion can often be managed conservatively with the administration of acetaminophen and diphenhydramine. Platelet refractoriness based on nonimmune and immune mechanisms remains a major issue when repeated transfusions are required. After platelet refractoriness following two transfusions have been documented, ABO matching, platelet crossmatching, and HLA matching may be used as initial strategies to address the situation. Because of the limitations of current storage techniques, research and development continue on platelet storage and substitutes. Thrombopoiesis-stimulating agents provide additional therapeutic alternatives for the management of thrombocytopenia in specific settings. However, additional research and development will be necessary in order to establish their safety and efficacy in patients receiving cancer chemotherapy.

## Introduction

Thrombocytopenia, commonly defined as a platelet count below the normal range, is one of the most common reasons for hematological consultation. Low circulating platelet numbers can be caused by platelet underproduction, sequestration, hemodilution, consumption, or destruction. This chapter explores the problem of immune-mediated thrombocytopenia (platelet “destruction”), including autoimmune conditions (e.g., primary immune thrombocytopenic purpura [ITP]), secondary immune conditions (e.g., drug-induced immune thrombocytopenia [DITP] and heparin-induced thrombocytopenia [HIT]), and alloimmune conditions (e.g., neonatal alloimmune thrombocytopenia [NAIT]). Immune thrombocytopenia is characterized by a shortened platelet lifespan caused by platelet–antibody interactions and, in primary ITP, reduced platelet production likely because of immune-mediated alterations to bone marrow megakaryocytes. We begin with a review of routine and specialized laboratory testing used for the investigation of thrombocytopenic conditions, followed by a description of the most common immune-mediated thrombocytopenic syndromes and a review of current management.

## Laboratory tests for the investigation of thrombocytopenia

### Complete blood cell count and blood film

Platelets are usually quantitated during a complete blood cell count with a particle counter. A normal platelet count is usually 150,000–400,000/ $\mu$ L, although the reference range may be lower in Mediterranean populations (125,000–300,000/ $\mu$ L) that have larger sized platelets.<sup>1</sup> The platelet count usually remains fairly stable throughout a normal human lifespan.<sup>2</sup> An exception occurs during pregnancy, when the platelet count decreases somewhat, perhaps the result of increased plasma volume (hemodilution).<sup>3</sup> An elevated platelet count is also normal 10–14 days after a major surgical procedure (postoperative thrombocytosis, 250,000–1,000,000/ $\mu$ L) before return to preoperative baseline by three weeks after the operation.<sup>4,5</sup> It is important to understand these expected excursions from a normal platelet count. For example, while a platelet count of 170,000/ $\mu$ L is within the normal range, if the sample was collected 10 days after an

operation in a patient with dyspnea who had received postoperative heparin prophylaxis, the diagnosis of pulmonary embolism complicating HIT should be considered. A useful general rule is that isolated thrombocytopenia is usually caused by increased platelet consumption or destruction, whereas bycytopenia or pancytopenia is usually attributable to marrow dysfunction, hypersplenism, or hemodilution. Furthermore, isolated, severe thrombocytopenia (platelet count less than 20,000/ $\mu$ L) often indicates platelet destruction by autoantibodies, alloantibodies, or drug-dependent immunoglobulin G (IgG) antibodies. While severe thrombocytopenia can occasionally occur in patients with HIT<sup>6</sup> or septicemia, platelet count nadirs are typically more than 20,000/ $\mu$ L in these two disorders characterized by in vivo platelet activation caused by heparin-dependent platelet-activating IgG antibodies or thrombin, respectively.

Examining the blood film is important to exclude pseudothrombocytopenia (spurious thrombocytopenia resulting from antibodies that cause ex vivo platelet agglutination) and to suggest various nonimmune causes of thrombocytopenia, such as toxic leukocytes indicating infection or fragmented red cells suggesting microangiopathic hemolysis. In contrast, primary immune thrombocytopenia is usually characterized by a reduction in platelet number with otherwise unremarkable morphologic features of all cell lines.

### Platelet size and platelet RNA

A particle counter is also used to determine average platelet size, or mean platelet volume (MPV), which usually ranges from 7.0 to 10.5 fL. Disorders of increased platelet destruction usually are characterized by large platelets, and MPV ranges from 10 to 15 fL. Normal-sized or small platelets are common in disorders of underproduction or sequestration of platelets.

Young platelets contain residual amounts of RNA, which can be detected by means of flow cytometric analysis of platelets labeled with either thiazole orange, auramine-O, or SYTO-13. However, such quantitation of reticulated platelets (immature platelet count [IPC]) has not gained the acceptance that red cell reticulocyte assays have. Elevated IPC is associated with greater risk of major adverse cardiovascular events<sup>7</sup> (although a causal vs. confounded relationship remains uncertain).<sup>8</sup> Elevated IPC can be seen in consumptive/destructive thrombocytopenic disorders,<sup>9</sup> including

ITP,<sup>10</sup> and reduced IPC may identify subgroups of patients with ITP who have a marked defect in platelet production.<sup>11</sup>

### Bone marrow examination

Disorders of increased platelet destruction are characterized by normal or increased numbers of megakaryocytes in the marrow.<sup>12</sup> Sometimes examination of the marrow yields enough information to determine the cause of the thrombocytopenia, such as myelodysplasia or megaloblastic anemia.

### Measurement of platelet lifespan

A platelet survival study is the definitive test for classifying the cause of thrombocytopenia and determining the organ site(s) of platelet destruction (or sequestration). Indium-111 is the radiolabel of choice because of its higher labeling efficiency and efficient range of  $\gamma$  emissions. Three patterns of platelet survival can be observed: (1) normal platelet recovery (60–75%) and a normal survival time (7–10 days) characterize thrombocytopenia caused by underproduction; (2) markedly reduced platelet lifespan (hours) is found in patients with thrombocytopenia caused by increased platelet destruction; and (3) reduced platelet recovery (10–30%) with a normal or near-normal platelet survival time is consistent with platelet sequestration (hypersplenism). Platelet survival studies are rarely performed because these tests are complex and experienced physicians can usually infer the mechanism of the thrombocytopenia from the clinical situation. Nonetheless, platelet survival studies can be informative. For example, one study<sup>13</sup> found that spleen-predominant platelet sequestration in ITP predicted a durable remission following splenectomy.

### Platelet-antibody assays

There are two broad categories of platelet antibody assays: (1) platelet-associated IgG assays and (2) assays that identify the protein target of the antibody (protein-specific assays).

#### Platelet-associated IgG assays

Measurement of platelet-associated IgG (PAIgG) has been widely available for many years. It can be used to detect surface-associated immunoglobulin or complement directly on the patient platelets using a labeled anti-immunoglobulin (and/or anticomplement) probe or total PAIgG measured after platelet lysis. Although these assays are simple, a disadvantage is that platelet membranes nonspecifically adsorb IgG and other proteins from the plasma and can transfer them to internal compartments. Furthermore, even monoclonal anti-immunoglobulin probes may not differentiate specific from nonspecific bound IgG. These assays have limited diagnostic usefulness because a positive test result does not differentiate immune from nonimmune thrombocytopenia.<sup>14</sup> Nevertheless, this type of assay can be diagnostically useful in certain situations, such as the laboratory evaluation of drug-induced ITP, by detecting a drug-dependent increase in platelet surface-bound IgG in the presence of patient serum and implicated drug, using an anti-immunoglobulin probe labeled with a fluorescent marker.<sup>15</sup>

#### Protein-specific platelet-antibody assays

The diagnostic usefulness of platelet-antibody assays has increased dramatically with the introduction of various protein-specific assays that help identify the platelet protein target of antibodies with either monoclonal antibodies or electrophoretic techniques. Current protein-specific antibody assays use detergents to extract the glycoprotein (GP) target from the membrane. This process increases the specificity of the test, but may affect antigenicity

because the use of detergents and certain inhibitors (e.g., EDTA) may alter the structure of certain GP targets, such as the GPIIbIIIa complex, reducing the reactivity of some antibodies to HPA-1a.<sup>16</sup>

These assays are only available in specialized reference laboratories (e.g., Versiti, Milwaukee, WI, USA; McMaster Platelet Immunology Laboratory, Hamilton, Canada). Further, the assays are usually developed “in-house” using reagents that can vary among laboratories. Although commercial kits are available for some tests for use in larger, nonreference laboratories, they generally have a reduced repertoire of antigens for testing and may be limited in their availability (e.g., the PakAuto<sup>®</sup> [Immucor] assay was discontinued in the USA). Although sensitivity of some assays is limited (e.g., protein-specific platelet-antibody assays for the diagnosis of ITP), other tests can be crucial for diagnosis and management, mandating referral of patient material to reference laboratories with the appropriate expertise (e.g., diagnosis and management of neonatal alloimmune thrombocytopenia).

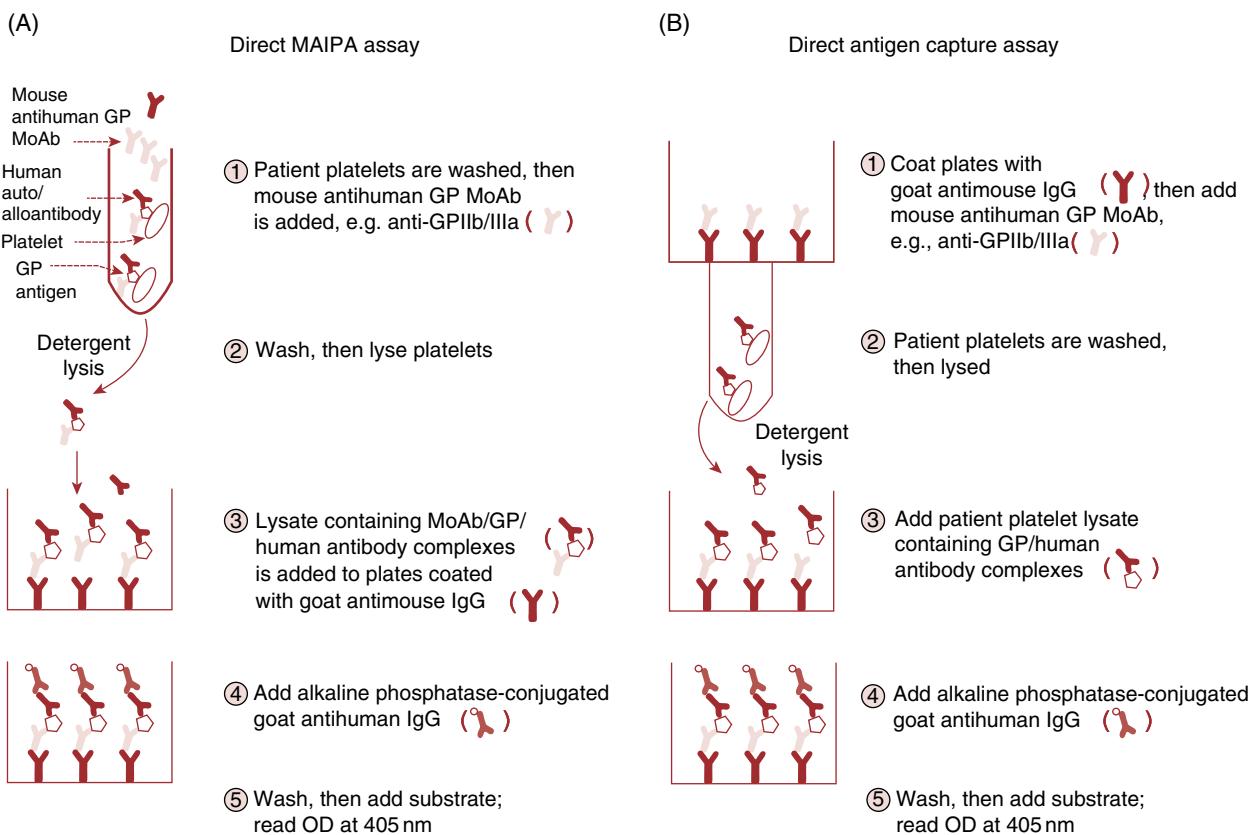

#### Monoclonal antibody-based assays

Various monoclonal antibody-based assays can be used to detect platelet antibodies. Perhaps most widely used is the monoclonal antibody immobilization of platelet antigen (MAIPA) assay. An improved modified MAIPA assay<sup>17</sup> is shown in Figure 36.1A. A technically simpler assay is the antigen capture enzyme immunoassay, in which platelet GP monoclonal antibodies interact with detergent-solubilized platelet samples (Figure 36.1B) rather than intact platelets.<sup>15,18</sup> Simplicity and improved specificity are advantages of these assays, especially the antigen capture assay. In addition to investigation of autoimmune thrombocytopenia, these assays can be adapted to study alloimmune disorders with a panel of platelet glycoproteins of known alloantigen phenotype, or drug-induced thrombocytopenia through demonstration of drug-dependent binding of antibody to specific platelet glycoproteins.<sup>15</sup> A disadvantage is that the identity of the target protein (and thus the monoclonal antibody to be used in the test) must be known in advance, and a number of different monoclonal antibodies are often needed. These assays also can give false-negative results if the patient antibody competes for the same epitope recognized by the monoclonal antibody. Some human sera contain antibodies that recognize murine IgG, which is why the modified MAIPA and antigen capture assays are preferred to the original MAIPA (to avoid a false-positive result).<sup>17</sup>

#### Immunoprecipitation

Immunoprecipitation has the advantage of being able to identify novel protein targets of platelet antibodies and does not require the use of a known monoclonal antibody in advance. It is performed by incubating patient serum or plasma with platelets labeled with iodine-125 or tagged with nonradioactive biotin.<sup>19</sup> The proteins are then solubilized by the addition of detergent, and the antibody-protein complex is precipitated by addition of an anti-immunoglobulin bound to a solid phase (e.g., immobilized staphylococcal protein A or G). The labeled protein-antibody complexes are washed, eluted from the beads, and the platelet proteins are separated by denaturing gel electrophoresis and detected by autoradiography or use of enzyme-conjugated streptavidin. The target antigen is identified according to its electrophoretic mobility. Either the patient's platelets are used (direct immunoprecipitation), or patient serum or plasma is mixed with target platelets (indirect immunoprecipitation).

Immunoprecipitation offers advantages over immunoblotting because the antibody reacts with native, rather than denatured, platelet proteins. In particular, this technique has allowed detection of clinically significant antibodies against previously unrecognized

**Figure 36.1** Modified monoclonal antibody immobilization of platelet antigen (MAIPA) assay and antigen capture assay. “Direct” versions of both assays are shown, that is, the patient’s platelets are tested for the presence of platelet glycoprotein (GP)-bound autoantibodies. (In indirect assays, the patient’s serum or plasma is added to target platelets to detect the presence of serum or plasma platelet glycoprotein antibodies.) (A) In the MAIPA assay, the antihuman GP monoclonal antibodies (MoAbs) are added to washed intact patient platelets before detergent lysis.<sup>17</sup> (B) In the antigen capture assay, the patient’s platelets are washed, then lysed, and added to capture GP MoAb precoated on the EIA plate.<sup>18</sup> However, both assays resemble each other in the final stages in which enzyme-conjugated antihuman IgG is added followed by substrate (steps 4 and 5). A relative advantage of the antigen capture assay is that the platelet lysate can be stored and the assay performed later using any MoAb of choice, making this a technically simpler and more versatile assay. OD: optical density.

platelet proteins, such as anti-HPA-15 (anti-Gov) on CD109, a 175-kD glycosylphosphatidylinositol (GPI)-anchored protein.<sup>20</sup> The main disadvantage of immunoprecipitation is technical difficulty. In addition, not all platelet proteins are optimally labeled (e.g., GPVI).

#### Immunoblotting (Western blotting)

In immunoblotting, patient serum is allowed to interact with platelet proteins that have been electrophoretically separated and then immobilized onto a solid phase (nitrocellulose). The test serum is added, and binding of patient antibody to specific protein bands is detected with labeled anti-immunoglobulin. Although immunoblotting offers the advantage of simplicity and the opportunity to store the immobilized proteins for long periods, a major disadvantage is that protein antigens are denatured in this method. This can destroy some platelet antigens (e.g., HPA-5 and HPA-15) and may modify or expose epitopes to which normal sera can react (e.g., vinculin and talin), making interpretation difficult.<sup>20,21</sup>

#### Surface plasmon resonance (SPR)

A problem with many immunoassays is the requirement for wash steps. Even relatively gentle washes and dilutions can disrupt the binding of lower affinity antibodies to their glycoprotein targets. SPR was developed to investigate interactions between biomolecules

in real time. The change in refractive index at the interface between a gold surface and media can be measured as molecules in the fluid phase are passed over their targets bound to the surface. SPR has been used to investigate serum platelet antibodies, which may be low avidity and thus may escape detection by conventional protein binding assays. For example, SPR was used to confirm the diagnosis of NAIT in women who were suspected of having the disease but tested negative in other conventional immunoassays.<sup>22,23</sup> An alternative method for measuring low affinity binding uses a dip-and-read platform, and has the potential for higher throughput than SPR. Biolayer interferometry (BLI) measures interference patterns associated with binding of protein in a well to its partner immobilized on the biosensor.<sup>24</sup> A disadvantage of both SPR and BLI is the requirement for purified target protein to bind to the gold surface or sensor, limiting the method to abundant platelet glycoproteins that can be isolated efficiently. SPR and BLI have not yet been adopted into routine practice for platelet antibody investigations.

#### Tests for heparin-induced thrombocytopenia

Special tests are required to detect the antibodies that cause HIT. These assays are classified as platelet activation or platelet factor 4 (PF4)-dependent antigen assays (or PF4-dependent immunoassays).<sup>25</sup>

### Platelet activation assays

Heparin-induced thrombocytopenia antibodies have potent heparin-dependent, platelet-activating properties. Aggregation of platelets (prepared as citrate-anticoagulated platelet-rich plasma) by patient plasma detected with conventional platelet aggregometry once was widely used for HIT; however, the sensitivity of this assay is relatively low (~70%) for detecting HIT antibodies.<sup>26</sup> In contrast, assays performed with washed platelets that have been resuspended in calcium-containing buffer, such as the platelet serotonin release assay (SRA) or heparin-induced platelet activation assay (HIPA), have both high sensitivity (~95%) and specificity (~95%) for detecting clinically significant HIT antibodies.<sup>25</sup> These assays are not widely available because they are technically demanding, require careful platelet donor selection, and require a panel of strong and weak positive serum controls. HIT antibodies have a characteristic activation profile: platelet activation at therapeutic, but not high, heparin concentrations and inhibition of activation by Fc receptor-blocking monoclonal antibodies. It should be noted that strong serum-induced platelet activation that occurs in the absence of heparin is a feature of severe HIT, including “delayed-onset” and “spontaneous” HIT (discussed in this chapter). In recent years, PF4-dependent platelet activation assays have been developed;<sup>27–29</sup> here, PF4 (with or without heparin) is added, so as to improve diagnostic sensitivity, given that occasional HIT sera test is negative in the SRA (so-called “SRA-negative HIT”).<sup>30,31</sup>

### PF4-dependent enzyme immunoassays

In 1992, Amiral *et al.*<sup>32</sup> identified PF4-heparin complexes as the antigen of HIT. Both commercial and in-house antigen assays based on enzyme immunoassay (EIA) methods have since become available. An intriguing feature of the HIT antigen is that certain polyanions other than heparin render PF4 antigenic. This is the basis of the PF4-polyvinylsulfonate EIA for PF4-heparin antibodies.<sup>33</sup> PF4-heparin EIAs are highly sensitive for HIT (>99%) but have relatively low diagnostic specificity.<sup>25</sup> An important phenomenon is that greater reactivity in a PF4-heparin EIA (expressed in optical density units) predicts for a greater likelihood of platelet-activating antibodies being detectable, and hence a diagnosis of HIT.<sup>34,35</sup>

### Rapid (on-demand) PF4-dependent immunoassays

Although EIAs can be performed in a few hours, in most situations, samples are tested in batches, and so results are often obtained one or more days after ordering the test. In contrast, several rapid “on-demand” PF4-dependent immunoassays have become available in recent years. Two are available in the United States: the latex-enhanced immunoturbidimetric assay (LIA)<sup>35</sup> and the chemiluminescence immunoassay (CLIA).<sup>36</sup> Both assays have high (~90–98%) sensitivity, and specificity that is higher than EIAs. For both the LIA and CLIA, results are reported semiquantitatively (in “units per mL”), and—as with EIAs—greater reactivity predicts for a higher likelihood of SRA-positive status and hence a diagnosis of HIT. Two other rapid PF4-dependent immunoassays that are widely used outside of the United States are the particle gel immunoassay (PaGIA)<sup>37</sup> and the lateral flow immunoassay (LFI).<sup>38</sup> Recently, approaches have been described in which clinical probability has been integrated with testing using two different immunoassays (e.g., LIA and CLIA;<sup>39</sup> PaGIA and CLIA<sup>40</sup>) so as to optimize diagnostic sensitivity and provide real-time Bayesian (integrated clinical/laboratory probability-based) diagnosis.

### Platelet genotyping

Serologic assays are generally reliable for detecting platelet alloantibodies. They also have been used to identify platelet antigens (platelet phenotyping). However, a disadvantage of antibody-based analysis is that there may not be sufficient platelets available from a patient with severe thrombocytopenia (e.g., post-transfusion purpura [PTP]) to allow determination of the reciprocal platelet alloantigen phenotype.<sup>41</sup> Second, specific phenotyping sera are available for only a few of the platelet antigens. Molecular techniques provide a reliable alternative to serologic phenotyping. Genomic DNA is used to determine the corresponding platelet alloantigen genotype and is readily available from a number of sources. Molecular techniques are particularly useful in the evaluation of suspected NAIT. Analysis of fetal cells (obtained by amniocentesis, chorionic villus sampling, or sampling of fetal blood) can determine whether a fetus is at risk for this complication. Small amounts of tissue can be studied (e.g., 5–10 mL of amniotic fluid) because the technique of polymerase chain reaction (PCR) greatly amplifies the DNA. The possibility of significant maternal DNA contamination of a fetal sample can be assessed with the forensic technique of variable-number tandem repeat analysis of the sample.<sup>42</sup>

### Polymerase chain reaction and restriction fragment length polymorphism

For all platelet alloantigen polymorphisms but one (HPA-4), the single-base substitution responsible for the change in the expressed amino acid is associated with a restriction endonuclease recognition site.<sup>41</sup> Accordingly, restriction fragment length polymorphism (RFLP) analysis was the first genotyping assay developed to identify platelet alloantigens. In the PCR-RFLP method, a section of DNA that encompasses the polymorphism is amplified using a pair of sense–antisense primers. The amplified product is subjected to restriction enzyme digestion, which cuts the amplified DNA into fragments depending on the nucleotide sequence. These are separated using agarose gel electrophoresis to identify the size and number of fragments, which indicate the platelet antigen genotype. One limitation is the possibility that another polymorphism within the amplified fragment could confound the genotyping by interfering with the restriction enzyme.<sup>43</sup> Phenotyping methods do not appear to be affected, suggesting that multiple methods for antigen typing may be warranted.<sup>44</sup>

### Allele-specific polymerase chain reaction

Because PCR-RFLP is a comparatively labor-intensive technique, allele- or sequence-specific PCR (SSP-PCR) is commonly used. For this technique, one of the primers is specific for the particular allele to be amplified.<sup>45</sup> When the specific nucleotide corresponding to the allelic polymorphism is positioned at the 3' end of the oligonucleotide primer, efficient amplification occurs only when the primer is 100% complementary to the genomic sequence. The advantage of this method is that the PCR product is visualized directly in agarose gels to determine the genotype. Appropriate controls must be included in the assay, including additional primers to amplify a ubiquitous gene (e.g., human growth hormone) to ensure that all assay constituents are working properly.

### Real-time polymerase chain reaction

A modification of SSP-PCR is real-time PCR. Real-time PCR has improved both the speed and accuracy of genotyping.<sup>46</sup> The use of specifically designed hybridization probes tagged with fluorescent

dyes for the PCR allows direct determination of the platelet genotype without gel electrophoresis or restriction enzymes in a single reaction. One hybridization probe, the donor, is tagged with a dye (fluorescein) and emits light at a specific wavelength when excited by a light source. The other probe, the acceptor, is tagged with a different dye. It straddles the single nucleotide polymorphism of interest and is 100% homologous to one of the platelet alleles. The acceptor probe usually is one nucleotide away from the donor probe in a head-to-tail arrangement, that is, the dyes are juxtaposed. The energy emitted by the dye of the donor probe is transferred to the adjacent dye of the acceptor probe, which emits light at a different wavelength. The intensity of the second light emitted is proportional to the amount of double-stranded DNA present. Unbound donor probe in the mixture can be excited but cannot transfer energy to the acceptor probe. On completion of the PCR, the platelet genotype is determined by means of melting curve analysis. Because the acceptor probe straddles the polymorphism and is 100% homologous to one of the alleles, the melting curve has a different temperature midpoint ( $T_m$ ) depending on whether a mismatch is present. The acceptor probe can have as much as 5–8 °C difference in  $T_m$  between the two platelet alleles. In all, three melting curves are seen, one for each polymorphism and a composite melting curve when the heterozygous situation is present.<sup>46</sup> The advantage of fluorescence-based real-time PCR with melting curve analysis is that the PCR product is measured directly, and no further manipulation is required. Any additional polymorphism in the region of the acceptor probe is detected in the melting curve analysis. Rapid thermal cycling and DNA extraction permit the determination of a platelet genotype within two hours of specimen collection. Noninvasive prenatal diagnosis requires higher sensitivity to detect fetal DNA in maternal plasma. PCR methods using next-generation sequencing (NGS), bead chip techniques, or droplet digital PCR have shown promise for these investigations.<sup>47,48</sup>

### Immune-mediated thrombocytopenic syndromes

The principal mechanism for immune-mediated thrombocytopenia is antibody-mediated destruction of platelets. The IgG-sensitized platelets are phagocytosed by monocytes and macrophages of the reticuloendothelial system. Reticuloendothelial cells are located throughout the body but are concentrated in the spleen, liver, lungs, and marrow. Pathogenic antibodies bind to platelets via their Fab termini, usually against specific autoantigen or alloantigen epitopes. Sometimes the target antigen is induced by a drug or drug metabolite. The result is a ternary complex that involves IgG, a drug, and a specific region on a platelet glycoprotein. Heparin-induced thrombocytopenia is an exception to these generalizations: Although HIT antibodies bind to PF4-heparin complexes via the Fab terminus, the Fc portion of IgG interacts with platelet Fc $\gamma$ IIa receptors, resulting in platelet activation.<sup>6</sup>

The rate of platelet destruction is determined by the quantity and subclass distribution of IgG on the platelet, the amount of complement, and the efficiency of reticuloendothelial clearance. The severity of thrombocytopenia reflects the balance between the rate of platelet destruction and the compensatory marrow thrombopoiesis. Immune mechanisms can also target megakaryocytes in the bone marrow leading to reduced platelet production.<sup>49</sup>

### Immune thrombocytopenia (ITP)

Immune thrombocytopenia (ITP), previously known as primary idiopathic thrombocytopenic purpura, is a common disorder characterized by increased platelet destruction and impaired platelet production. It is a diagnosis of exclusion, defined by isolated thrombocytopenia with no other clinically apparent cause. Secondary ITP can occur in the setting of human immunodeficiency virus (HIV), hepatitis C, and *Helicobacter pylori* infections; systemic lupus erythematosus (SLE); certain drugs; and lymphoproliferative disorders. Causes of nonimmune thrombocytopenia that are often confused with ITP include myelodysplastic syndrome, splenomegaly, and familial thrombocytopenia.<sup>50–52</sup> Platelet-antibody assays detect platelet GP-reactive autoantibodies in 40–80% of patients;<sup>53</sup> this variability results from heterogeneity of the patient population studied and the particular tests performed. Overall, low assay sensitivity indicates that a negative test does not exclude the diagnosis of ITP.<sup>18,54</sup>

### Pathogenesis

Over 50 years ago, Harrington *et al.*<sup>55</sup> showed that ITP plasma infused into healthy volunteers caused acute severe thrombocytopenia. The platelet-destroying plasma factor was later shown to be IgG, although in some patients, IgM and IgA antibodies may be pathogenic. The immune target of the autoantibodies usually is one of the two major platelet glycoprotein complexes, with GPIIb/IIIa implicated more often than GPIb/IX.<sup>56</sup> Other less common autoantigen targets include GPIa/IIa,<sup>56</sup> GPV,<sup>57</sup> and, possibly, nonprotein targets such as glycosphingolipids. The autoantibodies bind to platelets by way of their Fab terminus and cause premature platelet destruction via Fc receptor (Fc $\gamma$ R)-mediated phagocytosis by macrophages in the spleen and other reticuloendothelial tissues. Platelet autoantibodies can also activate complement in vitro. Another proposed mechanism of platelet destruction is direct platelet lysis by cytotoxic T cells.<sup>58,59</sup>

Platelet production is also impaired in ITP. Platelet turnover is lower than expected, as shown by radiolabeled autologous platelet studies,<sup>60</sup> and some patients who respond to thrombopoietin (TPO)-based treatments have demonstrated an increase in the number of reticulated platelets, suggesting that this compensation was not maximal.<sup>11</sup> An increased megakaryocyte mass that has been observed in some patients may account for the relative TPO deficiency because these cells bind free TPO. Conversely, platelet underproduction may result from megakaryocyte injury caused by autoantibodies.<sup>61–63</sup> Another mechanism that may cause impaired platelet production is antibody-mediated desialylation of platelet glycoproteins, which leads to platelet clearance by the Ashwell-Morell receptors in the liver<sup>64</sup> as well as to impaired platelet production.<sup>65</sup>

The cause of autoantibody formation in ITP is not known. Light chain and immunoglobulin subclass restriction of platelet-reactive antibodies suggests an oligoclonal origin of autoantibodies in chronic ITP.<sup>66</sup> Furthermore, the autoepitopes involved may be fairly restricted in scope. Autoantibodies are produced by B lymphocytes, and the loss of T-cell tolerance to platelet proteins is a key feature.

### Clinical and laboratory features

Stages of ITP have been defined by the international ITP Working Group: newly diagnosed ITP (within three months), persistent ITP (3–12 months), and chronic ITP (more than 12 months).<sup>67</sup> The prevalence of ITP has been estimated at 12.1 (95% confidence interval [CI], 11.1–13.0) per 100,000 adults.<sup>68</sup> If the clinical evaluation

reveals other signs or symptoms, e.g., weight loss, fever, lymphadenopathy, hepatomegaly, or splenomegaly, other diagnoses should be considered. Laboratory testing for patients with ITP should include evaluation of the peripheral blood film and testing for HIV, hepatitis C, and (when rituximab treatment is anticipated) hepatitis B, as well as quantitative immunoglobulin levels, thyroid function screening, and antiphospholipid antibody testing.<sup>51,52</sup> *H. pylori* testing should be considered, especially for patients from Japan.

Mucocutaneous bleeding is the hallmark of ITP and manifests as purpura (petechiae and ecchymosis), epistaxis, menorrhagia, oral mucosal bleeding, and gastrointestinal bleeding. Severe bleeding occurs in 9.6% of adults and 20.2% of children, and the incidence of intracerebral hemorrhage is 1.4% for adults and 0.4% for children.<sup>69</sup> The frequency of severe bleeding is highest among patients with chronic ITP, patients with previous bleeding, and patients over 60 years of age.<sup>70</sup> Male sex and heavily pretreated ITP are also risk factors for severe bleeding.<sup>71</sup> On the other hand, many patients have minimal or no bleeding despite very low platelet count levels, possibly because of the presence of young, reticulated platelets with enhanced  $\alpha$ -granule release to platelet agonists.<sup>72</sup> When choosing whether and how to treat ITP, clinicians should remember that morbidity in ITP patients is often attributable to adverse effects of the treatments administered rather than the disease itself.<sup>73</sup>

### Treatment overview

Treatment strategies for ITP are based on the following principles:

- 1** Many patients do not bleed, even with low platelet counts ( $<30 \times 10^9/L$ ), and many patients may not need treatment.
- 2** The goal of treatment is to achieve a safe platelet count, not necessarily a normal count.
- 3** The urgency of treatment will dictate the type of therapy: platelet transfusions may be useful when immediate (but transient) hemostasis is needed, intravenous immunoglobulin (IVIG) will start to increase the platelet count in most patients by 12–24 hours, and corticosteroids typically result in a platelet count response within 3–7 days.
- 4** Most adults have chronic ITP and only approximately 20% will have a spontaneous remission, whereas most children have acute ITP that often improve spontaneously or with minimal treatment.
- 5** Many adults will require treatment beyond first-line therapies, but the least amount of treatment should be used to maintain a hemostatic platelet count in patients with chronic ITP.
- 6** Drugs that interfere with platelet function—particularly aspirin, nonsteroidal anti-inflammatory agents, and alcohol—should be avoided.

### First-line therapies

#### Corticosteroids

Corticosteroids, either prednisone (0.5–2 mg/kg/day, maximum dose 80 mg, followed by a taper) or high-dose dexamethasone (40 mg/day for four consecutive days, repeated monthly if necessary), are considered first-line treatments. To avoid toxicity from long-term exposure, the prednisone dose should generally be tapered and discontinued after eight weeks (and perhaps more rapidly in patients who do not achieve a platelet count response). Two prospective studies<sup>74,75</sup> compared conventional and lower dose prednisone therapy (1 mg/kg/day vs. 0.25 mg/kg/day in one trial; 1.5 mg/kg/day vs. 0.5 mg/kg/day in the other), and in neither study was there a significant difference in remission at six-month follow-up evaluation. In the larger study,<sup>75</sup> however, the higher dose

regimen showed a trend to a higher rate of complete remission (46% vs. 35%) as well as higher platelet counts at 14-day follow-up evaluation (77% vs. 51% having a platelet count greater than 50,000/ $\mu L$ ).

High-dose dexamethasone has been used with success in patients with newly diagnosed ITP. In one study ( $n = 125$ ), 84% of patients with acute ITP treated with a single course of high-dose dexamethasone (40 mg/day for four days) achieved a platelet count response ( $>50,000/\mu L$ ), and of those, 50% had a response that lasted from 2 to 5 years.<sup>76</sup> In another study ( $n = 37$ ), six courses of monthly high-dose dexamethasone resulted in an overall response rate of 83.8%, and a sustained response of 64.9% after two years.<sup>77</sup> However, repeated cycles of high-dose dexamethasone were often poorly tolerated, and these high rates of durable response have not been consistent in practice. In patients with chronic ITP, responses with high-dose dexamethasone are variable. In one study, all 10 treated patients achieved a response that lasted six months following six cycles of high-dose dexamethasone (40 mg/day for four days).<sup>78</sup> However, other subsequent studies were less encouraging. Using the same regimen, Stasi *et al.*<sup>79</sup> reported that 13 of 32 patients (40.6%) had transient responses only, and in the study by Warner *et al.*,<sup>80</sup> none of nine patients responded, and five could not tolerate the treatment.

In a systematic review<sup>81</sup> of randomized trials comparing high-dose dexamethasone and prednisone in adults with previously untreated ITP ( $n = 533$ ), treatment with dexamethasone resulted in improved overall (79% vs. 59%;  $p = .048$ ) and complete platelet count response (64% vs. 36%;  $p = .040$ ) without excess toxicity. Platelet count responses occurred more rapidly with high-dose dexamethasone (within 14 days); however, sustained responses at six months were not different between groups.

Adverse effects of corticosteroids include facial swelling, weight gain, and behavioral changes in up to 20% of patients.<sup>50,82</sup> Less common (1–5%) complications include infection, myopathy, hyperglycemia, psychosis, hypertension, hypokalemia, and osteoporosis. Osteonecrosis, most commonly involving the femoral head, occurs as a late side effect in approximately 5% of patients who undergo prolonged therapy, but it may occur even after intensive short-term exposure.<sup>83</sup>

#### Intravenous immunoglobulin

High-dose IVIG has been used to treat patients with ITP since 1981.<sup>84,85</sup> Reticuloendothelial blockade is the principal mechanism of action of IVIG, but many other mechanisms have been proposed, including the reduction of antibody synthesis, IgG molecules against the Fab regions of pathogenic autoantibodies (“anti-idiotypic antibodies”),<sup>86</sup> cytokine-induced pro- or anti-inflammatory effects,<sup>87</sup> up- or downregulation of various Fc $\gamma$ Rs, or the formation of soluble immune complexes. In a mouse model of ITP, the inhibitory IgG receptor, Fc $\gamma$ RIIB, was required for IVIG to cause an elevation in platelet count,<sup>88</sup> and the transfer of IVIG-primed dendritic cells has been shown to recapitulate the effect of IVIG.<sup>89</sup>

The use of IVIG is indicated for patients with ITP with bleeding or for whom an invasive procedure is planned to raise the platelet count quickly. A French study of 122 adults with ITP showed that IVIG (0.7 g/kg/day for three days) raised the platelet count to over 50,000/ $\mu L$  within five days more frequently than did corticosteroids (methylprednisolone, 15 mg/kg/day for three days).<sup>90</sup>

The usual dose of IVIG is 1–2 g/kg, given either as 0.4 g/kg for five consecutive days or as 1 g/kg over two days. One trial showed no difference between one and two doses of 1 g/kg.<sup>91</sup> Thus, our approach

**Table 36.1** Comparison of High-Dose IVIG and Intravenous RhIG for Management of Immune Thrombocytopenic Purpura

Characteristic	High-Dose IVIG	Intravenous RhIG
Side effects	Common: headache, hypertension, fever, and chills	Common: mild hemolysis
Response rate	Rare: hemolysis, renal failure, myocardial infarction, and stroke	Rare: severe hemolysis necessitating transfusion or hemodialysis, and DIC
Response duration	Usually transient	Usually transient
Pattern of platelet increase	Rapid increase (12–24 h), high platelet peak, and shorter duration of response	Slower increase, lower peak, and longer duration of response
Influence of ABO, Rh type	No influence	Only RhD-positive patients respond
Influence of splenectomy	Unknown	Minimal or no response in patients without a spleen
Suitability for emergency management of ITP	Recommended	Not recommended

IVIG: intravenous immune globulin; RhIG: Rh immune globulin; DIC: disseminated intravascular coagulation; ITP: immune thrombocytopenic purpura.

is to give 1 g/kg as a single dose and to repeat the dose one or two days later if no significant platelet count increase has occurred.<sup>92</sup>

IVIG increases the platelet count to greater than 50,000/ $\mu$ L in approximately 80% of adult patients. Responses are usually transient, lasting 2–6 weeks. Tachyphylaxis after repeated courses may be observed in patients with severe ITP.

Common but mild side effects include headache in 10% of patients, backache, nausea, flushing, and fever.<sup>93</sup> Aseptic meningitis may occur rarely. Chest pain, hypertension, hypotension, bronchospasm, and laryngeal edema have been reported. A boxed warning concerning the risk of thrombosis with IVIG was issued by the US Food and Drug Administration (FDA) in 2013 (<http://www.fda.gov>) because arterial and venous thrombosis have rarely been reported, particularly in elderly patients<sup>94</sup> (Table 36.1). Because IVIG is prepared from pooled plasma from thousands of donors, infection transmission is theoretically possible, but this risk has been significantly mitigated by use of viral inactivation methods. Transfusion-related acute lung injury following IVIG has also been described.<sup>95</sup>

#### RH immune globulin

Like IVIG, the mechanism of action of Rh immune globulin (RhIg) is believed to be reticuloendothelial blockade, which occurs through occupancy of the reticuloendothelial cell Fc $\gamma$ Rs by IgG-sensitized red cells.

Doses of 50–75  $\mu$ g/kg of RhIg have been shown to produce a rapid increase in platelet count.<sup>96</sup> Hemolysis is an expected side effect, and rarely severe hemolysis with disseminated intravascular coagulation and renal failure has been reported with fatal outcomes<sup>97,98</sup> (Table 36.1). Because of this, RhIg was voluntarily withdrawn from some European markets in 2009. Its use is usually restricted to nonsplenectomized patients who are Rh-positive and have a negative direct antiglobulin test.

#### Second-line therapies

The principal second-line therapies for ITP are splenectomy, rituximab, and TPO receptor agonists. Immune suppressant medications can also be used as second-line therapy. A new treatment option is fostamatinib, an oral SYK inhibitor (see below). Randomized trials comparing different second-line treatments for ITP are lacking; thus, the choice of therapy depends on individual factors such as patient characteristics and preferences, access, and cost, as described in evidence-based guidelines.

#### Splenectomy

Complete remission of ITP occurs in 70% of patients within 4–6 weeks of splenectomy,<sup>99</sup> presumably because in many patients the spleen is the major site of both autoantibody production and

platelet destruction. In complete responders, normal platelet counts are reached within seven days in 90% and within six weeks in 98% of patients; remission is encountered rarely thereafter. In a further 5–10% of patients, partial remission is achieved. In a systematic review of the efficacy of splenectomy for patients with ITP, younger age was an independent predictor of response to splenectomy;<sup>99</sup> however, other investigators have shown that response to IVIG<sup>100–102</sup> and splenic clearance of platelets (determined by radionuclide platelet imaging techniques)<sup>103</sup> are also useful predictors. The risk of relapse after a complete remission following splenectomy is low (approximately 10–15% at 10 years). Splenectomy is commonly performed using a laparoscopic approach.

Perioperative management of splenectomy involves (1) optimization of the platelet count before surgery, (2) vaccination against encapsulated bacteria to minimize the risk of overwhelming post-splenectomy infection, and (3) prevention of thromboembolism. Adequate perioperative hemostasis can usually be achieved with preoperative high-dose IVIG or corticosteroids, and TPO receptor agonists may be a suitable alternative.<sup>104</sup> However, most patients do not have excessive bleeding; therefore, platelet transfusions should not be administered prophylactically but rather be reserved for the treatment of perioperative bleeding.

The presence of residual accessory spleen should be considered when splenectomy fails, or when patients relapse months or years after surgery.<sup>105</sup> Postsplenectomy blood film changes (e.g., Howell-Jolly bodies) do not necessarily eliminate the possibility of a residual accessory spleen. Unfortunately, a durable platelet count response following accessory splenectomy performed because of postsplenectomy relapse of ITP is uncommon and can be expected in less than 50% of patients.

Perioperative morbidity after splenectomy is less than 10%. The most frequent complications are pleuropulmonary (pneumonia, subphrenic abscess, and pleural effusion) in 4% of patients, major bleeding in 1.5%, and thromboembolism in 1%. Morbidity is lower with a laparoscopic approach by an experienced surgeon. Overall mortality is approximately 1% following laparotomy and 0.2% following laparoscopic splenectomy.<sup>99</sup>

The risk of bacterial infection is higher among asplenic patients. The risk of overwhelming postsplenectomy infection is approximately 1–2%.<sup>106</sup> In a population-based study of 3812 patients who underwent splenectomy, the overall incidence rate of infection was 7.7 per 100 person-years (odds ratio compared to nonsplenectomized patients with an indication for splenectomy, 1.7 [95% CI, 1.5–2.1] in the first 90 days).<sup>107</sup> In a review of the literature, the frequency of infection was 2.1% and mortality was 1.2% among 484 patients who had splenectomy for ITP.<sup>108</sup> Life-threatening infections may occur many years after splenectomy, suggesting that the

risk of severe infection may persist.<sup>109</sup> To reduce the risk of bacterial infection, all patients who undergo splenectomy should receive vaccinations against the encapsulated bacteria *Streptococcus pneumoniae*, *Hemophilus influenzae* type B (HIB), and *Neisseria meningitidis*.

Postoperative thromboembolism is the most common cause of postoperative mortality; thus, for patients with delayed postoperative mobilization, thromboprophylaxis should be considered.

After the diagnosis of ITP, it is recommended to wait at least 12 months before considering splenectomy, as about 20% of patients can achieve a remission within the first year of the disease. Now that additional treatments are available including the TPO receptor agonists, the use of splenectomy has declined; however, it remains a therapeutic option with a high response rate.<sup>110</sup>

### **Rituximab**

Rituximab is a chimeric monoclonal anti-CD20 indicated for the treatment of lymphoma, chronic lymphocytic leukemia, rheumatoid arthritis, and Wegener's granulomatosis. The Fab portion binds to CD20 on B lymphocytes, which results in Fc<sub>Y</sub>R-mediated B-cell lysis by complement-dependent<sup>111</sup> and antibody-dependent pathways.<sup>112–114</sup> In ITP, rituximab depletes CD20-positive B cells, which are responsible for platelet autoantibody production. It can also correct T-cell dysfunction which has been associated with platelet count improvements after rituximab.<sup>115</sup> Rituximab has been associated with durable remissions in up to 20–30% of patients.<sup>116,117</sup>

A systematic review<sup>118</sup> of observational studies described outcomes with rituximab in adults who had ITP for 1–360 months (50% had splenectomy). A complete response to rituximab (platelet count greater than 150,000/ $\mu$ L) was seen in 43.6% of patients (95% CI, 29.5–57.7%) and an overall response (platelet count >50,000/ $\mu$ L) in 62.5% (95% CI, 52.6–72.5%). The median time to response was 5.5 weeks (some responses may occur up to 8–12 weeks), and responses lasted a median of 10.5 months. Data from randomized trials were less optimistic. In a meta-analysis, rituximab plus standard of care was more often associated with a complete platelet count response (platelets >100  $\times$  10<sup>9</sup>/L without rescue treatment) compared with standard of care alone (46.8% vs. 32.5%;  $p = 0.002$ ); however, responses were generally not sustained past 12 months.<sup>119</sup> In some studies, responses were more frequent in females, younger patients (<40 years), patients who had ITP for less than 12 months, and patients with other autoimmune conditions.<sup>120–123</sup>

Results with rituximab in children are less encouraging. In a prospective single-arm study of 36 children with chronic ITP treated with rituximab, 11 (30.6%) achieved a platelet count of 50,000/ $\mu$ L or greater for four consecutive weeks.<sup>124</sup>

Toxicities of rituximab include infusional reactions, hepatitis B reactivation, and a possible association with progressive multifocal leukoencephalopathy.<sup>125</sup> Rituximab has been shown to impair vaccine responses for up to six months.<sup>126</sup>

### **Thrombopoietin receptor agonists**

TPO receptor agonists (TPO-RAs) bind to and activate the c-Mpl receptor on hemopoietic stem cells and megakaryocytes, ultimately leading to increased platelet production. They do not resemble endogenous TPO, and thus do not induce the formation of anti-TPO antibodies (which had previously occurred with pegylated recombinant human megakaryocyte growth and development factor [PEG-rHuMGDF]).<sup>127</sup>

In 2008, two TPO-RAs—romiplostim and eltrombopag—were approved for the treatment of patients with chronic ITP. In 2019,

another TPO-RA, avatrombopag, was also approved by the FDA. Romiplostim is administered by weekly subcutaneous injection, while eltrombopag and avatrombopag are oral daily medications. The clinical success of these medications has been one of the most important advances in ITP treatments since the discovery of IVIG. In phase III trials, each has been shown to be effective in increasing platelet counts compared with placebo or standard of care<sup>128–130</sup> in 60–80% of patients. Responses are sustained as long as the medication is continued even after prolonged use.<sup>131,132</sup> Once the medication is stopped, the platelet counts may drop to pretreatment levels, at which point patients may be at increased risk of bleeding.<sup>133</sup> However, up to 20–30% of patients maintain durable platelet count responses even after TPO-RA cessation.<sup>134</sup>

Side effects of TPO-RAs include thrombosis and bone marrow reticulin formation,<sup>135</sup> however, the risk of thromboembolism appears to be only slightly higher than the baseline risk in patients with ITP. The risk of clinically meaningful bone marrow reticulin formation is low and reticulin formation generally improves when the medication is stopped. Eltrombopag has been associated with serum liver function test abnormalities in approximately 10% of patients. Due to the high response rates, the use of these medications in ITP patients has steadily increased. Their use early in the course of ITP has been associated with improved short-term outcomes.<sup>136</sup> Despite being a safe and effective treatment option, the high cost may limit the prolonged use of TPO-RAs.

### **Fostamatinib**

In April 2018, the spleen tyrosine kinase (Syk) inhibitor, fostamatinib, was approved by the FDA as a novel therapy for the treatment of chronic ITP with an insufficient response to at least one prior therapy. The mechanism of action is to block platelet destruction secondary to antibody-mediated phagocytosis. Two parallel randomized trials<sup>137</sup> for ITP patients with a median disease duration of 8.5 years (many of whom had failed splenectomy, TPO agents, and/or rituximab) showed an overall response rate (platelet count  $\geq$ 50,000/ $\mu$ L) of 43% (vs. 14% on placebo) with the initial dose of fostamatinib 100 mg twice daily. The time to response was a median of 15 days. Stable response (platelets  $\geq$ 50,000/ $\mu$ L for at least four of six weeks) was achieved in only 18% of patients. Diarrhea and hypertension were the most frequent side effects.<sup>138</sup>

### **Immunosuppressive agents**

Mycophenolate, azathioprine, and cyclosporin are immunosuppressive agents that have been used to treat patients with refractory ITP. Cyclophosphamide, an alkylating agent given in doses of 1–2 mg/kg/day, has also been used. Azathioprine and mycophenolate are purine antimetabolites that inhibit lymphocyte proliferation. Cyclosporin is a calcineurin inhibitor that selectively blocks T-cell-dependent biosynthesis of lymphokines, particularly interleukin-2, at the level of messenger RNA transcription.

These drugs, alone or in combination, have shown moderate success, with up to two-thirds of patients exhibiting a platelet count response.<sup>139–141</sup> The combination of azathioprine, mycophenolate, and cyclosporin may achieve an overall response rate of 73.7%.<sup>142</sup> However, only 20–30% have responses that persist after stopping the drug(s). Responses may occur as early as two weeks and as late as three months after initiation of treatment. The early use of mycophenolate added to corticosteroids is currently being evaluated in a randomized trial.<sup>143</sup> Azathioprine can have myelosuppressive effects on hematopoietic cells and may cause severe bone marrow toxicity in patients who lack activity of the enzyme

thiopurine methyltransferase (TPMT) (1 in 300 individuals).<sup>144</sup> Mycophenolate may also be associated with leukopenia. Cyclosporin can be associated with hypertension and renal failure. Concerns over leukemic transformation and other toxicities (hepatic, hemorrhagic cystitis) have limited the use of cyclophosphamide.<sup>145</sup>

### Danazol

Danazol is an attenuated androgen with mild virilizing effects that can be used to treat men and nonpregnant women with ITP. Its mechanism of action is to decrease Fc<sub>γ</sub>R numbers and the rate of Fc<sub>γ</sub>R-mediated clearance of IgG-sensitized cells. Danazol decreases the number of monocyte IgG Fc receptors.<sup>146</sup> Usually, 400–800 mg is administered daily in divided doses. Time to response is approximately one to two months.

Danazol can produce an increase in platelet count in approximately 30–40% of patients. The response rate may be higher among patients with associated rheumatologic disorders.<sup>147</sup> Danazol must be continued to maintain the platelet count response, although attempts at dose reduction should be made. Danazol is generally well tolerated but may be associated with virilizing side effects in women, liver dysfunction, and rash.

### Vinca alkaloids

Vinca alkaloids (vincristine and vinblastine) can produce generally short-lived increases in platelet count in approximately 65% of patients.<sup>148</sup> These drugs bind to platelet microtubules and may work by being delivered to, and thereby inhibiting, reticuloendothelial macrophages. Repeated doses of vinca alkaloids are rarely used to treat patients with chronic ITP, mostly because of dose-dependent neuropathy.

### Special treatment situations

#### *Emergency treatment of a bleeding patient*

For life-threatening bleeding, platelet transfusions may transiently increase platelet counts and improve hemostasis. Other treatments should be used in combination to provide a rapid increase in platelet count, including high-dose IVIG to block the reticuloendothelial system and corticosteroids for longer-term disease control. TPO receptor agonists can also be considered, in addition to other hemostatic medications such as tranexamic acid and recombinant factor VIIa if life-threatening bleeding cannot be controlled.

#### *Preparation for invasive procedures*

High-dose IVIG usually is the treatment of choice for severely thrombocytopenic patients with ITP who need urgent surgery or an invasive procedure. When at least two or three days are available before the planned procedure, less expensive corticosteroids may be an option, but these are associated with toxicities that are particularly concerning in the perioperative period, including delayed wound healing and hyperglycemia. In a randomized trial, eltrombopag was shown to be noninferior to IVIG at achieving and maintaining surgical platelet count thresholds (50,000/ $\mu$ L for minor surgery or 100,000/ $\mu$ L for major surgery) during the perioperative period.<sup>149</sup>

#### *Immune thrombocytopenia in pregnancy*

Thrombocytopenia during pregnancy is usually not caused by ITP. Rather, a benign condition known as *gestational thrombocytopenia*, or *incidental thrombocytopenia of pregnancy*, is more common, occurring in approximately 5% of pregnancies at term. In this condition, maternal platelet counts fall moderately, but usually not

below 70,000/ $\mu$ L.<sup>150</sup> Newborns of mothers with incidental thrombocytopenia are not at increased risk of neonatal thrombocytopenia.<sup>151</sup> The second most likely cause of thrombocytopenia is pregnancy-related thrombocytopenic disorders (e.g., preeclampsia and syndrome of hemolysis, elevated liver enzymes, and low platelet count [HELLP syndrome]). Preeclampsia occurs in approximately 10% of pregnancies and causes thrombocytopenia in one-fourth of affected mothers. Preeclampsia is associated with increased maternal and fetal morbidity and mortality. Secondary causes of immune thrombocytopenia that can occur in young women, such as SLE or HIV infection, should also be considered in the appropriate clinical context.

Nonetheless, when ITP occurs in pregnancy it is an important disorder to recognize because of the treatment implications for the mother and the possibility of fetal or neonatal thrombocytopenia caused by transplacental passage of IgG platelet autoantibodies. In the past, infants of mothers with ITP were delivered by cesarean section; however, today, this procedure is not routinely recommended for two reasons. First, the frequency of severe fetal thrombocytopenia (platelet count less than 20,000/ $\mu$ L) is low (approximately 4%).<sup>152</sup> Second, there is no evidence that cesarean section leads to less intracranial bleeding compared with vaginal delivery.

Many pregnant women with ITP do not need specific treatment, unless the platelet count decreases below 20,000/ $\mu$ L or there is evidence of impaired hemostasis. The two preferred treatment options are intermittent high-dose IVIG and prednisone; however, IVIG is generally the treatment of choice (1 g/kg every 2–4 weeks) because of its favorable side effect profile compared with prednisone (which is associated with maternal hypertension and hyperglycemia and, possibly, fetal complications). Splenectomy is rarely indicated in pregnancy and should only be considered in the second trimester.<sup>50</sup> Azathioprine is safe in pregnancy but other immunosuppressant medications should generally be avoided. Rituximab is not recommended, although it appears to be relatively safe. Similarly, TPO receptor agonists are not recommended in pregnancy, but cohort studies have demonstrated success without significant toxicities.<sup>153</sup>

The mode of delivery should depend on obstetrical indications since vaginal deliveries are safe for mothers with ITP. Reasonable platelet count thresholds are 20,000–30,000/ $\mu$ L for vaginal delivery, 50,000/ $\mu$ L for caesarean section, and 80,000–100,000/ $\mu$ L for epidural anesthesia. In a relatively large cohort of infants born to mothers with ITP (119 pregnancies in 97 women), 10% of infants had a platelet count below 50,000/ $\mu$ L at birth, 15% required hemostatic treatments, and 1% died.<sup>154</sup> Unfortunately, there are no good predictors of fetal thrombocytopenia, not even the severity of maternal thrombocytopenia (indeed, women cured of ITP by splenectomy can bear infants with passive autoimmune thrombocytopenia).

### Immune thrombocytopenia in children

Acute ITP of childhood is a relatively common and generally self-limited autoimmune disorder.<sup>155</sup> In children, ITP has a peak incidence between 2 and 6 years of age. Boys and girls are equally affected, except for infants, in which males predominate.<sup>156</sup> Most children (80–90%) with acute ITP recover completely within six months; the others have persistent thrombocytopenia.

The typical clinical manifestations are bleeding and bruising following a viral infection. The mortality is approximately 0.4%, and most deaths are caused by intracranial hemorrhage. Laboratory abnormalities include isolated thrombocytopenia and normal or increased MPV. A marrow examination is usually not performed

on a child with typical clinical features of ITP but is indicated for unexpected clinical or laboratory findings. Normal or increased numbers of megakaryocytes are observed. Sometimes, morphologically distinct lymphoid cells, called *hematogones*, constitute up to one-half of the marrow cells and may cause confusion with acute leukemia.<sup>157</sup> These nonneoplastic cells have the surface immunophenotypic profile of immature lymphocytes.

Acute ITP in children is usually a benign disease. Although rare, intracranial hemorrhage is the most feared complication. Clinical trials have focused on the time to increase the platelet count to safe levels as a surrogate end point for avoiding intracranial hemorrhage.

In a randomized trial of IVIG versus observation for children aged 3 months to 16 years with severe acute ITP (platelet count 20,000/ $\mu$ L or less) and mild to moderate bleeding ( $n = 206$ ), the frequency of chronic ITP—defined as a platelet count <150,000/ $\mu$ L at 6 months—was 18.6% in the IVIg group and 28.9% in the observation group (relative risk 0.64; 95% CI, 0.38–1.08).<sup>158</sup> Grade 4 to 5 bleeding occurred in 9% of the patients in the observation group versus only 1% in the IVIg group.

In a meta-analysis of six randomized trials ( $n = 410$  children), IVIG was associated with a more rapid platelet count increase compared with corticosteroids.<sup>159</sup> On the basis of these results, high-dose IVIG is generally recommended for initial treatment of severe acute ITP in children. Oral prednisone or an additional dose of IVIG is added if the platelet count remains below 20,000/ $\mu$ L by 48 hours. It appears that lower doses of IVIG (e.g., 250–500 mg/kg/day for two days rather than the standard 1 g/kg/day) may also be effective.<sup>160</sup>

High-dose corticosteroid therapy (e.g., intravenous methylprednisolone at 30 mg/kg/day for three days; or oral methylprednisolone at 30–50 mg/kg/day for seven days) also rapidly increases the platelet count in children with acute severe ITP.<sup>161</sup> Combined treatment with IVIG and pulse methylprednisolone may be indicated for those children felt to be at very high risk of intracranial hemorrhage.<sup>162</sup>

Approximately 10–20% of children will develop chronic ITP, defined as a platelet count less than 100,000/ $\mu$ L for more than six months. As many as one-third of children who meet this definition can still enter late spontaneous remission, sometimes 5–10 years after diagnosis. Chronic ITP in children resembles chronic ITP in adults.

Some children have no symptoms despite marked thrombocytopenia. These children generally do not need treatment. For children with symptoms, options include rituximab, TPO receptor agonists, intermittent IVIG or RhIG, splenectomy, and immunosuppressive agents.<sup>163</sup>

Intravenous immune globulin (2 g/kg over 2–5 days) increases the platelet count of most children with chronic ITP<sup>84,163</sup> and repeated courses of IVIG have been used to defer or avoid splenectomy.<sup>164</sup> Low-dose, alternate-day corticosteroid therapy may improve the results with maintenance IVIG.

Intravenous RhIG is effective in increasing the platelet count for many Rh-positive children with chronic ITP<sup>165,166</sup> and, at a dose of 75  $\mu$ g/kg, it appears to be as effective as IVIG.<sup>167</sup> The benefit is transient, however, with a median duration of approximately three weeks. RhIG can also be considered splenectomy sparing in some patients.<sup>166</sup> RhIG is generally ineffective after splenectomy.<sup>166</sup>

Splenectomy is sometimes performed in children with chronic ITP who cannot be maintained on other treatments. However, in general, splenectomy is avoided in children, especially young

children, because of the long-term risk of postsplenectomy sepsis, the possibility of late spontaneous remissions, and the efficacy of other medical treatments. As with adults, children must receive vaccines for *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b at least two weeks before splenectomy.<sup>168</sup>

Results of use of immunosuppressive agents (azathioprine or cyclophosphamide) and vinca alkaloids to treat children with chronic ITP are variable and based on uncontrolled studies.<sup>163</sup> About one-third of pediatric patients with chronic ITP may respond to rituximab.<sup>124</sup>

### Drug-induced immune thrombocytopenia

Drugs can produce several immune-mediated thrombocytopenic disorders<sup>6,169–174</sup> (Table 36.2). The most common is HIT (discussed separately below), which paradoxically is associated with increased risk of thrombosis but not bleeding. In contrast, many other drugs in rare instances cause severe thrombocytopenia and bleeding, a syndrome called *drug-induced immune thrombocytopenic purpura* (DITP). Some drugs have atypical clinical features (e.g., abciximab-induced thrombocytopenia) or trigger an illness that resembles TTP or HUS.

### Typical drug-induced immune thrombocytopenia

The most common drugs that have been confirmed by laboratory testing to cause DITP are quinine, quinidine, trimethoprim/sulfamethoxazole, vancomycin, penicillin, rifampin, carbamazepine, and ceftriaxone.<sup>171,173</sup> The risk of DITP is approximately 1 case in 1000 for quinine and 1 in 25,000 for sulfamethoxazole-trimethoprim.<sup>175</sup> Quinine is present in certain beverages (e.g., tonic water), and consequently patients may not be aware of exposure.

Clinical criteria supporting a diagnosis of DITP are as follows: (1) thrombocytopenia occurs during drug treatment and is corrected completely after discontinuation of the drug; (2) the implicated drug was the only one used when thrombocytopenia occurred, or platelet count recovery occurred or persisted despite continuation or reintroduction of the other drugs used; (3) other causes of thrombocytopenia are excluded; and (4) re-exposure to the implicated agent resulted in recurrent thrombocytopenia.<sup>170</sup> For reasons of patient safety, the fourth criteria, drug re-exposure, is rarely evaluated deliberately, but sometimes the outcome of unintentional re-exposure can provide important diagnostic information (e.g., recurrent thrombocytopenia following ingestion of tonic water suggests quinine-induced thrombocytopenia). Meeting all four criteria provides definite evidence of causation, whereas meeting the first three criteria suggests a probable cause.<sup>170</sup>

Although many dozens of drugs have been suspected as causing DITP, laboratory evidence confirming the presence of drug-dependent platelet antibodies exists for relatively few drugs.<sup>171,173</sup> Supporting evidence for the drugs claimed to cause DITP is available (<http://www.ouhsc.edu/platelets/>).

Drug-induced immune-mediated thrombocytopenia typically begins abruptly and is severe; most patients have a platelet count less than 20,000/ $\mu$ L.<sup>6,172,176</sup> Although the interval between starting the drug and development of thrombocytopenia usually is one or two weeks, occasionally it can be abrupt (if the patient was previously exposed to the drug and drug-dependent antibodies remain present),<sup>177</sup> or begin several months or longer after administration of the drug is started. Sometimes, thrombocytopenia persists for several weeks even after the drug is stopped, possibly because some of the IgG antibodies formed have drug-independent platelet reactivity.

**Table 36.2** Drug-Induced Immune Thrombocytopenic Syndromes

Syndrome and Drug(s)	Comment
<b>Heparin-induced thrombocytopenia</b>	Prothrombotic reaction caused by heparin-dependent platelet-activating IgG antibodies that recognize platelet factor 4/heparin complexes; caused less often by low-molecular-weight heparin and fondaparinux than by unfractionated heparin
<b>Drug-induced immune thrombocytopenic purpura (DITP)</b>	Prohemorrhagic reaction caused by IgG antibodies that recognize drug (or drug metabolite) bound to platelet glycoprotein (GP); patients have severe thrombocytopenia and mucocutaneous bleeding.
• Quinine • Quinidine • Rifampin • Sulfa antibiotics • Vancomycin • Iodinated contrast • Acetaminophen • Many others	Quinine-dependent anti-GPIIb/IIIa and GPIb/IX IgG implicated; drug is widely available (e.g., tonic water) Antibodies usually distinct from quinine-dependent antibodies Rifampin-dependent anti-GPIIb/IIIa and GPIb/IX IgG implicated Occurs in <1 of 25,000 patients receiving trimethoprim-sulfamethoxazole Vancomycin-dependent anti-GPIIb/IIIa IgG; most common cause of DITP in hospitalized patients Severe thrombocytopenia begins after radiologic procedure IgG recognizes metabolite of acetaminophen See published lists
<b>Atypical DITP</b>	Abrupt onset of severe thrombocytopenia (platelet count nadir, 15,000–35,000/ $\mu$ L) by naturally occurring antibodies that recognize murine sequences within chimeric (human-murine) abciximab “Fibin” drug (ligand) reacts with GPIIb/IIIa, inducing neoepitope(s) (ligand-induced binding sites) recognized by antibodies Thrombocytopenia can persist for months after gold therapy is stopped (mimics chronic ITP) Transient autoimmune thrombocytopenia (anti-GPIIb/IIIa) that occurs a few weeks after vaccination (resembles childhood acute ITP)
<b>DITP: hapten mechanism</b>	Indicates that IgG recognizes drug that remains bound to platelet surface even following platelet washing Not well established
<b>Drug-induced TTP/HUS</b>	Estimated frequency, 1/2000 to 1/5000 Estimated frequency, 1/20,000 Quinine-dependent IgG against platelets and other cells found May be pathogenic factor in transplantation-associated TTP/HUS See text

MMR: measles–mumps–rubella; ITP: immune thrombocytopenic purpura; TTP: thrombotic thrombocytopenic purpura; HUS: hemolytic uremic syndrome.

The pathogenesis of DITP involves the formation of a ternary complex involving a platelet glycoprotein (usually, the GPIIb/IIIa complex, less often GPIb/IX), drug (or drug metabolite), and the Fab terminus of IgG.<sup>15,178,179</sup> Such a mechanism has been invoked for quinine, quinidine, sulfonamide, rifampin, vancomycin,<sup>178</sup> and pentamidine, among others. Unlike the mechanism of HIT, platelet Fc $\gamma$ Rs are not involved. Furthermore, the drug does not function as a hapten, that is, drug-dependent IgG does not bind to platelets that have been washed after pretreatment with the implicated drug.<sup>172</sup> Limited evidence of a hapten mechanism of DITP has been suggested only for penicillin (and possibly for piperacillin and certain cephalosporins),<sup>171</sup> that is, penicillin-dependent IgG binds to platelets that have been washed after pretreatment with penicillin. A proposed model suggests that drug-dependent antibodies are derived from a pool of naturally occurring antibodies with weak affinity for self-antigens residing on platelet membrane glycoproteins; certain drugs are able to affect both antibody and antigen in such a way that their interaction is greatly enhanced, provided that B cells expressing such antibodies are induced to produce these.<sup>172,180</sup>

In a case of suspected DITP, as many drugs as possible should be discontinued. If further drug treatment is necessary, an immunologically non-crossreactive substitute should be prescribed. Platelet transfusions should be given to patients with life-threatening bleeding or who are judged to be at high risk of bleeding (e.g., severe thrombocytopenia plus “wet purpura”). High-dose IVIG, 1 g/kg given over 6–8 hours for two consecutive days, may be of value, but can be ineffective if the relevant drug is not discontinued.<sup>178</sup> Corticosteroids are relatively ineffective in the management of this condition.<sup>176</sup>

### Atypical drug-induced immune thrombocytopenia

#### Glycoprotein IIb/IIIa antagonist-induced thrombocytopenia

Thrombocytopenia is a relatively common side effect of the three approved GPIIb/IIIa antagonists—abciximab, tirofiban, and

eptifibatide.<sup>181</sup> Often, the thrombocytopenia begins within hours of a first exposure; this is caused by naturally occurring antibodies.<sup>171,182</sup> In other patients, the thrombocytopenia begins about one week after initial—or abruptly upon repeat—drug administration; this clinical presentation reflects drug-induced antibody formation.<sup>183</sup>

Abciximab (ReoPro, Eli Lilly) is a humanized chimeric Fab fragment of a murine monoclonal antibody specific for an epitope on GPIIIa. It is used to prevent restenosis after coronary angioplasty. Approximately 0.5% of patients have moderate or severe thrombocytopenia within several hours of treatment with this drug.<sup>181</sup> Although approximately 20% of the normal population have antibodies that react against the papain cleavage site in abciximab, the remainder (1.6% overall) react against murine sequences incorporated into abciximab that confer specificity for GPIIb/IIIa. It is this latter group of antibodies that evinces pathogenicity. Perhaps surprisingly, given the degree of thrombocytopenia and use of a major platelet glycoprotein inhibitor, most patients do not have petechiae or bleeding<sup>181</sup> (although fatal bleeding episodes have been reported). Treatment with platelet transfusions and, perhaps, IVIG may benefit bleeding patients.

For approximately one-third of patients with apparent abciximab-associated thrombocytopenia, the examination of the blood film shows platelet clumping. This finding suggests that pseudothrombocytopenia (ex vivo platelet clumping) is caused by abciximab.<sup>184</sup> Such patients are not at risk for bleeding and do not need treatment.

Tirofiban and eptifibatide are synthetic compounds that mimic or contain the RGD (arg-gly-asp) peptide and bind tightly to the RGD recognition site in GPIIb/IIIa.<sup>181</sup> As with abciximab, the frequency of naturally occurring antibodies (approximately 1–2%) correlates roughly with their risk of inducing abrupt-onset thrombocytopenia upon first exposure. Delayed-onset thrombocytopenia beginning about one week after exposure has also been reported.

For tirofiban, some drug-dependent antibodies produce platelet activation and increased risk of ischemic events.<sup>185</sup>

#### **Drug-induced autoimmune thrombocytopenia**

Approximately 1–3% of patients treated with gold-containing medications have thrombocytopenia that sometimes persists for weeks or months despite stopping the drug; thus, the disorder resembles chronic ITP.<sup>186</sup> It remains uncertain whether this is true drug-induced autoimmune thrombocytopenia or is caused by gold-dependent IgG antibodies that are slowly released from tissues. Procainamide,  $\alpha$ -methyldopa, sulfonamide antibiotics, and interferons alfa and beta may also cause autoimmune thrombocytopenia.<sup>172,187</sup> In rare instances (~1/20,000 exposures),<sup>188</sup> measles-mumps-rubella vaccination causes an acute ITP-like illness in which anti-GPIIb/IIIa IgG is formed.<sup>189</sup>

#### **Drug-induced thrombotic microangiopathy**

Drugs may cause a thrombotic microangiopathy (TMA) that closely resembles TTP or HUS.<sup>190</sup> Two general mechanisms for drug-induced TMA include immune (idiosyncratic, non-dose-dependent) and toxic (dose-dependent) etiologies. Immune-mediated drug-induced TMA is caused by quinine,<sup>191</sup> with endothelium and other target cells affected by quinine-dependent antibodies. Paradoxically, immune-mediated TMA may be caused by the antiplatelet agents ticlopidine<sup>192</sup> and clopidogrel.<sup>193</sup> Ticlopidine-induced TTP is estimated to occur in 1 in 2000–5000 patients who receive this drug after coronary stenting. The characteristic onset is between one and eight weeks after administration of the drug is started. Clopidogrel-induced TTP occurs in approximately 1 in 20,000 recipients, generally within the first two weeks of treatment. Autoantibodies to von Willebrand factor-cleaving metalloproteinase have been identified in these patients and may contribute to the pathogenesis.<sup>194</sup>

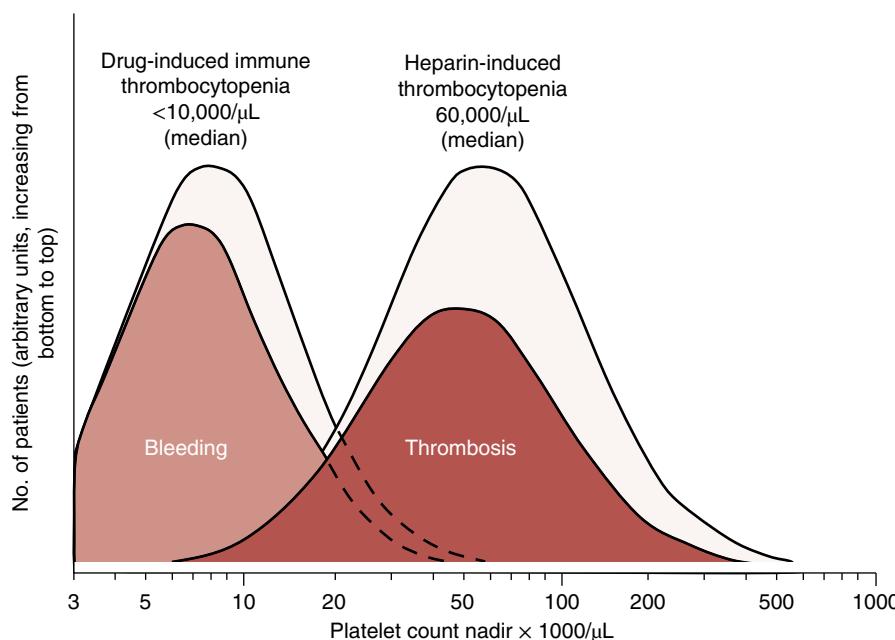

Other drugs that cause an illness that resembles HUS due to toxic effects include antineoplastic agents (e.g., gemcitabine, mitomycin C, cisplatin, bleomycin, and proteasome inhibitors such as carfilzomib,<sup>195</sup> ixazomib,<sup>196</sup> and bortezomib<sup>196</sup> used to treat multiple

myeloma) and immunosuppressive agents (e.g., cyclosporine and tacrolimus). Because some of the medical conditions leading to use of these drugs can be associated with microangiopathic blood film changes (neoplasia, organ rejection, graft-vs.-host disease, and vasculitis), causal relationships to the various drugs listed can be problematic.

The mortality of drug-induced TMA is high. Early recognition and discontinuation of the drug are essential. Response to plasma exchange is usually poor, particularly if ADAMTS13 levels are not severely reduced. Many physicians would also give corticosteroids, although the efficacy remains unproven. Specific therapy for drug-induced HUS (corticosteroids, eculizumab) is individualized depending on the clinical situation. The prognosis is poor for drug-induced TTP in the setting of hematopoietic stem cell transplantation (HSCT).

#### **Heparin-induced thrombocytopenia**

Heparin-induced thrombocytopenia (HIT) is a relatively common, IgG-mediated, adverse reaction to heparin that has a strong association with venous and arterial thrombosis.<sup>4–6,197,198</sup> HIT is a clinicopathologic syndrome, that is, the diagnosis is made most reliably on both clinical and serologic grounds.<sup>198–200</sup> Thus, HIT antibody formation without thrombocytopenia or other abnormalities is not HIT, whereas HIT antibody formation accompanied by an otherwise unexplained 50% or greater postoperative decrease in platelet count (even if the platelet count remains greater than 150,000/ $\mu$ L)<sup>5</sup> or complicated by necrotizing skin lesions at heparin injection sites<sup>197</sup> are examples of HIT syndrome. Indeed, the thrombocytopenia usually is much less severe in HIT<sup>6</sup> than in DITP<sup>176</sup> or GPIIb/IIIa antagonist-induced thrombocytopenia<sup>181</sup> (Figure 36.2). Another contrast from DITP is that even when severe thrombocytopenia occurs in HIT, petechiae and other types of bleeding typically are not observed.<sup>197,201</sup> Indeed, even the one characteristic hemorrhagic complication of HIT—bilateral adrenal hemorrhage—is caused by thrombosis (adrenal vein thrombosis leading to hemorrhagic necrosis).<sup>197</sup> HIT is an antibody-mediated disorder, and a minimum of five days is required for an immunizing exposure

**Figure 36.2** Platelet count nadirs ( $\log_{10}$  scale) and clinical profile of classic drug-induced immune thrombocytopenic purpura (DITP) and heparin-induced thrombocytopenia (HIT). Classic DITP (e.g., caused by quinine, vancomycin, or glycoprotein IIb/IIIa antagonists, among many others) typically produces severe thrombocytopenia (platelet count nadir, ~10,000/ $\mu$ L) and associated mucocutaneous bleeding. In contrast, HIT typically results in mild to moderate thrombocytopenia (median platelet count nadir, ~60,000/ $\mu$ L) and associated venous or arterial thrombosis. Note that the relative heights of the two peaks are not drawn to scale; HIT is much more common than all other causes of DITP combined. Source: Warkentin (2007).<sup>6</sup> Reproduced with permission of Massachusetts Medical Society.

to heparin to generate sufficient levels of antibodies to cause thrombocytopenia.<sup>202</sup>

Sometimes, onset of thrombocytopenia and thrombosis begins—or worsens—after all heparin has been stopped (“delayed-onset” or “autoimmune-like” HIT),<sup>203–205</sup> in some of these patients, thrombocytopenia and thrombosis risk persist for several weeks (“persistent” or “refractory” HIT).<sup>206,207</sup> Occasionally, small amounts of heparin (“flushes”) are implicated.<sup>208</sup> Some patients who have not previously been exposed to heparin will develop abrupt onset of thrombocytopenia, thrombosis and have detectable platelet-activating anti-PF4/heparin antibodies; such patients with so-called “spontaneous HIT syndrome”<sup>209–211</sup> have often had recent infection<sup>212,213</sup> or surgery, particularly, knee replacement surgery.<sup>214–216</sup> It is now recognized that such atypical clinical pictures of HIT—now named “autoimmune HIT” [aHIT]<sup>210</sup>—are explained by anti-PF4/polyanion antibodies that are able to strongly activate platelets in vitro and in vivo even in the absence of heparin (“heparin-independent platelet activation”). As discussed later, there are special treatment considerations for such patients, most notably, adjunctive therapy with high-dose intravenous immunoglobulin (IVIG).

The target antigen recognized by HIT antibodies consists of a multimolecular complex between PF4 (a platelet  $\alpha$ -granule protein of the CXC family of chemokines) and heparin.<sup>32</sup> The HIT antibodies bind to one or more PF4 regions that have undergone conformational modification through binding to heparin. The formation of the antigen is somewhat nonspecific because PF4 can be rendered antigenic by binding to certain other polyanions, such as pentosan polysulfate or polyvinylsulfonate.<sup>33</sup> At least 12–14 saccharide units are needed for heparin to form the antigen complex with PF4. This may explain why LMW heparin preparations are less immunogenic than unfractionated heparin and are less likely to cause HIT.<sup>4,5</sup> Although LMW heparin sometimes causes HIT, it is likely that very small heparin preparations (e.g., fondaparinux, a synthetic antifactor Xa-binding pentasaccharide) or specially engineered heparins (e.g., highly sulfated heparin moieties bridged with nonsulfated spacer regions) only rarely cause HIT.<sup>217,218</sup>

Figure 36.3 illustrates several possible mechanisms to explain the intense thrombin generation that occurs in HIT.<sup>219</sup> These include an important role for the classic complement pathway both in triggering the HIT immune response (by facilitating binding of PF4/heparin/natural IgM complexes to B lymphocytes)<sup>220,221</sup> as well as in facilitating activation by HIT antibodies of cells other than platelets.<sup>222</sup> Further, platelet-activating anti-PF4/heparin antibodies induce formation of procoagulant, platelet-derived microparticles<sup>223</sup> that result from cell signaling triggered by clustering of platelet Fc $\gamma$ RIIa. Recent data suggest that in situ formation of IgG/PF4/heparin complexes on the platelet surface leads to progressive platelet activation.<sup>224</sup> In vivo platelet activation is indicated by expression of P-selectin by circulating platelets in HIT.<sup>225</sup> Tissue factor expression by endothelium<sup>226,227</sup> or monocytes<sup>228,229</sup> activated by HIT antibodies that recognize PF4 bound to surface glycosaminoglycans, as well as HIT antibody-induced neutrophil activation and release of procoagulant neutrophil intracellular nets (“NETosis”),<sup>230,231</sup> constitute other potential procoagulant events. Endothelial injury with release of von Willebrand factor “strings” that bind PF4 helps to localize prothrombotic events to endothelium.<sup>232</sup>

Marked in vivo thrombin generation helps explain several clinical features of HIT, including its association with venous and arterial thrombosis (hypercoagulable state), the occurrence of decompensated disseminated intravascular coagulation (DIC) with low fibrinogen levels and/or elevated prothrombin time in

approximately 10–20% of patients, and the potential for deep vein thrombosis (DVT) to progress to venous limb gangrene, particularly in patients treated with warfarin.<sup>233</sup> This last syndrome results from impaired procoagulant–anticoagulant balance: Warfarin-induced protein C depletion leads to microvascular thrombosis caused by ongoing intense thrombin generation. Patients with warfarin-induced venous gangrene typically have a supratherapeutic international normalized ratio (INR), usually more than 3.5. The explanation is a concomitant severe decrease in factor VII that parallels the decrease in protein C. The importance of in vivo thrombin generation in HIT provides a rationale for consensus recommendations that an agent that reduces thrombin generation or directly inactivates thrombin be used for the management of this syndrome.<sup>234,235</sup>

The frequency of HIT varies among different patient populations. Medical patients appear to develop HIT less often than do surgical patients, and female gender is a minor risk factor for HIT.<sup>236</sup> The frequency of HIT can be as high as 5% when multiple risk factors are present (thromboprophylaxis with unfractionated heparin administered for two weeks to a female patient following major surgery), whereas the risk is very low or negligible in other settings (e.g., administration of LMW heparin during pregnancy).<sup>4,5,237</sup>

### **Iceberg model of HIT**

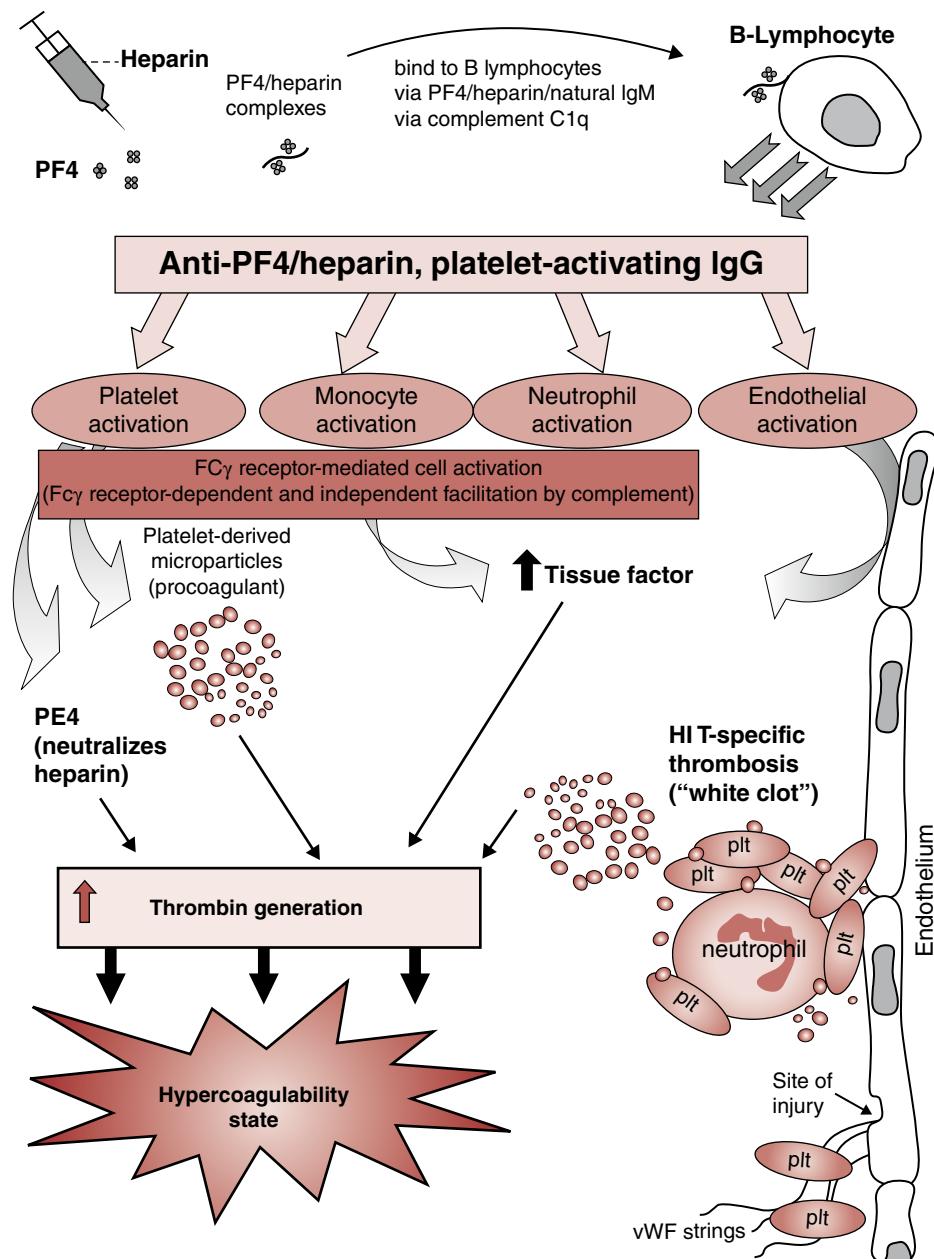

Figure 36.4 illustrates the relation between clinical HIT and detectability of anti-PF4/heparin antibodies by either washed platelet activation assay or PF4-dependent EIA.<sup>234</sup> The key concept is that whereas both types of assays have high sensitivity for diagnosis of clinical HIT, the former assay has greater diagnostic specificity. It is estimated that substantial overdiagnosis (~50%) of HIT will result<sup>238</sup> if a positive EIA of any magnitude is considered diagnostic of HIT irrespective of the patient’s clinical likelihood of HIT, as judged using a clinical scoring system (the 4Ts)<sup>239</sup> and the gold standard assay (platelet SRA).

### **Heparin-independent platelet-activating antibodies**

US reference laboratories that perform the SRA usually use the assay at low (0.1–0.5 U/mL heparin) and high heparin (100 U/mL heparin) concentrations;<sup>240</sup> a positive result is indicated when HIT patient serum produces serotonin-release at low, but not at high, heparin concentration.<sup>241</sup> However, by performing the SRA also in the absence of heparin (0 U/mL heparin, i.e., “buffer control”), the lab can determine if the HIT antibodies have heparin-“independent” platelet-activating properties, an important serological feature pointing to an aHIT disorder (delayed-onset HIT, persisting HIT, etc.).<sup>203,208,210,240</sup> As discussed in the following section, high-dose IVIG is an important treatment for patients who have a severe aHIT syndrome.

### **Management of heparin-induced thrombocytopenia-associated thrombosis**

*High-dose IVIG* is increasingly used as adjunctive treatment (along with anticoagulation) for HIT, especially severe aHIT.<sup>242</sup> The usual dose is 1 g/kg for two consecutive days (i.e., 2 g/kg total dose); the treatment appears to rapidly raise the platelet count and reduce hypercoagulability.<sup>242</sup> IVIG works through competitive inhibition of HIT antibody-induced platelet activation through the platelet Fc $\gamma$ IIa receptors; accordingly, there is no change in EIA reactivity, but blood samples obtained after IVIG treatment may show a negative SRA.<sup>243,244</sup> High-dose IVIG may also be effective in passivating the effect of HIT antibodies in situations of deliberate heparin rechallenge in patients who have heparin-dependent

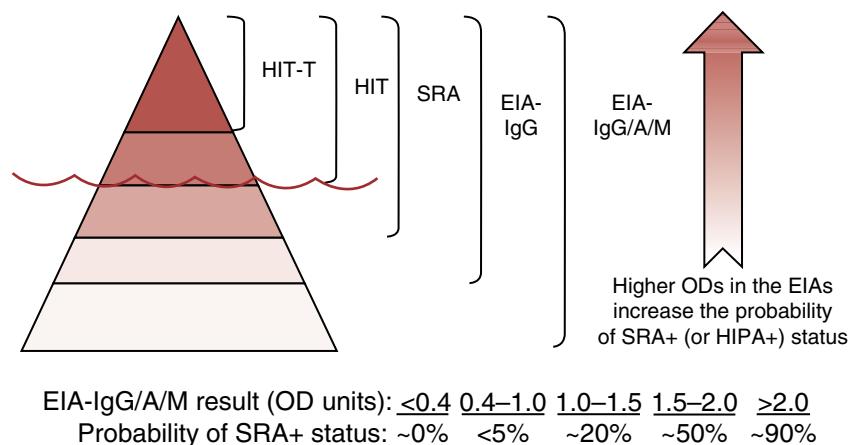

**Figure 36.3** Pathogenesis of heparin-induced thrombocytopenia. Ultralarge PF4/heparin complexes, interacting with natural IgM and complement, stimulate B-lymphocyte activation and subsequent formation of anti-PF4/heparin antibodies that, when platelet-activating, have the potential to cause HIT. Platelet activation by PF4/heparin/IgG complexes, mediated through platelet Fc $\gamma$ IIa receptors, results in thrombin generation, e.g., through platelet-derived procoagulant microparticles and PF4 neutralization of heparin's anticoagulant effects. "Pancellular" activation indicates activation of cells other than platelets, including monocytes, neutrophils, and endothelium. Recently, a role of the classic complement pathway in facilitating downstream cellular activation has been identified. Activated monocytes and endothelium express tissue factor; activated neutrophils release procoagulant "neutrophil extracellular traps" (NETs), a process known as "NETosis." PF4 binds to DNA within NETs, further promoting platelet activation. Release of von Willebrand factor (vWF) strings from injured endothelium binds PF4, further directing HIT-related prothrombotic effects to these vascular sites. These multifaceted pathological effects are responsible for the marked prothrombotic risk of HIT, which can involve large veins and arteries, as well as small vessels (microvascular thrombosis).

platelet-activating antibodies (e.g., because of recent HIT), e.g., for urgent vascular or cardiac surgery.<sup>245,246</sup>

Results of prospective and retrospective studies<sup>4,5,201</sup> indicate that approximately 50–75% of patients with HIT have new, progressive, or recurrent thrombosis (relative risk of thrombosis is ~12).<sup>247</sup> Thus, the need for an alternative anticoagulant is a common issue in the care of these patients.

**Argatroban** is a small-molecule DTI approved in the United States for the management and prevention of HIT-associated thrombosis.<sup>235,248</sup> Features of argatroban include its short half-life (40–50 minutes) as well as its hepatic route of metabolism. No dose adjustments are needed for patients with moderate renal failure, although dose reduction is needed in the presence of hepatic insufficiency. Anticoagulant monitoring is usually performed using the

**Figure 36.4** “Iceberg model” of HIT. Clinical HIT, comprising HIT with (HIT-T) or without thrombosis (HIT), is represented by the portion of the iceberg above the waterline; the portion below the waterline represents subclinical anti-PF4/H seroconversion. Three types of assays are highly sensitive for the diagnosis of HIT: the washed platelet activation assay (e.g., the serotonin-release assay [SRA], heparin-induced platelet activation [HIPA] test, or P-selectin expression assay [PEA; not shown]), the IgG-specific PF4-dependent EIAs (EIA-IgG), and the polyclonal EIAs that detect anti-PF4/H antibodies of the three major immunoglobulin classes (EIA-IgG/A/M). In contrast, diagnostic specificity greatly varies among these assays, being the highest for the SRA and lowest for the EIA-IgG/A/M. The approximate probability of SRA+ status in relation to a given EIA result, expressed in OD units, was obtained from the literature. With permission from Warkentin (2011).<sup>234</sup>

aPTT; although simple, aPTT monitoring can result in systematic underdosing of argatroban in patients with baseline (pretreatment) elevation in aPTT, for example because of severe HIT-associated DIC (“aPTT confounding”).<sup>249,250</sup> Argatroban also prolongs the INR,<sup>251,252</sup> which complicates the transition from argatroban to warfarin therapy. It is important to postpone introduction of warfarin until the thrombocytopenia has substantially recovered (platelet count at least 150,000/ $\mu$ L).<sup>235</sup>

**Bivalirudin** is an oligopeptide (20 amino acid) analog of hirudin, i.e., a DTI.<sup>252–254</sup> Bivalirudin is widely used for anticoagulation during percutaneous coronary intervention and is also approved for this indication in patients with HIT. It is sometimes used “off-label” for treatment of HIT, especially in critically ill patients. Its half-life is short (~25 min); bivalirudin is eliminated primarily through nonorgan metabolism (proteolysis), with minor renal elimination (~20%). As with argatroban, aPTT confounding can occur when treating patients with severe HIT-associated DIC.

**Danaparoid sodium** is a mixture of anticoagulant glycosaminoglycans with predominant antifactor Xa activity that decreases thrombin generation in patients with HIT.<sup>255</sup> A randomized trial showed a higher thrombosis resolution rate among patients treated with danaparoid and warfarin than among those treated with dextran and warfarin, especially for patients with severe thrombosis (92% vs. 33%;  $p < 0.001$ ).<sup>256</sup> Although some HIT sera show in vitro crossreactivity with danaparoid (i.e., enhanced platelet activation in the presence of danaparoid), this effect is usually weak; moreover, platelet-activating effects of many HIT sera are inhibited by danaparoid at therapeutic concentrations.<sup>257</sup> Because in vitro crossreactivity is not predictive of adverse outcome,<sup>255</sup> danaparoid should be given without preceding in vitro testing for crossreactivity. The success rate is high (approximately 85–90%), as defined by platelet count recovery without new thrombosis.<sup>255,258</sup> The anticoagulant effect of danaparoid is monitored with a chromogenic antifactor Xa assay, which must be performed using a standard curve prepared with danaparoid. The target range is generally 0.5–0.8 antifactor Xa U/mL, although levels of 1.0 U/mL or higher are used by some in the treatment of patients with severe thrombosis. Recommended

therapeutic dosing includes an initial intravenous bolus followed by continuous infusion (usually 200 U/hour with monitoring of antifactor Xa levels, if available). Danaparoid does not interfere with INR measurements. This is an advantage in the care of patients with venous thromboembolism in whom overlapping warfarin anticoagulation is usually performed after resolution of thrombocytopenia. Danaparoid is approved therapy for HIT in the European Union, Canada, and elsewhere, but it is neither approved for HIT management nor currently available in the United States.

**Fondaparinux** is a synthetic pentasaccharide anticoagulant modeled after the antithrombin-binding region of heparin; it has exclusive antifactor Xa activity. Although fondaparinux is associated with the formation of anti-PF4/H antibodies at a frequency similar to that seen with LMW heparin, it is uncommon for fondaparinux to increase platelet activation by HIT antibodies (i.e., it has a low frequency of in vivo “crossreactivity”).<sup>259</sup> Although not approved to treat HIT, fondaparinux is frequently used “off-label” for the treatment of HIT with or without thrombosis.<sup>260</sup> Indeed, observational studies of patients with well-characterized HIT suggest a high success rate (at least 90%) with fondaparinux.<sup>218,261–263</sup> Anticoagulant monitoring is not required, and thus the aforementioned problem of “aPTT confounding” seen with DTIs such as argatroban is not seen with fondaparinux.<sup>234</sup>

There are several important contraindications to therapy for acute HIT, including warfarin monotherapy and LMW heparin.<sup>235</sup> Warfarin therapy can lead to acute depletion of protein C, which can cause microvascular thrombosis in HIT and lead to venous limb gangrene.<sup>233</sup> However, once thrombocytopenia has resolved completely, it is reasonable to overlap warfarin cautiously with one of the agents that can reduce thrombin generation in HIT (danaparoid, fondaparinux, and argatroban). Alternatively, one can transition to a direct oral anticoagulant (DOAC; discussed subsequently). Use of LMW heparin is contraindicated because of a high chance of treatment failure (approximately 50% of patients have further thrombocytopenia or thrombosis). Prophylactic platelet transfusion is relatively contraindicated because even patients with severe thrombocytopenia do not usually have evidence of hemostatic

dysfunction, such as petechiae, and platelet transfusions theoretically may contribute to increased risk of thrombosis. It should be noted that one database study<sup>264</sup> that suggested greater risk of arterial thrombosis with platelet transfusion in HIT is methodologically flawed in that it could not account for severe thrombocytopenia per se as independent explanations for both greater risk of thrombosis as well as for platelet transfusion. Other observational studies have not found evidence to suggest that platelet transfusion in HIT is associated with thrombotic events.<sup>265,266</sup>

DOACs such as Xa inhibitors (rivaroxaban and apixaban) are increasingly used to treat HIT, either as primary therapy or by way of transition from initial therapy with a parenteral agent (e.g., DTI, fondaparinux, and danaparoid).<sup>235,267</sup> They may be especially helpful in patients with aHIT disorders as there is no risk of aPTT confounding.<sup>240,250</sup>

### **Management of isolated heparin-induced thrombocytopenia**

Isolated HIT is defined as HIT that is recognized because of thrombocytopenia without evidence of HIT-associated thrombosis.<sup>201</sup> Unfortunately, simply stopping administration of heparin or substituting warfarin for heparin is inadequate treatment for these patients. In a retrospective cohort study,<sup>201</sup> the risk of thrombosis among these patients was approximately 10% at two days, 40% at seven days, and 53% at 30-day follow-up evaluations. Other investigators<sup>268</sup> with a similar approach subsequently found a 38% rate of thrombotic events despite stopping administration of heparin. The frequency of thrombosis surprisingly was not any lower in the subgroup of patients for whom heparin was stopped fairly promptly (<48 hours) after the onset of thrombocytopenia than it was among patients with later cessation of heparin (45% vs. 34%;  $p = 0.26$ ).

For patients strongly suspected (or confirmed) to have isolated HIT, the authors discontinue heparin, start administration of an alternative rapidly acting anticoagulant, and screen for subclinical DVT by means of compression ultrasonography (approximately 50% of patients are shown to have DVT with this approach). Whether or not thrombosis is found, a therapeutic dose of anticoagulant is given to these patients. This is because prophylactic-dose anticoagulation appears to have a higher failure rate than does therapeutic-dose anticoagulation.<sup>258</sup> After platelet count recovery, the absence of venous thrombosis is confirmed before discharge. For patients found at initial or follow-up imaging to have venous thrombosis, overlapping warfarin anticoagulation is usually begun for longer term antithrombotic control, although as previously mentioned transition to a DOAC is increasingly performed.

### **Re-exposure to heparin in a patient with a history of heparin-induced thrombocytopenia**

Patients who have circulating HIT antibodies can have an abrupt decrease in platelet count if heparin is administered. However, the risk of such abrupt-onset HIT on re-exposure to heparin is restricted to the first few months after use of heparin. This is because HIT antibodies begin to decline after heparin is discontinued, and usually they are no longer detectable by the three-month follow-up evaluation.<sup>269</sup> Under exceptional circumstances (e.g., need to perform heart or vascular surgery), it is recommended to readminister heparin to a patient with previous HIT, provided that HIT antibodies are no longer detectable with a sensitive and reliable assay (e.g., SRA or PF4-dependent EIA).<sup>235,270,271</sup> Such patients often do not form HIT antibodies after the brief re-exposure to heparin, and if they do, these antibodies are not formed before Day 5. Nevertheless,

it seems prudent to limit the heparin re-exposure to the operation itself and to use an alternative anticoagulant for perioperative anti-coagulation, and also to perform platelet count monitoring for HIT for up to 10 days.

For patients who require heart or vascular surgery who still have circulating platelet-activating HIT antibodies, there is uncertainty about optimal management. Sometimes nonheparin anticoagulation is administered (e.g., bivalirudin),<sup>235</sup> but others prefer to remove HIT antibodies through plasma exchange and then administer heparin, and still others administer high-dose IVIG to passivate the effect of residual HIT antibodies prior to using heparin.<sup>245,246</sup>

### **Vaccine-induced immune thrombotic thrombocytopenia**

Rarely, adenoviral vector vaccines (ChAdOx1 nCoV-19 [Oxford-AstraZeneca]; Ad26.COV2 [Johnson & Johnson/Janssen]) used for the prevention of severe coronavirus disease 2019 (COVID-19) can cause a prothrombotic disorder characterized by oftentimes unusual, severe, or multiple thrombotic events (e.g., cerebral venous sinus thrombosis, splanchnic vein thrombosis, aortic and limb artery thrombosis, and venous thromboembolism), thrombocytopenia (often severe), and hypercoagulability (elevated d-dimer levels and hypofibrinogenemia), with high mortality.<sup>272–275</sup> Named “vaccine-induced immune thrombotic thrombocytopenia” (VITT) (an alternate designation is “thrombosis with thrombocytopenia syndrome” [TTS]), two features strongly implicate preceding vaccination as its trigger: (a) characteristic timing, with onset of symptomatic thrombosis between 5 and 30 days (occasionally later) postvaccination (day 0 = day of vaccination) and (b) (usually) strong-positive EIA for anti-PF4 antibodies plus positive platelet activation testing (especially when PF4 is supplemented in the assay), despite absence of proximate heparin exposure. Moreover, as seen in HIT, the VITT antibodies activate platelets through their FcγIIa receptors. Unlike in HIT, however, rapid HIT immunoassays (e.g., latex-enhanced and chemiluminescence) usually yield negative results.<sup>276,277</sup> It is not known how the vaccines trigger a strong platelet-activating immune response against PF4, but crossreactivity of antibodies reactive against anti-COVID-19 “spike protein” (the immune response triggered by COVID-19 vaccines) and PF4 is not likely;<sup>278</sup> rather, PF4-binding components within the vaccine are possible.<sup>279</sup>

Treatment of VITT includes upfront high-dose IVIG (1 g/kg for two consecutive days) and anticoagulation.<sup>280,281</sup> Although nonheparin anticoagulation (e.g., fondaparinux, DOAC, and DTI) is generally recommended (given the strong clinical and serological resemblance to severe aHIT), it seems likely that heparin is also effective, based upon (a) frequent in vitro inhibition of VITT serum-induced platelet activation by heparin, (b) platelet count improvement with heparin treatment seen anecdotally, and (c) the intriguing observation that VITT antibodies recognize the heparin binding site on PF4.<sup>282</sup>

### **Alloimmune thrombocytopenia**

Alloantigens are genetically determined molecular variations of proteins or carbohydrates that can be recognized immunologically by some healthy persons. Exposure to alloantigens occurs during pregnancy, transfusion, or transplantation. If alloantibodies form against platelet alloantigens, alloimmune thrombocytopenia can result from platelet clearance mediated by the reticuloendothelial system. Five alloimmune thrombocytopenic disorders have been described (Table 36.3),<sup>283</sup> the most common being neonatal alloimmune thrombocytopenia (NAIT).

**Table 36.3** Five Alloimmune Thrombocytopenic Syndromes**Classical Alloimmune Thrombocytopenic Syndromes**

**Alloantigens**

More than 30 platelet alloantigens have been identified.<sup>283–285</sup> Table 36.4 classifies the platelet alloantigens by glycoprotein localization and gene frequency, the latter divided into public and private (or low frequency, arbitrarily less than 0.02). A database of genetically confirmed alloantigens is maintained by the European Bioinformatics Institute with 29 antigens in the current list (<http://www.ebi.ac.uk>) and a database of 35 HPA polymorphisms and references is listed on the Versiti (Milwaukee, WI) website (<https://www.versiti.org/medical-professionals/precision-medicine-expertise/platelet-antigen-database/hpa-gene-database>).

More than one-half of the alloantigens that have been identified are located on one of the two glycoproteins that constitute the GPIIb/IIIa complex (platelet fibrinogen receptor). One of these alloantigens, HPA-1a (previously, Pl<sup>A1</sup>), is located on GPIIIa. It is responsible for most alloimmune thrombocytopenia in populations of European ancestry, including almost all patients with severe alloimmune thrombocytopenia. In contrast, the other major platelet glycoprotein complex (GPIb/IX, von Willebrand-factor-binding complex) is rarely implicated in alloimmune thrombocytopenia. However, the GPIa/IIa complex (platelet collagen receptor), which bears the HPA-5a/5b (Br<sup>a/b</sup>; Zav<sup>a/b</sup>) alloantigen system, is a relatively common cause of moderately severe alloimmune thrombocytopenia.<sup>286,287</sup> The HPA-15a/15b (Gov<sup>a/b</sup>) alloantigen system is expressed on CD109. It has been shown to be a relatively common cause of alloimmune thrombocytopenia that, like HPA-5a/5b, tends not to be severe.<sup>288</sup>

**Immunogenetics and frequency of alloimmune thrombocytopenia**

The HPA-1a alloantigen is far more immunogenic than its corresponding allele, HPA-1b. For example, consider the frequency of NAIT caused by either anti-HPA-1a or anti-HPA-1b alloantibodies

**Table 36.4** Platelet Antigens Classified According to Glycoprotein Location and Gene Frequency

Platelet-Specific Alloantigen (Alternative Nomenclature)	GP	Gene Frequency in Whites	NAIT	PTP	PAT	TAT	PTR

in relation to the genotype frequency of HPA-1a (0.85) and HPA-1b (0.15). Thus, a homozygous HPA-1bb (Pl<sup>A1</sup>-negative) female, representing approximately 2% ( $0.15 \times 0.15$ ) of the population, would have an 85% probability of being exposed to the HPA-1a alloantigen during pregnancy. In contrast, a homozygous HPA-1aa female, representing approximately 72% ( $0.85 \times 0.85$ ) of the population, would have a 15% probability of being exposed to the HPA-1b alloantigen during pregnancy. Thus, if both alloantigens were equally immunogenic, one would expect anti-HPA-1b to occur approximately six times more often than anti-HPA-1a:  $(0.72 \times 0.15)/(0.02 \times 0.85) = 6.4$ . However, the *opposite* is actually observed: anti-HPA-1a is far more common than anti-HPA-1b (Table 36.5).<sup>286,289</sup> In a classic study of 348 cases of suspected NAIT,<sup>286</sup> only one case caused by anti-HPA-1b was found, compared with 144 cases of proven or suspected NAIT secondary to anti-HPA-1a. Thus, the observed ratio of NAIT caused by anti-HPA-1a/anti-HPA-1b (1:144 or 0.007) is almost 1000 times less than predicted by the theoretical ratio (6.4).

Immunogenetics is a major factor determining alloimmunization against HPA-1a. There is a strong association between formation of anti-HPA-1a and *HLA-DRB3\*0101* and *HLA-DQB1\*0201* (odds ratio, 25 and 40, respectively).<sup>290</sup> A recent meta-analysis<sup>291</sup> confirmed the strong role of *HLA-DRB3\*0101* in predicting for NAIT in HPA-1a negative women. Although the presence of *HLA-DRB3\*0101* predicts for immunization to HPA-1a, there is no association of gene dose with ICH and severity of the thrombocytopenia.<sup>292</sup> In contrast, no HLA association exists for immunization against HPA-1b.<sup>293</sup> Thus, it appears that persons with certain HLA genotypes are much more likely to generate an alloimmune response when GPIIa bears the leucine<sup>33</sup> substitution that determines the HPA-1a phenotype.

Overall, on the basis of the observed allelic frequencies, the expected theoretical ratio of NAIT for anti-HPA-5b, compared with anti-HPA-5a, should be approximately 8 (Table 36.5). A similar ratio (47:3 or 15.7) has been observed. However, although the expected and observed ratios are similar (contrasting the HPA-1a/1b system), a role for immunogenetics and alloimmunization also exists for the HPA-5a/5b system.<sup>294</sup>

**Table 36.5** Observed Frequencies of Neonatal Alloimmune Thrombocytopenia and Post-transfusion Purpura in Relation to Expected (Theoretic) Frequency of the HPA-1ab (Pl<sup>A1/A2</sup>), HPA-5ab (Br<sup>a/b</sup>), and HPA-3ab (Bak<sup>a/b</sup>) Alloantigen Systems

Target Alloantigen	Percentage of Pregnancies at Theoretic Risk of NAIT <sup>†</sup> (Descending Order)	Observed Cases of NAIT <sup>‡</sup>	Observed Cases of PTP <sup>§</sup>
HPA-3b	14.5	0	0
HPA-1b	10.8	0	29
HPA-3a	9.3	1	9
HPA-5b	8.7	6	11
HPA-1a	1.9	44	105
HPA-5a	1.1	0	7

<sup>†</sup> Percentage of pregnancies at theoretic risk of NAIT for a given target alloantigen is determined as follows:

$x(1 - x)^2 \times 100$ , where  $x$  is the gene frequency of the target alloantigen. Note the lack of correlation between the theoretical and observed risk for NAIT.

<sup>‡</sup> Data are from Mueller-Eckhardt et al.,<sup>192</sup> and represent serologic investigations using a defined protocol over an 18-month period ending 30 June 1988.

<sup>§</sup> For comparison, the serologic findings for cases of PTP are shown for which only one platelet alloantigen specificity was identified (from January 1990 to August 2006 at the Blood Center of Wisconsin).<sup>289</sup>

## Severity of alloimmune thrombocytopenia

In general, the severity of thrombocytopenia is greater for alloimmune thrombocytopenia that involves the GPIIb/IIIa complex, compared with the GPIa/IIa complex (Table 36.6).<sup>283,286,289,295</sup> Because there are approximately 20 times more GPIIb/IIIa molecules compared with GPIa/IIa complexes on the platelet surface (40,000 vs. 2000), this suggests that greater numbers of alloantibodies binding to the more numerous GPIIb/IIIa receptors result in greater platelet destruction. Similarly, thrombocytopenia is less severe when alloimmunization is to HPA-15 on CD109 (2000 receptors).<sup>296</sup>

## Neonatal alloimmune thrombocytopenia

NAIT is a transient but potentially life-threatening thrombocytopenic disorder limited to fetal and neonatal life. It is caused by maternal IgG alloantibodies that cross the placenta and cause premature destruction of platelets bearing paternally derived platelet alloantigens (analogous to hemolytic disease of the fetus and newborn). NAIT occurs in approximately 1–1.5 per 1000 live births.<sup>297</sup>

Approximately 75% of cases in a population of European ancestry are caused by fetomaternal incompatibility for the platelet-specific alloantigen HPA-1a and 20% by HPA-5b.<sup>286</sup> Other alloantigens implicated in NAIT, including private alloantigens identified in only one or a few families (e.g., HPA6b [Tu<sup>a</sup>/Ca] and HPA-7b [Mo<sup>a</sup>]), are shown in Table 36.4. In East Asian populations, anti-HPA-4b (Pen<sup>b</sup>) is more common than anti-HPA-1a. Although HLA or ABO alloantibodies have been claimed to cause NAIT,<sup>298,299</sup> in most cases, undetected platelet-specific alloantibodies or another diagnosis caused the thrombocytopenia.<sup>300</sup> The role of anti-HLA was specifically examined in a study of 144 cases of NAIT, and it was found that the presence of maternal anti-HLA class I antibodies was not associated with neonatal platelet count or morbidity. The authors concluded that presence of anti-HLA antibodies is not a risk factor for NAIT.<sup>301</sup>

The typical clinical presentation of NAIT is isolated severe thrombocytopenia in an otherwise healthy neonate, especially if fetomaternal incompatibility involves an alloantigen on the GPIIb/IIIa complex (Table 36.6). Petechiae are found in 90%; gastrointestinal tract hemorrhage in 30%; and hemoptysis, hematuria, and retinal bleeding in fewer than 10% of patients. Isolated intraocular hemorrhage is rare.<sup>302</sup> Approximately 15% have intracranial hemorrhage.<sup>286</sup> The thrombocytopenia usually resolves within 1–3 weeks. Serious sequelae of fetal and neonatal intracranial bleeding include hydrocephalus, porencephalic cysts, and epilepsy. First-born offspring constitute approximately one-half of patients. This suggests that, unlike the situation for Rh-hemolytic disease of the fetus and newborn, sensitization can occur early during the first pregnancy.<sup>286</sup> Subsequently affected siblings usually have thrombocytopenia to a similar or greater extent, an observation used to emphasize preventive treatment in subsequent pregnancies. In the case of heterozygous fathers of affected children, an antigen risk assessment should be performed using fetal cells (obtained through amniocentesis) or cell-free fetal DNA (obtained from maternal blood)<sup>303</sup> in future pregnancies.

Laboratory investigation of suspected NAIT involves three steps. First, there must be a high index of suspicion: isolated thrombocytopenia in an otherwise well infant should be assumed to indicate NAIT until proved otherwise. The second step is to type maternal and paternal platelets to determine whether they are incompatible for a major platelet alloantigen. Commonly, the mother lacks

The data show that alloimmune thrombocytopenic syndromes that involve GPIIb/IIIa are more likely to cause severe thrombocytopenia than are those involving GPIa/IIa. The data are combined for alloimmune thrombocytopenic syndromes involving either allele of the HPA-3ab and HPA-4ab alloantigen systems, whereas the data are shown separately for the alleles of the HPA-1ab and HPA-5ab systems.

NAIT: neonatal alloimmune thrombocytopenia; PTP: post-transfusion purpura; PAT: passive alloimmune thrombocytopenia; TAT: transplantation-associated alloimmune thrombocytopenia.

certain platelet alloantigens that are often associated with alloimmune thrombocytopenia; for example, maternal homozygous HPA-1bb (PI<sup>A1</sup>-negative) status confers risk of NAIT caused by anti-HPA-1a. The third step is to determine whether the mother has platelet alloantibodies in her serum. Sometimes, no alloantibodies can be detected in maternal serum despite severe neonatal thrombocytopenia. Indeed, for approximately one-fourth of HPA-1bb mothers with infants believed to have had NAIT, anti-HPA-1a cannot be detected.<sup>286</sup> Evidence for delayed appearance of anti-HPA antibodies until several weeks after birth suggests repeat testing for maternal antibodies 2–8 weeks postpartum.<sup>304</sup> The potential for low-incidence platelet-specific alloantigens to explain fetomaternal incompatibility means that maternal serum should be crossmatched with paternal platelets whenever possible. Although maternal immunization to low-frequency antigens can explain some cases of NAIT,<sup>305,306</sup> evidence from large studies indicates that low-frequency antigens account for only a minority of NAIT cases unresolved following investigations for the common HPA antigens.<sup>307</sup> Specific recommendations for the laboratory investigation of NAIT were recently presented by the Subcommittee on Platelet Immunology of the ISTH.<sup>308</sup>

Debate continues as to whether the titer of alloantibodies predicts severity of fetal thrombocytopenia. The maternal alloantibody is sometimes detectable for years following the birth of the child with NAIT. Patients with a history of NAIT must not donate blood because their plasma can trigger passive alloimmune thrombocytopenia. It is also possible that these patients may also be at risk for transfusion reactions and PTP should they receive incompatible blood products in future.

#### Neonatal treatment

The optimal treatment of a neonate in whom NAIT is suspected because of severe thrombocytopenia is to increase the platelet count urgently to safe levels, even before serologic confirmation of the diagnosis. In some centers (e.g., National Blood Service in the United Kingdom), HPA-1bb/HPA-5aa platelets can be obtained upon request; these should be effective for most patients.<sup>309</sup> When matched platelets are not available, washed and irradiated maternal platelets should be given to the neonate. These platelets are obtained by apheresis and are washed to remove the maternal alloantibodies.

Irradiation is performed to prevent graft-versus-host disease caused by maternal lymphocytes. In an emergency, immediate administration of whole-blood-derived platelets obtained from random donors may be of benefit to a bleeding infant.<sup>310,311</sup> It is uncertain if giving high-dose IVIG to the neonate increases the platelet count further beyond that of platelet transfusions.<sup>312</sup> Corticosteroids are not recommended.

#### Prenatal management

About one-half of the time, NAIT is suspected during the prenatal period, usually because the mother previously bore an affected infant, although the diagnosis sometimes is suggested in utero when fetal ultrasonography shows cerebral hemorrhage, hydrocephalus, or hydrops fetalis. One tenet of management is that thrombocytopenia in a subsequently affected offspring is generally as severe as, or more severe than, a previously affected sibling. Neonatal alloimmune thrombocytopenia caused by anti-HPA-1a is more likely to cause fetal morbidity and mortality than that caused by anti-HPA-5b and usually requires more aggressive treatment. When the father is known to be heterozygous for the implicated alloantigen (a situation that occurs approximately 25% and 20% of the time for NAIT involving the HPA-1a/b and HPA-5a/b systems, respectively), prenatal fetal typing is important, because it identifies the infant who is homozygous for the maternal antigen and is not at risk, obviating further treatment. For pregnancies at risk, general advice to the mother includes avoiding aspirin and nonsteroidal anti-inflammatory medications.

The general approaches that have been taken to manage pregnancies at high risk of severe NAIT<sup>313–315</sup> are regular administration of high-dose IVIG, repeated in-utero platelet transfusions, or both. The initial step is to obtain a fetal platelet count by means of percutaneous umbilical blood sampling, generally starting at 20–24 weeks of gestation. Because of the risk of fetal exsanguination, maternal platelets should be on hand for transfusion if the fetal platelet count is shown to be less than 50,000/ $\mu\text{L}$ . IVIG is given weekly at a dosage of 1 g/kg/week, starting within one week of documentation of fetal thrombocytopenia. Fetal blood sampling is repeated 4–6 weeks later; if no response is seen, glucocorticoid salvage treatment (prednisone, 60 mg/day) is started.<sup>313</sup> However, not all fetuses respond to this approach.

Another approach, which has been used in certain European centers, involves regular intrauterine platelet transfusions by means of percutaneous umbilical blood sampling, including a short time before delivery. This approach has led to good outcomes in situations in which previous siblings were severely affected.<sup>314</sup> However, each fetal platelet transfusion carries risk of hemorrhage and death<sup>315</sup> that likely depends on the experience of the fetomaternal unit. There is no consensus on which approach is preferred. A systematic review<sup>315</sup> concluded that noninvasive management with weekly maternal IVIG administration is generally effective without the relatively high rate of adverse outcomes seen with invasive strategies.

Regardless of the antenatal management, there is consensus that delivery should be by means of elective cesarean section, performed as soon as fetal maturity is documented. The major reason for this mode of delivery is that it allows an organized, multidisciplinary approach to the peripartum care of the newborn. This approach includes urgent determination of the cord platelet count; provision of washed, irradiated maternal platelets (or antigen-negative platelets); and, usually, the use of high-dose IVIG (1 g/kg/day for two consecutive days) to treat severe neonatal thrombocytopenia.

### **Post-transfusion purpura**

Post-transfusion purpura is a very rare disorder that typically manifests as severe thrombocytopenia and bleeding that begin 5–10 days after blood transfusion—usually red blood cells (RBCs), occasionally platelets or plasma—in a patient previously sensitized by pregnancy or transfusion.<sup>289,316</sup> In 85–95% of cases, women are affected; the median age is 52 years. The observation that previous blood transfusions can be sensitizing explains why, on occasion, males develop PTP. Sometimes the presumably sensitizing transfusion occurs only a few weeks earlier; consequently, PTP can present after just a few weeks of intermittent transfusions.<sup>289</sup>

Although thrombocytopenia usually lasts 1–4 weeks, the duration can be as short as three days<sup>317</sup> to as long as four months or more. The platelet count is usually less than 10,000/ $\mu$ L (Table 36.6). Mucocutaneous bleeding (wet purpura, petechiae, epistaxis, gastrointestinal, and urinary tract) is common, and approximately 5–10% of patients die, usually because of intracranial hemorrhage. Because effective treatments are available (discussed further in this chapter), it is important to diagnose PTP promptly to minimize morbidity and mortality. Diagnostic confusion with HIT can result because both syndromes can present 5–10 days following surgery, and sometimes PF4/heparin antibodies are present because of concomitant exposure to heparin.<sup>318–320</sup>

### **Pathogenesis**

Almost invariably, high-titer, platelet-specific alloantibodies are found in the patient's serum or plasma. Anti-HPA-1a is detected in 60% of cases, although several other platelet alloantigens have been implicated (HPA-1b, HPA-2a, HPA-2b, HPA-3a, HPA-3b, HPA-4b, HPA-5a, HPA-5b, and HPA-15b, and the isoantigen CD-36 [Nak<sup>a</sup>]).<sup>289,321</sup> Antibodies of more than one specificity (e.g., both anti-HPA-1a and HPA-2a alloantibodies)<sup>321</sup> are observed in approximately 15% of cases. As in NAIT, the HLA-DRB3\*0101 antigen is found in most HPA-1a-negative patients with PTP. As reported for NAIT, antibodies to HPA-3a may be difficult to detect in some patients with PTP.<sup>322</sup>

Although platelet-specific alloantibodies are usually identified, the pathogenesis of PTP remains obscure, and the quandary is that autologous platelets are also destroyed. The currently favored

hypothesis is that PTP represents a situation in which alloantibodies resulting from re-exposure to an incompatible platelet alloantigen have autospecificity (“pseudospecificity”). Although the platelet-specific alloantibodies are detectable for years following an episode of PTP, the autoreactive (or panreactive) antibodies are detectable only during the acute (thrombocytopenic) phase of PTP.<sup>321</sup> In keeping with this view, Taaning and Tonnesen<sup>323</sup> reported that panreactive GPIIb/IIIa antibodies are readily detected during, but not after, an episode of PTP. Kiefel *et al.*<sup>324</sup> reported that an antibody with allospecificity for HPA-1a, but not for HPA-1b, could be eluted from both autologous and donor HPA-1bb platelets that had been sensitized with acute-phase serum from a PTP patient, suggesting that use of adsorption and elution methods may help distinguish a reactivity profile of PTP sera from that seen with NAIT. One report<sup>325</sup> suggests that such alloantibodies with autoreactivity could arise spontaneously because a woman with HPA-1bb platelets and no history of blood transfusion developed “ITP” with antibodies showing specificity for HPA-1a. Cure of the thrombocytopenia by splenectomy was accompanied by disappearance of the HPA-1a-like antibodies. Studies by another group of investigators<sup>326</sup> indicate that two distinct types of antibodies—some with alloreactivity and others with autoreactivity—develop during the acute phase of PTP. Recently, an animal model was developed<sup>327</sup> in which cross-strain platelet immunization in mice commonly induces GPIIb/IIIa-specific alloantibodies combined with platelet-specific autoantibodies and varying degrees of thrombocytopenia, further supporting the view that PTP is a transient autoimmune disorder.

### **Treatment**

High-dose IVIG is the treatment of choice for PTP.<sup>316</sup> More than 90% of patients respond, attaining a platelet count greater than 100,000/ $\mu$ L in an average of four days.<sup>328</sup> Plasmapheresis may also be used. Although some physicians also give corticosteroids, this agent probably does not influence the course of disease and should be considered adjunctive rather than primary therapy.

Whole-blood-derived (unselected) platelets—which are likely to bear the HPA-1a antigen—are usually destroyed quickly, and can cause febrile or even anaphylactoid reactions. Antigen-negative platelets are the preferred component; however, the efficacy of HPA-1a-negative platelet transfusions (for patients with PTP caused by anti-HPA-1a) is also uncertain (but are appropriate to administer with life-threatening bleeding).<sup>316</sup>

For a patient who has recovered from PTP, future precautions usually include avoidance of incompatible blood components (i.e., only autologous, washed, or platelet alloantigen-compatible RBCs are given, or platelet alloantigen-compatible plasma or platelet products are given). However, PTP recurrence is uncommon even if incompatible blood is given,<sup>289</sup> possibly because residual high-titer platelet alloantibodies immediately clear the alloantigens. Patients with a history of PTP must not donate blood because their plasma can trigger passive alloimmune thrombocytopenia (PAT).

### **Passive alloimmune thrombocytopenia**

PAT is characterized by an abrupt onset of thrombocytopenia within a few hours after transfusion of a blood component, most often RBCs or plasma.<sup>283</sup> PAT is caused by the passive transfer of platelet-reactive alloantibodies in the component which rapidly clear the incompatible recipient platelets. In one study, glycoprotein-specific platelet–antibody studies confirmed that the alloantibodies were bound to the recipient's platelets *in vivo*.<sup>329</sup> Furthermore,

although the alloantibody can be detected in the blood donor's plasma, it may not be detectable in the recipient's plasma; this finding suggests that almost 100% of the transfused alloantibody binds to target platelets soon after transfusion.<sup>295,329</sup> Although anti-HPA-1a is most commonly implicated, antibodies to HPA-3a and HPA-5b have also been reported in this syndrome.<sup>283,295,329</sup> In general, the severity of bleeding parallels the degree of thrombocytopenia; thus, spontaneous mucocutaneous bleeding usually occurs only in patients with severe thrombocytopenia caused by anti-HPA-1a. The duration of thrombocytopenia is generally less than one week. It is important to investigate suspected passive alloimmune thrombocytopenia because the risk that numerous recipients can develop this syndrome means that the implicated blood donor must not donate blood in the future.

### Transplantation-associated alloimmune thrombocytopenia

In rare instances, alloimmune mechanisms explain thrombocytopenia that occurs in the setting of HSCT or transplantation of solid organs.

#### Hematopoietic transplantation

Panzer *et al.*<sup>330</sup> reported a 32-year-old man with chronic myeloid leukemia who had severe thrombocytopenia (platelet count, 17,000/ $\mu$ L) beginning 18 months after allogeneic marrow transplantation from his HLA-matched sister. High-dose IVIG produced transient increases in platelet count, and persisting remission followed splenectomy. Antibodies with HPA-1a specificity were eluted from the patient's platelets. This led to further investigations, which showed that a small number of residual, non-neoplastic lymphoid cells of host origin produced anti-HPA-1a against the HPA-1a-positive platelets formed by donor-derived megakaryocytes. Thus, host-versus-donor alloimmune thrombocytopenia resulted from mixed chimerism, in which residual host lymphoid cells derived from the HPA-1a-negative individual developed an alloimmune response against platelets derived from the engrafted HPA-1a-positive marrow.

A similar situation attributable to anti-HPA-5b after allogeneic marrow transplantation for chronic myeloid leukemia has been reported.<sup>331</sup> However, in this patient, HPA-5b alloantibodies were detectable both before and after transplantation, and the early post-transplantation thrombocytopenia gradually improved as elutable anti-HPA-5b became more difficult to detect.

#### Solid-organ transplantation

In rare instances, immunocompetent lymphoid cells within a transplanted solid organ cause alloimmune thrombocytopenia in the recipient of the organ. A dramatic scenario was reported by West *et al.*<sup>332</sup> Three organs obtained from a multiparous female donor with normal platelet counts (two kidneys and a liver) produced severe thrombocytopenia and bleeding within 5–8 days after transplantation into three separate recipients. The two recipients of renal transplants had thrombocytopenia refractory to high-dose IVIG and platelet transfusions. One of these patients died, but the other recovered after splenectomy performed 50 days after transplantation. The liver transplant recipient had organ rejection, which was accompanied by correction of the platelet count when he received a new liver allograft. HPA-1a alloantibodies were detected in the organ donor and post-transplant (but not pretransplant) recipient serum. These cases illustrate that passenger immunocompetent lymphoid cells occasionally induce severe

alloimmune thrombocytopenia when introduced into an alloincompatible recipient.

### Platelet transfusion refractoriness

Platelet transfusion refractoriness, which is failure to achieve the expected platelet increment after two consecutive platelet transfusion episodes, has several explanations (Table 36.7). Refractoriness is primarily due to anti-MHC class I antibodies produced by the recipient following multiple transfusions. However, nonimmune, patient-dependent factors are probably the most important, which means that poor platelet count recoveries can persist even when HLA alloimmunization is prevented with leukocyte-reduced blood components<sup>333</sup> and when HLA- or ABO-compatible platelets are given, especially in patients with marrow failure. High-titer anti-HLA antibodies can also account for transfusion refractoriness in perioperative settings.<sup>334</sup>

There is anecdotal evidence that platelet-specific alloantibodies sometimes cause refractoriness. However, prospective studies have shown that this is a relatively infrequent occurrence. For example, Novotny *et al.*<sup>335</sup> found that even when HLA alloantibody formation was largely prevented with blood components leukoreduced before storage, platelet-specific alloantibodies at most explained 4 of 79 (5%) cases of refractoriness. Similarly, while Wang and coworkers found anti-HLA alloantibodies in approximately 50% of patients with platelet refractoriness, only 2% had detectable platelet-specific alloantibodies.<sup>336</sup> There are occasions, however, on which the transfusion service needs to provide HLA- and platelet-specific antigen-compatible platelet products to manage some of these patients.<sup>337</sup> In one study, antibodies to HPA-15 were found in 2.3% of multiply transfused patients and were implicated in failure to obtain an adequate platelet count in one patient.<sup>338</sup> Anti-Nak<sup>a</sup> antibodies can also explain platelet transfusion refractoriness;<sup>339,340</sup> since anti-Nak<sup>a</sup> antibodies are formed by patients who are deficient in platelet GPIV (CD36), these are correctly termed *isoantibodies* rather than alloantibodies.

### Summary

A variety of platelet–antibody assays have improved the ability of the clinician to make an accurate diagnosis of immune thrombocytopenia in many diverse clinical settings that can involve pathogenic autoantibodies, alloantibodies, and drug-dependent antibodies. The treatment decisions that arise depend upon several relevant factors, including the nature of the specific diagnosis, the expected prognosis, and the presence of clinically evident bleeding or thrombosis.

**Table 36.7** General Causes of Platelet Transfusion Refractoriness, Listed in Probable Descending Order of Frequency

#### Nonimmune Mechanisms

- Septicemia, fever, disseminated intravascular coagulation, amphotericin B therapy, hypersplenism, and fixed platelet count requirements in severe thrombocytopenia

#### Platelet-Nonspecific Alloantibodies

- HLA alloantibodies
- ABO alloantibodies

#### Drug-Dependent Antibodies (e.g., vancomycin)

- Drug-dependent antibodies (e.g., vancomycin)
- Platelet-reactive antibodies

# Coagulation concentrates for inherited bleeding disorders

**Gary M. Woods & Robert F. Sidonio, Jr.**

Emory University School of Medicine, Aflac Cancer and Blood Disorders Center, Children's Healthcare of Atlanta, Atlanta, GA, USA

## Introduction

Congenital bleeding disorders can be categorized broadly into primary hemostatic defects (platelet disorders and von Willebrand disease) and secondary hemostatic defects (coagulation factor defects). Generally, mucocutaneous bleeding, including easy bruising, epistaxis, and heavy menstrual bleeding, is due to primary hemostatic defects, whereas secondary hemostatic defects are associated with deep, delayed bleeding especially into the joints and muscles.<sup>1</sup> Congenital bleeding disorders have historically led to significant disability in children, but advancements in the last 25 years have reduced both the morbidity and mortality associated with these conditions. Continuing research is underway and promising advancements in management modalities provide hope for ongoing improvements in the care of patients with congenital bleeding disorders. Nonetheless, there likely will always be a role for the use of coagulation concentrates in the care of this patient population.

underrepresented. Females can also be affected as a result of skewed lyonization, compound heterozygosity, or hemizygosity. In fact, up to 25% and 33% of patients with mild hemophilia A and B are women and girls.<sup>5</sup> Factor activity of <50% has been associated with increased bleeding in female carriers.<sup>6</sup>

Hemophilia A and B are clinically indistinguishable and are characterized by prolonged bleeding, hemarthroses, and soft tissue/muscle hematomas. While clinically they appear similar, FIX deficiency tends to be a milder disease with less severe orthopedic outcomes.<sup>2,7,8</sup> Laboratory screening results are similar in both disorders. Patients with hemophilia A and B will have a normal prothrombin time (PT), platelet count, and platelet function analyzer 100 (PFA-100), while their activated partial thromboplastin time (aPTT) will be variably prolonged (depending on the local reagents used) and will correct with a mixing study. Mild hemophilia cases, particularly those with levels >30%, may be missed due to aPTT sensitivity issues. Tests for FVIII and FIX activity will distinguish between the two diseases.

## Hemophilia

Hemophilia A and hemophilia B are the most common X-linked bleeding disorders and are the result of deficient or defective production of plasma clotting factors VIII (FVIII) and IX (FIX), respectively.<sup>2</sup> The gene for FVIII is located on the Xq28 band of the long arm of the X chromosome, and the FIX gene is located on the Xq27 band. Hemophilia A accounts for about 80% of all cases of hemophilia, with an incidence of 1:5000 live male births. Hemophilia B has an incidence of 1:20–30,000.<sup>3</sup> Hemophilia is present throughout the world and affects all races and ethnic groups. Approximately 1/3 of all new cases occur in families with no history of hemophilia and are due to spontaneous mutations.<sup>2,4</sup>

In affected males, FVIII and FIX activity levels generally correlate well with clinical bleeding severity and can help predict bleeding risk. Generally, all affected male members of a family will exhibit similar bleeding phenotypes and factor activity levels.<sup>2</sup> Severe disease is classified as FVIII or FIX activity of <1%, moderate is 1–5%, and mild disease is characterized by factor levels of 6–40%.<sup>2,4</sup> Approximately 20,000 individuals in the United States are affected by hemophilia, 43% of which are considered severe, 26% are moderate, and 31% are mild.<sup>3</sup> However, mild cases may be

## Genetics in hemophilia

As previously noted, the genes for FVIII and FIX are located on the long arm of the X chromosome. The FVIII gene is 186kb long and consists of 28 exons.<sup>1</sup> Over 2000 unique mutations have been described, with intron 22 inversion being the most common affecting almost 45% of individuals with severe hemophilia A.<sup>9–11</sup> FVIII is a complex glycoprotein containing 2351 amino acids separated into six domains: three A domains (A-1, A-2, and A-3), a connecting B domain, and two C terminal domains (C-1 and C-2).<sup>2,12,13</sup> While the B domain function is not well understood, it is not necessary for hemostatic activity.<sup>2</sup> Intracellular proteolytic cleavage by thrombin at the Arg1689 site results in the formation of a heterodimer with an N-terminal heavy chain (A-1, A-2, and partially proteolyzed B domain) bound to a C-terminal light chain (A-3, C-1, and C-2).<sup>12</sup> This heterodimeric FVIII circulates in the blood bound via the C2 domain with von Willebrand factor (vWF). vWF protects it from proteolytic degradation and concentrates FVIII at sites of injury.<sup>2</sup> Thrombin activates FVIII by cleaving sites in both the heavy and light chains to release FVIII from vWF.<sup>13</sup> The half-life ( $t_{1/2}$ ) of vWF-bound FVIII in the plasma is about 12 hours; low levels of vWF may reduce the  $t_{1/2}$  of infused FVIII.

FIX is shorter in length, only 34 kb long, and consists of eight exons.<sup>14,15</sup> Mature FIX is a serine protease that contains 415 amino acids, is synthesized in the liver, and requires a post-translational vitamin-K-dependent  $\gamma$ -carboxylation to become active. It has a  $t_{1/2}$  of about 24 hours.<sup>14,16</sup> Depending on the genetic defect, FIX deficiency may reflect a quantitative or qualitative abnormality in the FIX molecule. About 70% of FIX mutations are of the missense type.<sup>15</sup> Hemophilia B Lyden, a rare variant, occurs due to point mutations in the promoter region of FIX. These patients have severe deficiency in childhood; however, postpubertal androgen production or hormonal changes during pregnancy result in increased FIX promoter activity and thus increased FIX production, effectively correcting or significantly mitigating their disease.<sup>17</sup>

Hemophilia A and B are usually inherited in an X-linked recessive manner. Seventy percent of mild and moderate hemophilia cases have been shown to be familial on pedigree analysis, where only 57% of severe hemophilia B and 45% of severe hemophilia A are clearly familial. The remainder, designated as sporadic cases, are due to spontaneous mutations. Half of the patients with familial mild to moderate hemophilia or severe hemophilia B had an affected direct male ancestor and only 28% of familial severe hemophilia A had an affected direct male ancestor. In sporadic cases, 88% of mothers of affected individuals were found to carry the mutation, whereas only 19% of maternal grandmothers carried the mutation.<sup>18</sup> Many sporadic cases of the characteristic FVIII inversion originate from a de novo mutation found in the maternal grandfather's male germ cells.<sup>10</sup>

Hemophilia A can be diagnosed early in life by measuring FVIII levels on umbilical cord blood in individuals at risk for inheriting the disease, verifying the exact severity from the affected newborn. Prenatal diagnosis is now usually accomplished through molecular biological techniques analyzing various polymorphic markers from DNA obtained by chorionic villous sampling. These modern techniques, such as restriction fragment length polymorphism analysis, denaturing gradient gel electrophoresis, single-strand conformation polymorphism, and DNA sequencing, are accurate and can be obtained early in pregnancy.<sup>19</sup> The intron 22 inversion responsible for about half of the FVIII mutations can be detected by polymerase chain reaction in a potential carrier or using chorionic villous cells. This technique will diagnose almost all of the intron 22 inversions seen in severe hemophilia but has been shown to miss up to 4% of moderate and 12% of mild hemophilia A.<sup>20</sup> FIX levels are physiologically low at birth, and thus a low FIX level in the cord blood or from the affected newborn must be repeated at 6–12 months of age to confirm the severity of the hemophilia B diagnosis.<sup>1</sup>

### Clinical features

The clinical hallmark of hemophilia is bleeding, especially into the joints, muscles and soft tissue, but the site of bleeding and pattern of bleeding is widely varied based on disease severity and age.<sup>2,12</sup>

Individuals with mild hemophilia (activity 6–40%) usually have clinically mild disease and may only bleed after a hemostatic challenge such as surgery or trauma. These individuals are often diagnosed later in childhood if there is a lack of family history of hemophilia.<sup>4</sup> Those with moderate hemophilia have prolonged bleeding with surgery and trauma, but spontaneous bleeding is uncommon and variable. Severe hemophilia is associated with recurrent mucocutaneous bleeding, hemarthroses/deep soft tissue bleeds with minimal or no identified trauma, and severe postsurgical bleeding. Some patients with severe disease have a milder clinical disease; in contrast, some individuals with mild and moderate disease have a more severe

phenotype. It has been postulated that this considerable phenotypic heterogeneity might be related to the co-presence of a Factor V Leiden mutation and other prothrombotic conditions that counteract the bleeding tendency, differences in physical activity levels, and structural integrity of joints.<sup>12,21–24</sup> Additionally, some patients have a markedly different FVIII level if performed via one stage versus chromogenic assay.<sup>25</sup> If there is suspicion of a discrepancy in bleeding phenotype, both assays should be considered in both affected males and females.

The first hemostatic challenge experienced by a patient with hemophilia is birth. Up to 53% of patients with hemophilia experience a bleed by one month of age, with post-circumcision bleeding the most common (47.9%), followed by head bleeds (19.4%), and bleeding from heel sticks (10.4%).<sup>26</sup> The rate of intracranial hemorrhage (ICH) experienced in neonates with hemophilia is reported at 1–4%, much higher than the rate experienced in neonates without bleeding disorders. These hemorrhages have been associated with seizures, psychomotor retardation, and cerebral palsy.<sup>26–28</sup> Generally, prolonged labor and instrumentation during delivery (including forceps, vacuum assistance, and scalp electrodes) should be avoided in infants born to known hemophilia carriers to decrease the risk of ICH.<sup>27</sup> A screening cranial ultrasound to evaluate for ICH at birth is generally recommended.

Children become symptomatic more often after the newborn period and before two years of age.<sup>29</sup> The first symptomatic bleeding leading to the diagnosis of severe hemophilia has been shown to occur at a median of about 10 months of age (19 months with the presence of a prothrombotic risk factor). In patients with moderate hemophilia, the first symptomatic bleed may occur as late as 22 months, while mild hemophilia may go undetected for many years until a significant hemostatic challenge is encountered.<sup>21–23,30–32</sup> ICH is a serious complication in hemophilia at all ages, with 2% of patients older than two years facing this problem with an associated 20% mortality rate. Severe hemophilia and high titer inhibitors are independent risk factors for ICH development.<sup>33</sup>

Hemarthrosis or joint bleeding is pathognomonic of severe hemophilia. The age range for the first joint bleed in severe hemophilia varies significantly and has been reported as 0.2–5.8 years.<sup>34</sup> The factors that initiate the hemorrhage are often unknown and the onset can be random, occurring spontaneously or after minimal injury. Joint bleeds become more prevalent after individuals begin to bear weight. All synovial joints are at risk, but ankles are most commonly affected in children, and the knees, elbows, and ankles are more affected in adolescents and adults. Usually one joint is affected at a time, but a joint that experiences  $\geq 3$  bleeds in a six-month time period is referred to as a target joint.<sup>35</sup> Repeated hemorrhages into a joint leads to hemophilic arthropathy, which is associated with synovial hyperplasia, articular cartilage degradation, cystic changes in the subchondral bone, loss of joint space, and atrophy of the surrounding muscles, eventually leaving a deformed joint with contractures, pain, and decreased range of motion.<sup>12,36,37</sup>

Muscle hematomas are the second most common type of bleeding experienced in hemophilia, accounting for 10–25% of all bleeds.<sup>38</sup> Quadriceps, iliopsoas, and forearm muscles are commonly affected and, if the bleeds are large enough, can result in compartment syndrome leading to short- or long-term neurologic damage. Iliopsoas bleeding is a primary concern in hemophilia because significant blood loss can occur into this large muscle and nerve compression might follow.<sup>39</sup> Other bleeding encountered in hemophilia includes epistaxis, oral mucosal, gastrointestinal tract, and hematuria.

## Management of hemophilia

Hemophilia management is complex. It requires multidisciplinary comprehensive oversight focused on preventative care, factor replacement management, and treatment of disease complications.<sup>40</sup> Preventative care includes standard dental surveillance to reduce gingival disease; education on wearing medical alert devices and avoidance of aspirin, nonsteroidal anti-inflammatory drugs, and other platelet modifying medications; avoidance of contact sports; and vaccinations against blood borne pathogens.<sup>1</sup> Before the advent of factor replacement therapy, most patients with severe disease developed arthropathy prior to the age of 20 and the mortality rate due to ICH was significant. In the 1920s and 1930s, life expectancy of patients with hemophilia in developing countries, such as Finland and Sweden, was only 8–11 years and as recently as the 1960 life expectancy was still <30 years.<sup>41–43</sup> Many advancements in the medical management of hemophilia have been made since the 1960s (Figure 37.1). Unfortunately, as advancements were made in hemophilia management, significant setbacks were also encountered. Transmission of hepatitis C virus (HCV) and human immunodeficiency virus (HIV) complicated blood component therapy in the 1980s.<sup>44,45</sup> The implementation of scheduled factor replacement therapy led to the development of inhibitors and rising treatment costs, a major ongoing obstacle in developing countries.<sup>46</sup> Nonetheless, even with these setbacks, advancements in the last 30 years, including the emergence of comprehensive hemophilia treatment centers, recombinant factor concentrates, modified extended half-life concentrates, and a more widespread adoption of prophylactic home replacement therapy, have led to significantly improved outcomes in individuals with hemophilia.<sup>47</sup>

## Blood component therapy

Fresh-frozen plasma (FFP) and whole blood were the only preparations available to treat FVIII or FIX deficiency until 1964, when a method for concentrating FVIII into a cold-insoluble precipitate, or cryoprecipitate, was discovered.<sup>48</sup> Cryoprecipitate prepared from single plasma units contains about 50% of the FVIII, vWF, fibrinogen, and factor XIII (FXIII) of the original plasma unit, or about 100 IU of FVIII and 0.2 g of fibrinogen in 8–10 mL. Cryoprecipitate made elective surgery and outpatient treatment of bleeding episodes feasible for patients with hemophilia A. Cryoprecipitate is still used in many developing countries but has disadvantages over the newer commercially prepared concentrates, including increased risk of blood-borne pathogen transmission, marked variations

in FVIII and vWF content, larger volume, inadequate hemostatic protection, and required storage temperatures of <−20 to −30 °C.

In the 1970s, fractionation methods were developed that produced plasma-derived lyophilized concentrates of both intermediate-purity FVIII (containing vWF in addition to FVIII) and prothrombin complex concentrates (PCCs), which contain the vitamin-K-dependent clotting factors II, VII, IX, X, as well as proteins C and S. These new products allowed the adoption of home self-infusion replacement therapies for both hemophilia A and B and led to reduced morbidity compared to untreated patients. This even resulted in the pioneering of primary prophylaxis in Sweden, which achieved the goal of preventing bleeding episodes.<sup>49</sup> Hemophilia centers were able to focus on the development of comprehensive care programs since they were no longer overwhelmed with providing emergency treatments.<sup>50</sup> Subsequently, the discovery in 1977 of the effect of desmopressin on FVIII and vWF concentrations provided a relatively inexpensive and safe treatment option for many patients with mild to moderate hemophilia A (and mild vWD). This synthetic drug, which increases FVIII and vWF plasma levels by releasing them from Weibel Palade bodies in endothelial cells, reduced the use of plasma derived products in this population of nonsevere hemophilia A.<sup>4,51</sup>

The late 1970s and early 1980s were devastating in the care of hemophilia. Tragically, approximately half of the population with hemophilia in the United States, or 9300 individuals, became infected with HIV and 80% with hepatitis C.<sup>52</sup> As many as 90% of patients with hemophilia became seropositive for hepatitis B surface antigen. The first reported case of acquired immunodeficiency syndrome in individuals with hemophilia was reported in the early 1980s, and it became apparent that it was being transmitted via blood and blood components, including factor concentrates.<sup>53</sup> Approximately 90% of persons who received FVIII concentrates and 55% of those who received PCCs prepared in the United States between 1979 and 1984 became seropositive for HIV.<sup>54</sup> Fortunately, HIV proved to be heat labile, and by late 1984 almost all patients with hemophilia were receiving heat-treated concentrates. Additionally, in 1984, a solvent-detergent process for treating blood products was developed that drastically reduced the transmission of both hepatitis B and C.<sup>55</sup> By 1985, HIV seropositivity screening for blood and plasma donors was also in place. Shortly thereafter, methods to purify FVIII using murine monoclonal antibodies and immunoaffinity chromatography became commercially available in 1987. This purification process reduced viral contaminants by several logs and any residual viral risks were mitigated by pasteurization or solvent/detergent methods.<sup>56</sup> These measures greatly

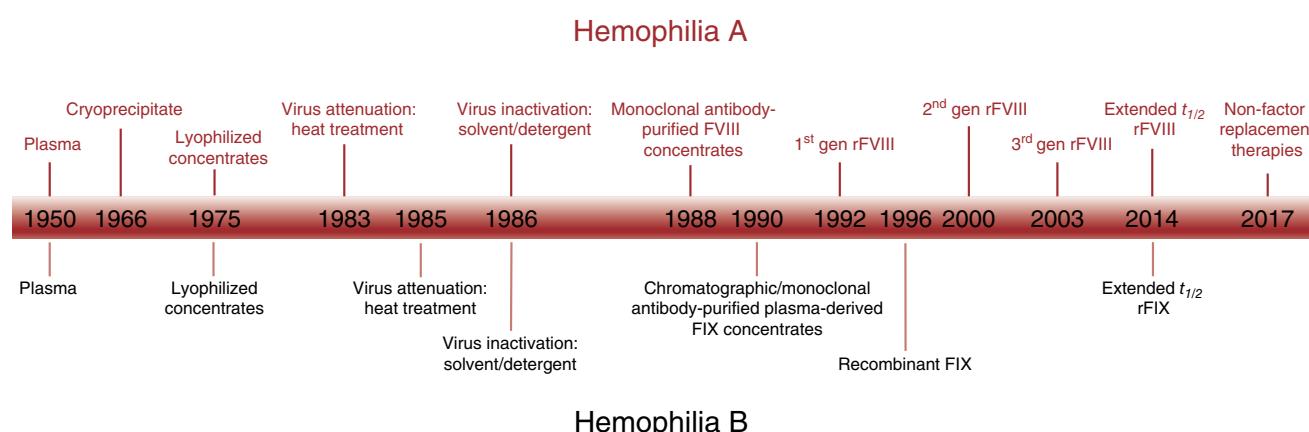

Figure 37.1 Evolution timeline of hemophilia A and hemophilia B treatment modalities.

improved the safety of plasma-derived FVIII and FIX products. Since 1987, HIV and hepatitis transmission by factor concentrates has not been reported in the North American population.<sup>54</sup>

Despite these advancements, the transmission of blood-borne viruses or novel infectious agents remained a concern. One of the most important innovations in hemophilia care came with the cloning of the FVIII gene in 1982 and the FIX gene in 1984, which allowed for the development and production of recombinant factor products, which were first shown to be clinically effective in 1989.<sup>57</sup>

### **Recombinant factor VIII**

Recombinant FVIII (rFVIII) was quickly developed after the molecular cloning of complementary DNA encoding human FVIII and the expression of human FVIII from recombinant DNA clones.<sup>58,59</sup> Three generations of standard half-life rFVIII products are commercially available with differences in their preparation. First-generation products utilized animal-derived proteins in cell culture and stabilized the final formulation of FVIII with human serum albumin. Second-generation products eliminated animal products during fermentation, and nearly all of the human albumin was eliminated in the final formulation as well. No human-derived proteins are used in the culture medium or final formulation of third-generation products.<sup>60</sup> Most patients in the United States and many other developed countries have been switched to rFVIII therapy for theoretical concerns over residual risks of blood-borne pathogen transmission. The commercially available rFVIII products are summarized in Table 37.1.

The only first-generation rFVIII product that remains on the market in the United States is Recombinate (Takeda, USA) and it has demonstrated the same pharmacokinetics and clinical effectiveness as plasma-derived FVIII products.<sup>61,62</sup>

Second-generation rFVIII products include Kogenate (Bayer, USA) and Helixate (CSL Behring, USA). Third-generation products include full length (Advate, Takeda, USA; Kovaltry, Bayer, USA; NovoEight, Novo Nordisk, Denmark) and truncated (Syntha, Pfizer, USA; Afystyla, CSL Behring, USA; Nuwiq, Octapharma, USA) preparations. The truncated preparations are B-domain-deleted (BDD) as the heavily glycosylated B domain is not needed for the hemostatic activity of FVIII.<sup>63</sup> BDD products have been shown to be safe, effective in the treatment of bleeding episodes, and well tolerated.<sup>64</sup> The important advancement with these products is that no human proteins are utilized in the initial preparation stages or in the final formulation. Nuwiq is a BDD product that was the second rFVIII product made in a human cell line with the rationale that it would potentially eliminate antigenic epitopes, and more closely resemble endogenous FVIII post-translational modifications, as compared to the use of nonhuman cell lines (hamster).<sup>65</sup> The Food and Drug Administration (FDA) has also approved the use of the extended  $t_{1/2}$  rFVIII products (Eloctate, Sanofi Genzyme, USA; Adynovate, Takeda, USA; Jivi, Bayer, USA). For Eloctate, BDD rFVIII is fused to the Fc portion of immunoglobulin G subclass 1 or IgG<sub>1</sub>.<sup>66,67</sup> This product has been proven to have prolonged circulation compared to other rFVIII products.<sup>68,69</sup> Adynovate and Jivi utilize PEGylation technology that has also been shown to prolong plasma circulation compared to standard half-life unmodified rFVIII products.<sup>70-72</sup>

### **Dosage and administration of factor VIII**

FVIII concentrates are routinely used to treat acute bleeding episodes in individuals with moderate or severe hemophilia and for those with mild hemophilia who show poor response to desmo-

pressin or are undergoing a major procedure. Factor replacement can be given “on demand” (after a bleeding episode), to treat a hemorrhage, or as “prophylaxis” (scheduled infusions to prevent or decrease the frequency or intensity of hemorrhages). Acute hemarthrosis, intramuscular bleeding, and surgical prophylaxis are common indications for factor replacement. Prompt treatment can prevent or reduce complications, like chronic joint disease, and can reduce the need for subsequent factor infusions (Table 37.2).<sup>73</sup> Usually, 1 U/kg of FVIII will increase the plasma FVIII concentration by 2% (0.02 IU/dL).<sup>12</sup> The  $t_{1/2}$  of FVIII is about 12 hours, but significant interpatient variability exists with ranges of 6–25 hours described.<sup>74</sup> The  $t_{1/2}$  may be shorter in patients that are younger, febrile, have ongoing extensive bleeding, or have an inhibitor.

Factor replacement can be performed using bolus dosing (more commonly) or administered as a continuous infusion. Continuous infusions are often utilized in operative and postoperative situations, as well as for managing central nervous system (CNS) hemorrhage and have the benefit of precision. Additionally, this is the only feasible way to maintain a level of 100% for a prolonged period of time.<sup>2</sup> A bolus dose of 50 U/kg of FVIII should be administered followed by a continuous infusion of 2–5 IU/kg/hour as initial dosing. FVIII activity levels should be monitored intermittently and infusion rates should be adjusted accordingly to ensure FVIII activity is in the desired hemostatic range, typically 80–120% for major procedures.<sup>2,75,76</sup>

### **Prophylaxis**

Primary prophylaxis refers to beginning factor replacement before a pattern of recurrent bleeding begins, particularly joint bleeding. Secondary prophylaxis refers to beginning the therapy after two or more joint bleeds but before the onset of joint disease.<sup>73</sup> The idea for prophylactic treatment started in Malmö, Sweden, after the observation that patients with moderate hemophilia had a significantly lower incidence of chronic arthropathy.<sup>77</sup> Patients with severe hemophilia A were monitored for 2–25 years on prophylactic factor infusions and were shown to have fewer bleeding events and less joint disease than those receiving on-demand treatment.<sup>78,79</sup> Randomized trials have demonstrated that prophylaxis administration improves outcomes and reduces joint disease in children with severe hemophilia when compared to episodic on-demand treatment.<sup>80</sup> Thus, prophylactic administration of factor to prevent bleeding episodes has become the standard of care for patients with severe hemophilia.

Prophylaxis in hemophilia A usually involves administration of FVIII every other day or three days a week at starting doses of 25–40 U/kg, targeting a trough level of >1% when feasible.<sup>81,82</sup> Since prophylaxis is now recommended to start at a young age, the frequent infusions may result in the need for a central venous access device (CVAD); although factor administration may be easier, CVAD placement requires careful consideration due to the risk of infections and thrombosis.<sup>82</sup> It is common to use an escalating dose/frequency schedule for prophylaxis in young children that entails starting with a once weekly infusion, escalating to twice weekly, and eventually thrice weekly. Some practitioners will increase to full dose prophylaxis regardless of bleeding phenotype, whereas others only increase dosing in those patients with a high incidence of bleeding.<sup>83</sup> Extended  $t_{1/2}$  products lessen the administrative burden by decreasing the frequency of prophylaxis dosing in some individuals with hemophilia or by providing a higher trough activity level in individuals with a high incidence of bleeding or shortened  $t_{1/2}$ .

Notes: In this table, the desired peak factor levels of CFC replacement shown for treatment of hemorrhages at different anatomical sites represent the ranges in global practice patterns depending on available resources. Importantly, it should be recognized that the goal of such treatment is effective control of bleeding and should be the same everywhere in the world. Lower CFC replacement levels require much closer observation for effectiveness of bleeding control, with a potentially greater chance of requiring additional CFC replacement to achieve the target plasma level as well as the hemostatic and musculoskeletal outcomes.

Abbreviations: CFC, clotting factor concentrate, NV, neurovascular.

<sup>a</sup> May be longer if response is inadequate.

<sup>b</sup> Sometimes longer as secondary prophylaxis during physical therapy.

<sup>c</sup> The duration of treatment refers to sequential days post-surgery. Type of CFC and patient's response to CFC should be taken into account.

<sup>d</sup> Depending on procedure; the number of doses would depend on the half-life of the CFC used.

## Recombinant factor IX

Until the late 1990s, intermediate-purity PCCs were the mainstay of treatment for hemophilia B. These products contained some inactivated as well as some activated coagulation factors and were associated with thromboembolic complications. Due to this thrombogenic potential, high-purity plasma-derived FIX concentrates (Mononine, CSL Behring, USA; Alphanine, Grifols, USA) were created and, although more costly, were less thrombogenic.<sup>84</sup> However, these products were plasma-derived and associated with the same theoretical risks seen with other plasma-derived products. Thus, recombinant FIX (rFIX) products were created.

Recombinant FIX products are made using no albumin, human plasma, or animal derived proteins, but are made in a mammalian cell line. The available rFIX products are summarized in Table 37.3. There are three standard acting products that have similar efficacies (Rixubis, Shire, USA; Benefix, Pfizer, USA; Ixinity, Aptev Biotherapeutics, USA), and three extended  $t_{1/2}$  rFIX products (Alprolix, Sanofi Genzyme, USA; Idelvion, CSL Behring, USA; and Rebinyn, Novo Nordisk, Denmark). Alprolix is similar to Eloctate in that rFIX is fused to the Fc portion of IgG<sub>1</sub>, which significantly prolongs the circulating plasma  $t_{1/2}$  of the FIX.<sup>85</sup> Rebinyn and

Idelvion use PEGylation technology to extend the circulating plasma  $t_{1/2}$ . Despite this prolonged circulating plasma  $t_{1/2}$ , there are reports of spontaneous bleeding and poor bleeding response in patients on extended  $t_{1/2}$  rFIX products, suggesting that the trough FIX activity levels alone may not predict bleeding phenotype.<sup>86</sup> This was corroborated in a phase IV study of rFIX-FP, in which arthralgia was the most commonly reported treatment emergent adverse event, and target joints developed in ~14% of study participants despite a trough FIX level of >7%.<sup>87</sup>

## Dosage and administration of factor IX

FIX requires a higher dose to achieve the same plasma concentrations as compared with FVIII replacement, although the extravascular distribution of FIX may provide additional hemostatic protection despite variable plasma levels. The recommended dosage for hemorrhage treatments varies based on the type and severity of bleed (Table 37.2).<sup>73</sup> The  $t_{1/2}$  of FIX is about 24 hours.<sup>74</sup> Plasma-derived FIX products will raise the FIX activity by 1% (0.01 IU/dL) when 1 U/kg is administered. Generally, 1 U/kg of rFIX will raise the plasma FIX activity by 0.8–1% (0.008 IU/dL).<sup>12</sup> Thus, to obtain 100% replacement, a patient with severe hemophilia B must

receive 100–120 IU/kg. Factor IX concentrates may be given in bolus or continuous infusions, with continuous infusions usually utilized perioperatively and with CNS bleeding. A bolus dose of 100–120 U/kg should be infused followed by 4–8 U/kg/hour with periodic FIX activity measurements to maintain appropriate hemostatic levels, typically 80–120% for major procedures.<sup>2,75,76,88</sup>

### Ancillary therapeutic options

#### Desmopressin

Desmopressin is the treatment of choice for individuals with mild hemophilia A and some cases of moderate hemophilia A where a fourfold increase in FVIII activity 30–60 minutes after administration is predicted to be adequate for the type of bleeding episode.<sup>51,73,89</sup> Not all patients with mild hemophilia will respond to desmopressin, so a trial dose must be administered and FVIII activity levels subsequently monitored. Trial administrations are usually a weight-adjusted 0.3 µg/kg IV/subcutaneous (SC) dose, or a fixed dose of intranasal spray at 150 µg (one spray) or 300 µg (one spray in each nostril) for patients weighing <50 kg or >50 kg, respectively. Desmopressin may be dosed every 12–24 hours, but 3–4 repeated doses over a short period can result in tachyphylaxis (decreased responsiveness). Desmopressin side effects are generally mild and include tachycardia, headache, and flushing. Significant fluid retention resulting in hyponatremia and seizures can occur particularly in young children and the elderly, and all patients must be fluid restricted for at least 24 hours following administration.<sup>90</sup>

#### Antifibrinolytic agents

Antifibrinolytic agents, such as lysine analogs  $\epsilon$ -aminocaproic acid and tranexamic acid, inhibit plasminogen activation and are usually used as an adjuvant therapy to maintain hemostasis. These agents can be useful in preventing lysis of a formed clot, especially when bleeding occurs in areas of high fibrinolytic activity like the oral mucosa.<sup>73,91</sup> The recommended dose of  $\epsilon$ -aminocaproic acid is 50–100 mg/kg IV or orally every 6–8 hours, while the dose of tranexamic acid is 10 mg/kg IV every 6–8 hours or 15–25 mg/kg orally every 6–8 hours. For invasive dental procedures, therapy can be started as early as the evening prior to the procedure and continued for 7–10 days.<sup>91</sup> The use of tranexamic acid mouth wash has been shown to be effective at decreasing post-operative bleeding and transfusion requirements in patients with hemophilia following oral surgery when used in conjunction with systemic antifibrinolytic therapy.<sup>92</sup> The recommended dosing is 10 mL of 4.8% tranexamic acid solution for two minutes four times a day.

#### Vaccinations

Despite the current low risk of post-transfusion hepatitis, all persons with hemophilia should receive both hepatitis A and B immunizations. While all blood products are screened for hepatitis viruses, testing may not be 100% effective, particularly in donors with window phase infections. The risk of transmission can be further increased with plasma-derived products, in which plasma collections from 2500 to 20,000 donors are used to produce one lot of concentrate. However, in 2003 the Centers for Disease Control and Prevention investigated seroconversion to hepatitis A or B in people with bleeding disorders and found that no cases could be attributed to factor products.<sup>93</sup> Nonetheless, hepatitis vaccination is strongly recommended. Hepatitis A and B vaccines should be given subcutaneously due to the risk of intramuscular (IM) bleeding associated with IM vaccines.<sup>73</sup>

#### Avoidance of drugs that cause platelet dysfunction

Certain drugs can induce platelet dysfunction, which can exacerbate bleeding in patients with congenital bleeding disorders. Aspirin irreversibly inhibits platelet cyclooxygenase resulting in the inhibition of prostaglandin synthesis and thus should be avoided. Other medications known to induce platelet dysfunction include antihistamines, phenothiazines, and nonsteroidal anti-inflammatory agents (indomethacin and ibuprofen). Acetaminophen can be used to relieve mild pain in conjunction with rest, cooling, and elevation. Cyclooxygenase 2 (COX-2) inhibitors have also been shown to be effective in managing hemophilic arthropathy pain without interfering with platelet function and are thus considered a safe alternative for pain management in this population.<sup>94</sup>

#### Inhibitors in hemophilia

One of the most serious complications associated with hemophilia is the development of a neutralizing IgG alloantibody, or inhibitor, to the deficient factor.<sup>95</sup> Approximately 30% of patients with severe hemophilia A, 5–10% with mild and moderate hemophilia A, and 2–5% of patients with hemophilia B will develop an inhibitor.<sup>96–98</sup> The significant discrepancy in inhibitor rates may be partially explained by the presence of cross-reactive material (CRM). Many patients with hemophilia B will have circulating FIX antigen despite low activity because many FIX mutations are missense. The presence of this FIX CRM could potentially explain the lower risk of developing neutralizing antibodies when FIX medications are administered.<sup>99</sup> For hemophilia A, inhibitors usually develop in early childhood, within the first 50 exogenous factor exposure days; the risk declines after 150 treatment days.<sup>100</sup> For hemophilia B, the highest risk for inhibitor development is believed to be in the first 50–75 exposure days. The first 20 exposure days for patients with severe hemophilia B should be performed under close clinical supervision due to the risk for severe allergic reactions.<sup>101</sup>

Inhibitor formation in hemophilia is a complex multifactorial process. Associated risk factors include family history of inhibitors, hemophilia genotype, race, and immune regulatory polymorphisms (tumor necrosis factor- $\alpha$ , interleukin-10, and cytotoxic T-lymphocyte antigen-4). Inhibitor development rate is also dependent on the type of genetic mutation. In hemophilia A, inhibitors develop in 88% of patients with a large deletion, 25–41% with moderate deletions, 16–21% with minor deletions, 20% with intron 22 inversions, and 5% with missense mutations.<sup>9,102</sup> In hemophilia B, large deletions or minor deletions associated with a stop codon are associated with an inhibitor rate of 50–100%.<sup>103,104</sup> Immunogenicity differences between plasma-derived and recombinant factor products have been debated, but no conclusive evidence has shown a significant difference in inhibitor development between these products.<sup>105–108</sup>

Inhibitory antibodies are measured in Bethesda units. Given that FVIII is present at 1 unit/mL in normal plasma, a Bethesda unit represents the number of dilutions of patient plasma that reduces FVIII activity by 50%. Thus, higher titer inhibitors will require a higher number of dilutions to titrate their inhibitory effect down to 50%, resulting in a higher Bethesda unit titer. FVIII antibodies of <5 BU/mL are low titer or low responding inhibitor, whereas those >5 BU/mL represent a higher titer or high responding inhibitor. High responding inhibitors tend to be more persistent, and even though they may become undetectable after long periods of no treatment, they usually have a recurrent anamnestic response 3–5 days after a challenge with factor products.<sup>73</sup> Inhibitors complicate hemophilia treatment because of diminished responsiveness to exogenous

factor concentrates and reliance on less hemostatically effective bypassing agents. Progressive joint disease and significant mobility impairment are more prevalent in patients with inhibitors than those without.<sup>109</sup> Also, life-threatening anaphylaxis has been reported in up to 50% of patients with hemophilia B with FIX inhibitors upon exposure to exogenous factor concentrates.<sup>110</sup>

### Management of inhibitors in hemophilia

Management of patients with inhibitors is twofold: management/prevention of acute bleeding and attempting to eliminate the inhibitor. Bleeding in patients with low titer inhibitors can often be managed with FVIII concentrates in more frequent or higher doses if hemostatic levels of FVIII can be achieved. However, patients with high titer (>5 BU) inhibitors often require alternative therapies. Bypassing agents, like the activated prothrombin complex concentrate, FEIBA, and activated recombinant factor VII (rFVIIa), have been used and are equally efficacious.<sup>111</sup>

Activated prothrombin complex concentrates (aPCCs), a combination of the vitamin-K-dependent factors II, VII, IX, X and protein C and S at varying concentrations, have been used in the management of patients with both FVIII and FIX inhibitor for many years. The recommended dose of FEIBA, one type of aPCC, is 50–75 IU/kg every 12–24 hours, but repeated doses of more than 3–5 days should be monitored carefully due to thromboembolic risks.<sup>112</sup> FEIBA has been shown to be effective at treating acute bleeding, controlling perioperative bleeding, and for prophylaxis in hemophilia patients with inhibitors.<sup>112–114</sup>

The development of rFVIIa (Novo Seven, Novo Nordisk, Denmark; Sevenfact, Hema Biologics, USA) was an important landmark in the management of hemophilia patients with inhibitors. It has been demonstrated that rFVIIa at concentrations much higher than normal circulating levels mediate a tissue-factor-independent conversion of factor X to its activated form on a phospholipid surface.<sup>115</sup> In the absence of FVIII and FIX, rFVIIa induces hemostasis likely by enhancing thrombin generation on activated platelet surfaces. This leads to thrombin activation, which recruits more platelets and enhances platelet adhesion. This thrombin also recruits factor XIII leading to a tighter fibrin clot structure.<sup>116</sup>

The first successful use of rFVIIa in patients with hemophilia was during and following an open synovectomy.<sup>117,118</sup> Although the  $t_{1/2}$  is short (2–3 hours), rFVIIa has been used with clinical success in patients with inhibitors presenting with life/limb-threatening bleeds, as prophylaxis for joint bleeding, and as prophylaxis for elective surgical procedures.<sup>110,119–122</sup> Dosing for Novo Seven is typically 90 µg/kg with repeated dosing every 2–3 hours until hemostasis is achieved, followed by dosing at increasing intervals thereafter. Clearance rates may be higher in younger children. Despite its short  $t_{1/2}$ , daily prophylactic doses of 90 or 270 µg/kg have been shown to be effective in decreasing the frequency of joint bleeding.<sup>122,123</sup>

For Sevenfact, typical dosing for mild to moderate bleeding is 75 µg/kg with repeated dosing every three hours until hemostasis is achieved followed by increasing intervals thereafter. Another dosing strategy is an initial dose of 225 µg/kg with monitoring; if hemostasis is not achieved within nine hours of the first dose, administer additional 75 µg/kg doses every three hours until hemostasis is achieved. For severe bleeding, an initial dose of 225 µg/kg should be given. A 75 µg/kg dose can be given 6 hours later with subsequent dosing every 2 hours until hemostasis is achieved.<sup>124</sup> For the majority of patients with hemophilia B who have had severe allergic reactions to FIX products, rFVIIa is regarded as their treatment of choice.<sup>125</sup>

Another option for the management of patients with hemophilia and inhibitors is nonhuman (porcine) FVIII protein. Porcine FVIII has limited cross-reactivity with antihuman FVIII antibodies. A recombinant porcine FVIII concentrate (Obizur, Takeda, USA) was recently approved by the FDA to treat bleeding episodes in adults with acquired hemophilia A, but further studies are needed to evaluate its safety and efficacy in the treatment of patients with congenital hemophilia A and inhibitors.<sup>126,127</sup>

Staphylococcal protein A immunoabsorption columns are available outside of the United States to rapidly reduce levels of very high titer inhibitors to FVIII and FIX. Due to the availability of bypassing agents, these columns are rarely used but may have some benefit especially in reducing the incidence of nephrotic syndrome in patients with hemophilia B if used prior to immune tolerance therapy.<sup>128</sup>

Most recently, nonfactor replacement therapies have become available. The FDA has approved an FVIII mimetic bispecific antibody (emicizumab, Genentech, USA) that binds to FIXa and the FX zymogen in appropriate positions to promote tenase formation and FX activation.<sup>129</sup> Emicizumab prophylaxis has been shown to significantly reduce the annualized bleeding rate in patients with hemophilia A and an inhibitor compared to on-demand bypassing agent use.<sup>130</sup> Thrombotic microangiopathy and thrombosis were reported as complications when high-dose aPCC were utilized to treat an acute bleeding event while on emicizumab. Due to this complication, rFVIIa is considered first line for treatment of acute bleeding events in patients with hemophilia A and an inhibitor on emicizumab with low-dose (25–50 IU/kg) aPCCs reserved rarely for patients not responding to rFVIIa.<sup>130,131</sup> There are other nonfactor replacement therapies (antitissue factor pathway inhibitor [TFPI], RNA interference therapeutic that targets antithrombin, and other bispecific antibodies) currently in development.

### Immune tolerance therapy

The ultimate goal in the management of inhibitors is complete eradication, which is achieved between 60% and 80% of the time with immune tolerance induction (ITI).<sup>128</sup> ITI is costly and requires good venous access as well as patient adherence to be successful. Deferring ITI until the inhibitor titer is <10 BU can be considered, but if the titer does not decline after a 1–2-year period and/or the inhibitor is associated with a severe or life-threatening bleed then ITI should be considered earlier.<sup>132</sup> More recent guidance suggests that starting ITI immediately, regardless of the titer, is preferred.<sup>133</sup> Inhibitors are divided based on “good risk” and “poor risk” features. “Good risk” features include an inhibitor titer of <10 BU, a maximum inhibitor titer of <199 BU, and ITI started less than five years since inhibitor diagnosis. “Poor risk” inhibitors do not meet all three criteria.

Currently, there are no strong recommendations for the optimal dose and frequency for ITI, and protocols vary by institution.<sup>132</sup> The International Immune Tolerance Study showed that high-dose (200 IU/kg/day) and low-dose (50 IU/kg/3 times/week) FVIII infusions were equally efficacious in achieving tolerance in “good risk” patients with high titer inhibitors, but the high-dose group achieved a negative titer faster and had less bleeding.<sup>134</sup>

With the development of emicizumab addressing the limitations of bypassing agents, it was unclear if ITI would continue to have as important of a role in inhibitor management. The “Atlanta Protocol” investigated this concern and showed that patients can safely receive ITI (up to 100 IU/kg thrice weekly) with emicizumab and that it could effectively tolerize these individuals.<sup>135</sup> The ability to effectively tolerize patients while utilizing emicizumab would again allow for the use of FVIII products in the event of an acute bleeding

complication or in a surgical setting. There are ongoing studies investigating the safety and efficacy of this approach.

The success rate for ITI in patients with hemophilia B with inhibitors is much less than that for hemophilia A and may involve the use of a cumbersome immunosuppressive regimen that includes desensitization, rituximab, and mycophenolate.<sup>136</sup> The success rate is reduced by the development of nephrotic syndrome of unclear etiology about 8–9 months after the start of ITI. While nephrotic syndrome generally resolves after FIX product avoidance, its occurrence complicates any further ITI.<sup>137</sup>

### Gene therapy

Gene therapy seeks to replace the missing factor or protein by transfecting target tissue with a nucleic acid expression construct followed by endogenous factor synthesis. Hemophilia is a monogenic hereditary disorder with well-understood genetics, making it a potential target for gene therapy.<sup>138</sup> Gene therapy has been in clinical trials in hemophilia B for many years with limited success using adeno-associated viral vector serotype 2 (AAV2), but the response was not sustainable.<sup>139</sup>

More recent gene therapy clinical trials for severe hemophilia B used adeno-associated serotype 8 viral vector (AAV8), which encoded for a codon-optimized FIX. The AAV8 serotype was chosen since it transduces hepatocytes well, with minimal interactions with antigen presenting cells and cross-reactivity with preexisting anti-AAV2 antibodies. Six subjects received low-, intermediate-, or high-dose vector doses and all subjects expressed between 2% and 11% FIX activities many months after therapy. Some were able to stop prophylaxis therapy all together, while the others required less frequent FIX infusions.<sup>139,140</sup> Although sustained improvement in FIX levels were obtained, the levels achieved were not sufficient to prevent bleeding in the setting of a severe trauma or surgery. AAV5 has also been shown to be an effective vector in phase 1 and 2 studies for hemophilia B with a sustained FIX response in the mild to normal range.<sup>141</sup> Ongoing efforts are underway to further optimize gene therapy in hemophilia B.

Utilizing the AAV in patients with hemophilia A is more challenging due to the large size of the FVIII transgene; however, an AAV5 vector has produced a sustained FVIII activity in the mild hemophilia range with a clinically relevant (decreased annualized bleeding rate) response.<sup>142</sup> Also, a codon-optimized FVIII has been created using a BDD FVIII; injection into hemophilia A mice using a spleen focus forming virus promoter within a self-inactivating HIV-based lentiviral vector showed a sustained 29–44-fold increase in expression of FVIII levels.<sup>143</sup> The gene size used would be small enough to fit into an AAV vector, suggesting a potential gene delivery system. Ongoing efforts are also underway to optimize gene therapy in hemophilia A.

### von Willebrand disease

von Willebrand disease is the most common autosomally inherited bleeding disorder. The estimated prevalence of vWD is about 1%, but clinically significant vWD prevalence is about 1 in 1000.<sup>144,145</sup> vWD usually presents with mucocutaneous bleeding and postoperative hemorrhage, but the degree of bleeding is less severe than in hemophilia. No geographical or ethnic predilection exists, and females outnumber males almost 2:1 in most populations despite autosomal inheritance.<sup>146</sup> This likely represents a diagnosis bias due to the hemostatic challenge of menses. vWD occurs secondary to a quantitative or qualitative deficiency in vWF.

von Willebrand factor is a large multimeric glycoprotein that has many roles in both primary and secondary hemostasis. vWF mediates platelet adhesion to exposed endothelium by binding to GPIB/IX/V platelet surface glycoprotein, assists in platelet aggregation by binding to the GPIIb/IIIA platelet surface glycoprotein, and it binds to circulating FVIII to prevent protein C mediated proteolytic degradation.<sup>1</sup>

The gene for vWF is located on the short arm of chromosome 12, spanning 178 kb with 52 exons that code for a 2813 amino-acid-containing protein.<sup>1,147,148</sup> Megakaryocytes and vascular endothelial cells are responsible for synthesizing pro-vWF subunits that dimerize in the endoplasmic reticulum.<sup>149</sup> The pro-vWF dimers form multimers within the Golgi bodies, and the final product protein can be released directly into the plasma or stored either in the Weibel-Palade bodies or within platelet  $\alpha$ -granules. vWF in circulation ranges from 500 kDa up to 20 million Da (high molecular weight [HMW]), with the higher molecular weight vWF more physiologically active.<sup>1,149</sup> Under high shear stress, the larger multimers bound to platelets may stretch and expose Tyr<sup>1605</sup>–Met<sup>1606</sup> bond in the A2 domain of vWF, where ADAMTS13 (a disintegrin and metalloprotease with thrombospondin 1 motif, member 13) proteolyses vWF into its characteristic cleavage products.<sup>1,147,149</sup> vWF, irrespective of multimer size, has a circulating  $t_{1/2}$  of about 20 hours.<sup>149</sup>

vWF levels are influenced by many factors. As an acute phase reactant, vWF rises with stress, infection, and exercise. Chronic elevations in vWF are seen in hyperthyroidism as well as diseases with chronic endothelial damage, like diabetes. Increased estrogen levels, as seen with hormonal contraception, hormone replacement, and pregnancy, have been reported to increase vWF levels as high as 300–400%. Age is another significant factor as vWF levels naturally increase 1–2% per year; whether this diminishes the effect on bleeding in those with mildly reduced VWF is not clear.<sup>150</sup> Race also affects vWF levels, with African Americans having higher average levels compared to Caucasian populations.<sup>151,152</sup> Hypothyroidism has been shown to decrease circulating levels of vWF. ABO blood groups also influence vWF levels, with lowest levels found in blood type O and highest in blood type A. Certain variants, like the exon 28 D1472H polymorphism, have artificially low VWF:RCO without affecting GpIb $\alpha$  binding or leading to a bleeding phenotype.<sup>150,153–155</sup>

### Clinical manifestation

Bleeding symptoms are generally mild in type 1 disease and increase in severity with type 2 and 3 diseases. Mucocutaneous bleeding, including easy bruising, epistaxis, and menorrhagia, is the most common manifestation. Postoperative bleeding, especially following oral procedures, is frequently seen. Hemarthroses are uncommon in type 1, but can be seen in type 3 and 2N due to the associated reductions in FVIII activity.<sup>148</sup>

### Classification and diagnosis

von Willebrand disease has been classified into three main categories: type 1 (quantitative deficiency), type 2 (qualitative defects, including subtypes A, B, M, and N), and type 3 (complete vWF deficiency).<sup>149</sup> Laboratory evaluation for suspected vWD should initially include nonspecific hemostasis tests, including a complete blood count (CBC), PT, aPTT, thrombin time (TT), and fibrinogen levels to evaluate for other potential bleeding diathesis.<sup>1</sup> Platelet dysfunction has similar presentations and should also be considered. Specific vWF quantification and function testing includes circulating levels of VWF:Ag, measurement of vWF function through either ristocetin-based platelet

aggregation (VWF:RCO) or through von Willebrand collagen binding assays, ratio analysis of VWF:RCO/VWF:Ag, vWF multimer analysis, and FVIII levels (Figure 37.2).<sup>148,156,157</sup> Newer platelet-binding activities of vWF assays (VWF:GP1bM and VWF:GP1bR) have been developed which are ristocetin-independent and likely more reflective of the bleeding tendency. Recently, an international group published guidelines suggested the use of these newer vWF platelet-binding assays over VWF:RCO for the diagnosis of VWD.<sup>158</sup>

### Type 1 vWD

Type 1 vWD accounts for 75–80% of all vWD cases<sup>1,147,150</sup> and is inherited in an autosomal dominant fashion with incomplete penetrance.<sup>148</sup> It is characterized by equivalent mild to moderate reductions in both VWF:Ag and VWF:RCO, with a VWF:RCO/VWF:Ag ratio >0.6, reduced platelet-binding activity of vWF (VWF:GP1bM, VWF:GP1bR), normal or prolonged PFA-100 closure, normal vWF multimeric distribution analysis, and normal PT and CBC.<sup>1,148,149,158</sup> aPTT may be prolonged due to decreased FVIII activity when VWF:Ag is <0.35 IU/dL, but a normal aPTT does not rule out vWD and in fact the vast majority of cases have a normal aPTT.<sup>1</sup> Consensus guidelines released in 2021 recommend using a VWF:Ag or platelet-dependent VWF of <0.3 IU/mL regardless of bleeding phenotype or <0.5 IU/mL in patients with abnormal bleeding, for the diagnosis of type 1 vWD.<sup>158</sup>

Vicenza-type vWD is a type 1 vWD subtype (commonly referred to as type 1C) and is inherited in an autosomal dominant manner. It is characterized by low-plasma vWF levels, normal platelet vWF content, and supranormal multimers.<sup>159</sup> Although not usually present in the plasma, the larger multimers are observed after DDAVP administration. It is now recommended to utilize a desmopressin trial with one- and four-hour postinfusion testing to confirm increased vWF clearance for the diagnosis of type 1C.<sup>158</sup> Despite larger than normal multimers, the functional vWF activity and hemostatic function are decreased. It is unclear if the abnormal function is due to a quantitative or qualitative defect.<sup>159</sup>

### Type 2 vWD

Type 2 vWD accounts for 20–25% of all vWD cases and is associated with a qualitative defect in vWF. It is clinically similar to type 1vWD, and all subtypes were historically characterized by a VWF:RCO/VWF:Ag ratio <0.6, but new consensus guidelines suggest using a platelet-dependent vWF activity/VWF:Ag ratio of <0.7.<sup>1,147,158</sup> Either vWF multimer analysis or the ratio of vWF collagen binding (VWF:CB)/VWF:Ag should be utilized to confirm the diagnosis of certain subtypes.<sup>158</sup>

### Type 2A vWD

Type 2A vWD is mainly inherited in an autosomal dominant pattern and is associated with loss of the HMW and intermediate-weight vWF multimers.<sup>147–149</sup> The loss of multimers is either due to a defect in their synthesis or increased sensitivity to cleavage by ADAMTS13.<sup>1,149,150</sup> The bleeding diathesis described is usually mild to moderate, but can have significant gastrointestinal bleeding secondary to arteriovenous malformations, and generally these patients have a poor response to desmopressin.<sup>149,160–162</sup>

### Type 2B vWD

Type 2B vWD is characterized by mutations in the A1 domain that result in enhanced affinity of vWF for platelet receptor GpIb.<sup>149,163</sup> Many individuals will have mild to moderate thrombocytopenia due to the increased platelet aggregation that can be exacerbated by stress and desmopressin, and these individuals will have significantly increased RIPA at low concentrations of ristocetin.<sup>158,164,165</sup> Although vWF is synthesized normally, type 2B vWD shows decreased large molecular weight multimers because large multimers bind platelets spontaneously upon secretion and are subsequently cleaved by ADAMTS13.<sup>165,166</sup> The cleaved multimers are small and do not mediate platelet adhesion or connective tissue binding well.<sup>166</sup> Consensus guidelines released in 2021 suggest that targeted genetic testing is preferred to low-dose RIPA testing to distinguish between type 2A and type 2B vWD.<sup>158</sup>

	Quantitative Disorders			Qualitative Disorders				
	Type 1	Type 1C	Type 3	Type 2A	Type 2B	Type 2M	Type 2N	Platelet Type vWD

Ag, antigen; FVIII, Factor 8; HMW, high molecular weight; IMW, intermediate molecular weight; Rco, Ristocetin Cofactor; RIPA, ristocetin induced platelet aggregation; VWF, von Willebrand factor

**Figure 37.2** Expected laboratory values in von Willebrand disease based on subtype.

### Type 2M vWD

Type 2M vWD is characterized by decreased vWF affinity for platelets without the loss of HMW.<sup>149</sup> These patients usually have a mutation within the A1 domain that impairs vWF binding to the GpIb platelet receptor.<sup>167,168</sup> Recent evidence suggests that individuals with 2M subtypes experience a milder bleeding phenotype than other subtypes.<sup>161</sup>

### Type 2N vWD

Type 2N or Normandy variant vWD is associated with mutations in the region of the vWF gene (exons 18–21 or 24–27) that is involved in binding vWF to FVIII.<sup>169,170</sup> These mutations result in decreased or absent vWF binding to FVIII, which in turn results in premature degradation of FVIII.<sup>169</sup> VWF:Ag and VWF:RCo can be normal or borderline low, but the FVIII activity is disproportionately decreased (5–40%). Bleeding symptoms mimic those of hemophilia A and the decreased FVIII levels make the diagnosis difficult. Diagnosis is based on either genetic analysis of vWF gene or by enzyme-linked immunosorbent assay-based VWF:FVIII binding assay.<sup>1,158</sup>

### Type 3 vWD

Type 3 vWD has an almost complete deficiency of vWF. It is inherited in an autosomal recessive manner, and heterozygous relatives have mild or no bleeding symptoms.<sup>171–173</sup> This type is characterized by vWF:Ag of <5%, VWF:RCo of <5%, FVIII levels of <10%, and a prolonged aPTT.<sup>149</sup> These individuals may have a more severe bleeding tendency than the other vWD subtypes, including mucocutaneous hemorrhage as well as hemarthroses and hematomas, similar to that of moderate hemophilia.<sup>148</sup> Due to the complete deficiency of vWF synthesis, these patients do not respond to desmopressin.

### Platelet-type vWD

Platelet-type vWD is similar to type 2B in both clinical presentation and laboratory features. It is characterized by platelet hyperresponsiveness to RIPA, but it is associated with a gain-of-function mutation in the platelet GPIBA gene, which codes for the vWF receptor GPIba. This causes an enhanced affinity for vWF that forms vWF–platelet complexes that are cleared from circulation quickly.<sup>174</sup> Macrothrombocytopenia may also be seen.<sup>175</sup>

### Treatment

Treatment for vWD is dependent on the subtype. FVIII and vWF levels of >50% are generally considered to be sufficient for maintaining hemostasis except in the setting of severe trauma or invasive procedures.<sup>90</sup>

Desmopressin can be used to increase vWF and FVIII plasma concentrations because it promotes their release from endothelial stores.<sup>90</sup> Typically, a 2–4-fold increase above basal levels is seen in 30–60 minutes, and hemostatic levels of vWF and FVIII are present for 6–8 hours after administration.<sup>148</sup> Over 80% of patients with type 1 vWD will respond to desmopressin with the likelihood of response dependent on their initial VWF:Ag level. The 2021 vWD guidelines do recommend performing a desmopressin trial to ensure effectiveness prior to utilizing as a treatment option. An adequate response is described as an increase of at least 2× the baseline vWF activity with a sustained FVIII and vWF of 50 U/dL for at least four hours after administration.<sup>176</sup> Baseline VWF:Ag of <10 U/dL often do not have substantial responses.<sup>89,160,177,178</sup> Patients with Vicenza variant show a promising initial response to DDAVP, but the response is not sustained, with VWF:Ag levels

near baseline levels at about 240 minutes following administration.<sup>159</sup> Except for some patients with 2A disease, type 2 vWD typically does not respond to desmopressin and in fact can exacerbate thrombocytopenia in type 2B. Individuals with type 3 disease are considered unresponsive.<sup>89,178</sup> Desmopressin is administered using 0.3 µg/kg IV/SC dosing, or fixed doses of 150 µg or 300 µg by intranasal spray for weights of <50 kg or >50 kg, respectively. A desmopressin trial is needed to confirm adequate response in all patients. Repeated doses over a short period can result in decreased responsiveness, or tachyphylaxis, and fluid restriction is required for 24 hours following doses to avoid hyponatremia.<sup>90</sup> Of note there may be some hemostatic benefit in those with an incomplete response based on laboratory values; this benefit may allow use in specific situations such as epistaxis at home.<sup>176</sup>

Plasma-derived VWF:FVIII concentrates should be used for major bleeding events, prophylaxis for major surgeries, in patients where desmopressin is not beneficial (type 3 and nonresponsive patients with type 1 and 2 patients), and where desmopressin is contraindicated (type 2B, patients with seizure disorders, and infants).<sup>1</sup> There are three commercially available licensed plasma-derived products for vWF replacement in the United States that are FDA approved: Humate-P (CSL Behring, USA), Alphanate SD/HT (Grifols, USA), and Wilate (Octapharma, USA). As described below, these products are not interchangeable as they have differing ratios of vWF to FVIII.

Humate-P contains 50–100 IU/mL of VWF:RCo and 20–40 IU/mL of FVIII activity; the median  $t_{1/2}$  of the VWF:RCo activity is about 11 hours.<sup>179</sup> Alphanate SD/HT contains a higher FVIII activity of 40–180 IU/mL and ≥16 IU/mL of VWF:RCo activity. Its median VWF:RCo  $t_{1/2}$  is about seven hours. Wilate contains 90 IU/mL of VWF:RCo activity as well as 90 IU/mL of FVIII activity, with a median  $t_{1/2}$  of VWF:RCo of 13–16 hours.<sup>180</sup> Dosing is usually based on the VWF:RCo units. Minor procedures may only need 1–5 days of coverage, whereas major surgeries can require as many as 7–14 days hemostasis. Additionally, minor procedures and spontaneous bleeds may only require a single dose of 20–40 U/kg of VWF:RCo to adequately control bleeding, while major spontaneous bleeding or surgical procedures require more aggressive management. For example, major spontaneous bleeding or surgical prophylaxis may require doses of 50–60 IU/kg of VWF:RCo, with the goal of obtaining peak VWF:RCo levels of 80–100 IU/dL for up to three days and a nadir of 50 IU/dL for at least 5–7 days.<sup>148,156</sup> A loading dose of 50 IU/kg of VWF:RCo can be given 30–60 minutes before surgery with doses of 20–60 IU/kg of VWF:RCo every 8–24 hours afterward to maintain hemostasis depending on the severity of the procedure. Monitoring VWF:RCo and FVIII trough and peak levels will aid in determining the subsequent dosing schedule.<sup>148</sup> Continuous infusions after initial boluses have been shown to successfully achieve surgical hemostasis and may be required in certain situations.<sup>181</sup> Adverse reactions associated with these concentrates are rare, but include allergic/anaphylactic symptoms like rash, edema, chest tightness, and pruritus.<sup>182</sup> Venous thromboembolism has been reported with the use of these concentrates, so caution is warranted with their use in patients with known risk factors for thrombosis. In patients requiring ongoing replacement therapy, monitoring FVIII levels has been recommended to ensure FVIII levels remain in a safe range.<sup>183–185</sup> Patients with vWD who may require replacement therapy should be vaccinated against hepatitis A and B due to the risk of acquiring blood borne pathogens although there has not been a documented case of viral transmission with these products in many years.<sup>186</sup>

The vWD International Prophylaxis (VIP) study investigated the use of prophylactic vWF concentrates in patients with clinically severe vWD. This was a nonrandomized study with dose escalation based on bleeding symptoms; any of the vWF concentrates were allowed to be used. An interim retrospective review evaluating one year prior to initiating prophylaxis to at least six months afterward showed that prophylaxis resulted in a significant decrease in the number of annual bleeding events (12–3) in the 55 evaluated patients.<sup>187</sup> While only 11 patients completed the study, final analysis confirmed that prophylaxis with vWF concentrates can be highly effective in preventing some hemarthrosis and mucosal bleeding events in patients with clinically severe vWD (reduced median annualized bleeding rate from 25 to 6.1).<sup>188</sup> The 2021 consensus vWD management guidelines now recommend the use of long-term prophylaxis in patients with a history of clinically severe and frequent bleeding events (including heavy menstrual bleeding) regardless of the subtype of VWD.<sup>176</sup>

Recently, a recombinant vWF (rVWF) product has been approved by the FDA (Vonvendi, Takeda, USA). Phase 1 and 3 data showed that the mean plasma VWF:RCo  $t_{1/2}$  is 19.6 hours, which is longer than the  $t_{1/2}$  of plasma-derived vWF (7–16 hours).<sup>189–191</sup> However, in contrast to plasma-derived vWF concentrates, rVWF has no significant FVIII activity. This concern was investigated during the clinical trials. Interestingly, even in the absence of the co-administration of an rFVIII product, rVWF use in type 3 vWD still led to normalization of FVIII activity in the plasma that was sustained for 48 hours after the infusion. This was believed to be due to the stabilizing effect of rVWF on endogenously secreted FVIII.<sup>190,191</sup>

While cryoprecipitate has historically been used in the management of vWD, this product is rarely used today due to the risk of blood borne pathogens, fluid overload, and increased thrombotic risk. Among the few acceptable uses of cryoprecipitate in this population are the presence of life- or limb-threatening situations in which no vWF concentrates are available.

Antifibrinolytic monotherapy may be used to treat mild mucocutaneous bleeding, whereas combining antifibrinolytics with desmopressin or vWF concentrates may be useful in controlling bleeding, especially in the oral cavity, gastrointestinal tract, and genitourinary tract. Menorrhagia is a common complaint among women with vWD and can be severe enough to cause symptomatic anemia. Treatment may require a combination of hormonal contraception, desmopressin when indicated, as well as antifibrinolytic therapy.<sup>156,176</sup>

## Other rare congenital clotting protein disorders

### Prothrombin deficiency

Prothrombin (FII), a vitamin-K-dependent glycoprotein synthesized in the liver, is the inactive zymogen of thrombin, an enzyme that cleaves fibrinogen into fibrin and activates factor XIII (FXIII) to covalently crosslink fibrin into a stable sheath.<sup>192,193</sup> Congenital prothrombin deficiency is one of the rarest congenital bleeding disorders, with an estimated incidence of 1 in 2,000,000 births, with higher incidences in consanguineous marriages.<sup>193</sup> The inheritance pattern is autosomal recessive with more than 40 mutations described within the 20.3 kb prothrombin gene on chromosome 11p11–q12.12. These mutations are only clinically relevant in those that inherit abnormal alleles from both parents.<sup>193,194</sup> Defects are classified as quantitative, or hypoprothrombinemia (homozygotes and compound heterozygotes); qualitative, or dysprothrombinemia (homozygotes or heterozygotes); or combined.<sup>193</sup>

### Clinical manifestations

Bleeding severity seems to correlate with prothrombin levels in hypoprothrombinemia, but a discrepancy in bleeding severity and genotype exists in dysprothrombinemia. Prothrombin deficiency may be classified as severe if levels are <5%, moderate if 5–10%, and mild if >10%, respectively.<sup>195</sup> Patients with prothrombin activity levels of 20–40% are usually asymptomatic, and the  $t_{1/2}$  of prothrombin is about three days.<sup>196,197</sup> Patients with homozygous and compound heterozygous prothrombin gene defects can have moderate to severe bleeding. Bleeding manifestations include easy bruising, mucosal bleeding (epistaxis, gingival bleeding, and menorrhagia), hemarthroses, subcutaneous/muscle hematomas, and postoperative bleeding. Gastrointestinal bleeding is less common.<sup>193,196</sup> In the neonatal period, intracranial hemorrhage, severe umbilical cord bleeding, hematomas, and increased bleeding after circumcision have all been reported.<sup>196,198</sup> Heterozygotes are usually asymptomatic, but mucocutaneous bleeding and bleeding following tonsillectomy and tooth extraction have been described.<sup>193,196</sup>

### Diagnosis

Typically, prothrombin deficiency will result in the prolongation of both the prothrombin time (PT) and activated partial thromboplastin time (aPTT), but results are reagent-dependent and abnormalities could be minimal. Prothrombin antigenic and activity assays are required for diagnosis after vitamin K deficiency and liver disease have been excluded.<sup>193,198</sup>

### Management

Fresh-frozen plasma (FFP) and PCCs are the treatments of choice, as no pure prothrombin concentrates are available.<sup>193</sup> These modalities can be used individually or simultaneously. FFP at 15–20 mL/kg, which should raise prothrombin levels by 25%, can be used to treat acute bleeds. For more severe bleeding episodes and surgical prophylaxis, consider a loading dose of 10–20 mL/kg of FFP, followed by 3 mL/kg every 12–24 hours to maintain adequate hemostasis.<sup>193,196</sup> Dosing for PCCs is based on the amount of each factor in the specific product; it is important to note that the amount of factors vary not only between products, but between manufacturer-produced lots. Typical dosing for PCCs is 20–50 units/kg.<sup>193</sup> Monotherapy with antifibrinolytic agents ( $\epsilon$ -aminocaproic acid and tranexamic acid) have been used for mild bleeding. Due to the long  $t_{1/2}$  of prothrombin, prolonged courses of treatment should be dosed to maintain prothrombin activity >25%.<sup>196</sup>

### Factor V deficiency

Factor V (FV) is a large glycoprotein synthesized in the liver that is activated by thrombin to serve as a cofactor for activated factor X (FXa) in the prothrombinase complex (FVa/FXa) to convert prothrombin to thrombin.<sup>199,200</sup> Congenital FV deficiency is a rare autosomal recessive bleeding disorder, with a reported incidence of about 1 in 1,000,000.<sup>198</sup> The FV gene is located on the long arm of chromosome 1p23, and the inherited defect can be either homozygous, which is more prevalent in consanguineous families, compound heterozygote, or heterozygote.<sup>199,200</sup> Mutations can result in either quantitative (type 1) or qualitative (type 2) defects.<sup>199</sup>

### Clinical manifestations

Bleeding severity correlates poorly with FV activity levels, but patients that are severely affected (<5–10% activity) tend to be more predisposed to severe bleeding episodes.<sup>195,199,200</sup> This is likely due to the fact that 20–25% of circulating FV is stored within platelet  $\alpha$ -granules, which is released upon platelet activation, and seemingly binds

immediately to surface receptors forming the prothrombinase complex.<sup>195</sup> The bleeding phenotype in FV deficiency is clinically heterogeneous.<sup>195,199,200</sup> Severe deficiency can present at birth or in early childhood with easy bruising and mucosal membrane bleeding, such as epistaxis and oral cavity bleeding, but ICH and umbilical stump bleeding have also been reported. Other bleeding manifestations may include muscle hematomas, hemarthroses, menorrhagia, and postsurgical bleeding. Heterozygote individuals and those with activity levels >10–15% are generally asymptomatic but may have mild bleeding phenotypes.<sup>195,198–200</sup>

### Diagnosis

FV deficiency is associated with both a prolonged PT and aPTT. Measurement of FV activity and/or antigen is required to confirm the diagnosis after liver disease has been ruled out.<sup>199</sup>

### Management

There is no commercially available purified FV concentrate. Antifibrinolytic agents alone may be sufficient to control minor bleeding episodes.<sup>199</sup> Severe bleeding episodes or perioperative management should be managed with FFP, dosed at 15–20 mL/kg, to maintain FV activities >20%. The  $t_{1/2}$  of FV is 13–36 hours, so daily FFP dosing is generally sufficient.<sup>199,200</sup>

### Combined factor V and factor VIII deficiency

Combined FV and FVIII (FV/FVIII) deficiency is a rare autosomal recessive disorder with a reported incidence of less than 1 in 1,000,000 in the general population, with the highest prevalence in those of middle eastern Jewish and non-Jewish Iranian decent (1:100,000). There is a higher prevalence in consanguineous marriages.<sup>201,202</sup> The molecular basis for this disorder is a mutation in either the LMAN1 (lectin mannose binding 1) gene on chromosome 18q21 in 70% of the cases or MCFD2 (multiple coagulation factor deficiency gene 2) gene on chromosome 2p21 in 30% of the cases. These genes encode proteins essential for the intracellular transport of both FV and FVIII.<sup>203–205</sup>

### Clinical manifestations

No strong association between activity levels and clinical bleeding has been established, but individuals with <20% activity are more likely to have spontaneous bleeding and those >40% are generally asymptomatic.<sup>195</sup> The combined deficiency of FV and FVIII does not lead to more significant bleeding than a similar isolated deficiency of FV or FVIII alone.<sup>206</sup> FV/FVIII deficiency is usually associated with a mild bleeding phenotype, and common bleeding symptoms include epistaxis, easy bruising, oral cavity bleeding, menorrhagia, and postsurgical. Bleeding after circumcision has also been frequently reported. Less frequently, ICH, umbilical cord bleeding, hemarthroses, and gastrointestinal bleeding have been reported.<sup>206,207</sup>

### Diagnosis

Both PT and aPTT will be prolonged in FV/FVIII deficiency and correct with mixing studies. A decrease in the plasma activity of both FV and FVIII to between 5% and 30% is usually seen. Liver disease and systemic consumptive processes (i.e., DIC) need to be excluded.<sup>206</sup> Diagnosis is confirmed by genetic testing for LMAN1 or MCFD2 mutations.

### Management

Bleeding episode treatment requires a source of both FV and FVIII. FV replacement is achieved with FFP; FVIII replacement is achieved with FFP, desmopressin, and plasma-derived or recombinant FVIII. FFP should not be utilized solely for FVIII replacement due to its

shorter  $t_{1/2}$  as compared to FV.<sup>206,207</sup> Recombinant FVIIa has been successfully used to control severe bleeds, but the safety of this off label use has not been established.<sup>208</sup> Monitoring of replacement treatment can be done with FV and FVIII assays.

### Factor VII deficiency

Factor VII (FVII) is a vitamin-K-dependent serine protease that, when activated, binds to exposed tissue factor (TF) to form the tissue factor complex, which activates FIX and FX and initiates the formation of a stable fibrin clot.<sup>209</sup> Congenital FVII deficiency is an autosomal recessive condition and is considered the most common rare congenital bleeding disorder, with an incidence of 1 in 500,000.<sup>197,210</sup> To date, over 130 mutations have been described in the FVII gene, located on chromosome 13q34.<sup>209,210</sup>

### Clinical manifestations

Bleeding symptoms do not correlate well with FVII activity levels, and there is a poor association between laboratory phenotype and clinical severity.<sup>195,197,210</sup> Heterozygotes are typically asymptomatic, while compound heterozygotes and homozygotes have bleeding symptoms ranging from asymptomatic to severe hemorrhagic diathesis.<sup>209,210</sup> Individuals with FVII activities >25% usually remain asymptomatic, while FVII activity of <5–10% may be associated with more severe spontaneous bleeding.<sup>195,210</sup> Commonly reported bleeding symptoms include epistaxis, easy bruising, oral cavity bleeding, and postoperative bleeding.<sup>209</sup> Menorrhagia is also a frequent complication and can be quite severe.<sup>210</sup> Muscle hematomas and hemarthrosis have less frequently been reported, and CNS and GI bleeding, while rarely encountered, can be severe.<sup>209</sup>

### Diagnosis

An isolated prolongation of the PT that corrects with a mixing study is characteristic of FVII deficiency. A FVII activity assay is required to confirm the diagnosis after vitamin K deficiency and liver disease have been excluded.<sup>209</sup>

### Management

Many interventions are available to manage FVII deficiency, and therapies should be individualized based on clinical situations due to the short *in vivo*  $t_{1/2}$  (6–8 hours) of FVII. The recombinant FVIIa product Novo Seven (Novo Nordisk, Denmark) is the treatment of choice. Sevenfact (Hema Biologics, USA) currently does not have an indication for the management of bleeding in congenital FVII deficiency. Novo Seven has a short *in vivo*  $t_{1/2}$  and increased clearance in children which requires a frequent dosing schedule of 15–30 µg/kg every 4–6 hours in certain clinical situations. It is notable that much lower dosing and decreased frequency of infusions are needed for FVII deficiency as compared to patients with hemophilia and inhibitors.<sup>209–211</sup> Single intermediate Novo Seven doses (60 µg/kg) have been shown to be effective in many mild to moderate bleeding episodes.<sup>212</sup> Although it has been associated with an increased thrombosis risk, recent studies have shown that the use of a minimally effective dose of Novo Seven is both safe and efficacious at obtaining and maintaining hemostasis in bleeding episodes and as surgical prophylaxis.<sup>211,212</sup>

Plasma-derived FVII (pdFVII) concentrates are similar to PCCs except for the higher content of FVII. Although effective in obtaining FVII activity sufficient for adequate hemostasis, the concentrations of the other vitamin-K-dependent factors are higher than FVII, conferring an increased thrombosis risk.<sup>209</sup> FFP, 10–15 mL/kg, is an inexpensive and readily available treatment modality and is often the only treatment available in many developing countries.

Challenges with using FFP, including increased risk of blood-borne pathogens, limited effectiveness, fluid overload, and the need for repeated administrations every 6–8 hours, have limited its use in clinical practice. aPCCs/PCCs can also be effective, but their use is limited in practice due to concerns similar to the use of FPP.<sup>209,210</sup>

Prophylaxis in FVII deficiency is generally limited to certain clinical situations. Menorrhagia and associated iron deficiency are common complications in women with FVII deficiency. If menorrhagia is not well controlled with antifibrinolytics and hormonal contraception, rFVIIa prophylaxis with Novo Seven could be considered.<sup>209</sup> Prophylaxis should also be considered in patients with a severe bleeding phenotype and recurrent bleeding episodes.<sup>210</sup>

Monitoring replacement therapy is accomplished by following FVII activity levels. FVII activity of 50% is associated with a normal PT.<sup>209</sup>

### **Factor X deficiency**

Factor X (FX) is a liver synthesized vitamin-K-dependent plasma glycoprotein that is essential for thrombin formation as it binds with FVa to form the prothrombinase complex.<sup>213,214</sup> Congenital FX deficiency is a rare autosomal recessive disorder with a reported incidence of 1 in 1,000,000; 1 in 500 are carriers. There is a higher prevalence in consanguineous marriages.<sup>201,214</sup> The FX gene is located on chromosome 13q34, and 105 distinct mutations have been described in individuals with FX deficiency resulting in either a quantitative (type 1) or qualitative (type 2) defect.<sup>213</sup>

### **Clinical manifestations**

FX deficiency has been classified into three groups: severe (<1% activity), moderate (1–5% activity), and mild (6–10% activity).<sup>214</sup> In patients with FX deficiency, bleeding symptoms correlate with activity levels. Patients with severe deficiencies tend to have more significant bleeding histories, while activity levels of <10% have been associated with spontaneous bleeding. Individuals with activities of 10–40% only have minor spontaneous or triggered bleeding if they have any symptoms at all, and those with activity >40% are generally asymptomatic.<sup>195</sup> Compared to other rare congenital bleeding disorders, severe FX deficiency tends to be associated with more severe bleeding symptoms. Easy bruising, epistaxis, oral cavity bleeding, menorrhagia, GI bleeding, hematomas, and hemarthroses are commonly reported. Intracranial hemorrhage, bleeding after circumcision, an umbilical cord bleeding have been reported in the neonatal period.<sup>213,214</sup>

### **Diagnosis**

The PT and aPTT are typically both prolonged in FX deficiency since it serves as the first enzyme in the common pathway. They both correct on mixing studies, and vitamin K-deficiency and liver disease need to be excluded. Both immunologic and functional assays are required to classify FX deficiency. Reductions in both FX activity and antigen suggest a type 1, or quantitative, defect, whereas a reduction in activity with normal antigen concentrations suggests a type 2, or qualitative, defect.<sup>213</sup>

### **Management**

A FX activity of 10–40% is generally accepted as hemostatic and should be the goal for replacement therapy, keeping in mind the relatively long FX  $t_{1/2}$  of 20–40 hours.<sup>214</sup> There is a plasma-derived FX (pdFX) concentrate available in Europe and the United States (Coagadex, Bioproduts Laboratory, United Kingdom). The safety and efficacy of pdFX has been established for on-demand, perioperative, and prophylactic therapies.<sup>215–221</sup> Dosing for on-demand

management is 30 IU/kg for patients aged <12 years and 25 IU/kg for patients ≥12 years of age with repeated doses every 24 hours until hemostasis has been achieved. For perioperative management, the initial dose is calculated based on the patient's baseline FX level and the desired level (usual goal is 70–90 IU/dL) with subsequent doses as needed to maintain an activity >50 IU/dL until the risk for bleeding has subsided. While data does exist to direct dosing in younger cohorts, it is more limited.

FX replacement therapy can also be accomplished with FFP or aPCCs/PCCs. Single doses of FFP (15–20 mL/kg) or aPCCs/PCCs are usually sufficient to control most bleeding symptoms, but daily doses may be required if prolonged hemostasis is required. Due to thrombosis concerns with these factor replacement therapies, individuals should be monitored clinically for symptoms of thrombosis and monitoring with FX levels and D-dimers should be considered in those receiving prolonged treatments.<sup>213</sup> Minor bleeding symptoms may be controlled with just topical therapies and/or antifibrinolytics.<sup>214</sup>

Prophylaxis is generally limited to certain situations. Menorrhagia that is uncontrolled with hormonal therapy and antifibrinolytics may benefit from prophylaxis with FFP or aPCCs/PCCs. Prophylaxis should be considered in patients with severe deficiency and repeated bleeding episodes, especially CNS bleeds, hemarthrosis, and hematomas.<sup>222</sup> Prophylaxis for a child born to family already with one severely affected child may prevent complications, like ICH.<sup>213</sup> For prophylaxis using pdFX, the dosing is 40 IU/kg twice weekly for patients aged <12 years and 25 IU/kg twice weekly for patients ≥12 years of age with a goal trough FX level of ≥5 IU/dL with a max peak not to exceed 120 IU/dL.

### **Factor XI deficiency**

Factor XI (FXI) is a plasma glycoprotein synthesized in the liver that circulates as the zymogen of a serine protease (FXIa) bound in a complex with high-molecular-weight kininogen (HMWK). Once activated by FXIIa, FXIa activates FIX, which maintains thrombin production at vascular injury sites.<sup>223</sup> Congenital FXI deficiency is generally inherited as an autosomal recessive trait, but the structure of circulating FIX could result in a dominant negative effect, leading to a dominant inheritance pattern. More than 220 mutations have been described in the FXI gene, located on the long arm of chromosome 4 (4q35.2).<sup>224</sup> The estimated prevalence is about 1 in 1,000,000 in most populations but is substantially higher at 1 in 450 among the Ashkenazi Jewish population.<sup>224</sup>

### **Clinical manifestations**

FXI activity levels do not correlate well with bleeding tendencies.<sup>195,224</sup> Severe FXI deficiency is defined as activity levels <20%, while activities between 20% and the lower limit of the normal activity (65–80%) are considered mildly deficient.<sup>224</sup> Overall, FXI deficiency is associated with a mild bleeding diathesis, but bleeding may occur at the time of the injury or hours later. Spontaneous bleeding is rare in even with severe FXI deficiency.<sup>195,224,225</sup> Epistaxis and menorrhagia may occur. Postoperative and post-trauma bleeding is common, especially in areas with high fibrinolytic activity such as the oral cavity, nose, and genitourinary tract.<sup>224,225</sup> Bleeding is less common at other trauma sites including circumcisions, cutaneous lacerations, orthopedic surgery, and appendectomy.<sup>226</sup> Mild deficiency is generally associated with an asymptomatic state, but a low risk of postoperative bleeding still exists.<sup>195</sup>

Inhibitor development has been described in congenital FXI deficiency following exposure to FFP or FXI concentrates. Although

these individuals still rarely have spontaneous bleeds, they may suffer prolonged bleeding during surgery even with appropriate therapy. FXI inhibitors should be suspected in individuals receiving appropriate therapy that continue to bleed and continue to have prolonged aPTTs.<sup>224</sup> Interestingly, FXI deficiency likely conveys a decreased ischemic stroke risk as well, as recent evidence showed FXI activity >95% was a potential risk factor for ischemic strokes but does not protect against myocardial infarctions, as postulated in Hemophilia A and B.<sup>224,225</sup>

### Diagnosis

Factor XI deficiency is characterized by an isolated prolonged aPTT. The aPTT will be greater than two standard deviations above normal values in homozygotes and may be normal or only slightly prolonged in heterozygotes; however, this depends upon the sensitivity of the PTT reagent utilized. After liver disease is excluded, confirmation of FXI deficiency is achieved by demonstration of reduced FXI activity. Since FXI deficiency can remain asymptomatic until an injury occurs, patients of Ashkenazi Jewish descent undergoing surgery or invasive procedures should consider screening with an aPTT; FXI activity should be measured if the screening test is abnormal.<sup>226</sup>

### Management

Perioperative replacement therapy should be utilized for higher risk surgical procedures in areas of high fibrinolytic activity. FXI replacement is achieved with the use of FFP or FXI concentrates. FFP is typically dosed at 15–20 mL/kg, but again caution must be used as the potential for fluid overload, transmission of infectious agents, and allergic reactions are all present.<sup>224,226</sup> Plasma-derived FXI concentrates have been available since the 1980s.<sup>226,227</sup> Each FXI concentrate also contains antithrombin so caution must be applied with use in the elderly, those with cardiovascular disease, and those with other thrombotic risk factors due to the 10% risk of arterial and venous thrombosis after FXI concentrate administration.<sup>224,226,227</sup> The goal of FXI replacement therapy for severe FXI deficiency is to attain approximately 40–45% activity for seven days with major surgery and approximately 30% for five days for minor procedures.<sup>224,226</sup> Since the  $t_{1/2}$  of FXI is about 45 hours, prolonged courses of therapy can be managed with bolus dosing on alternating days.<sup>227</sup>

In individuals with FXI inhibitors, rFVIIa (Novo Seven, Novo Nordisk, Denmark) has been used successfully off label in small single and repeated doses (15–30 µg/kg) with concurrent antifibrinolytic therapy to manage major surgeries, including open heart for dissecting aortic repair. Caution must be again applied as both of these agents do have an associated thrombotic risk. Fibrin sealants may be an appropriate alternative to antifibrinolytic therapy in some situations.<sup>224</sup>

Minor procedures (i.e., tooth extraction, colonoscopy with biopsy, and skin biopsy) do not usually require factor replacement therapy. These situations can typically be managed with antifibrinolytic therapy. Fibrin sealants may also be used in some situations.<sup>224,226,227</sup>

### Factor XIII deficiency

Factor XIII (FXIII) is a transglutaminase heterotetramer consisting of two catalytic subunits (A) and two carrier subunits (B). Thrombin, along with cofactors fibrinogen and calcium, cleaves the activation peptide from the A subunit of FXIII to initiate its activation. The major function of FXIIIa is the crosslinking of fibrin chains, resulting in a mechanically stronger thrombus. Congenital FXIII deficiency is a rare autosomal recessive bleeding

disorder with a reported incidence of about 1 in 2,000,000, with severe disease present in individuals who are homozygotes or compound heterozygotes. Congenital FXIII deficiency is more commonly seen in consanguineous marriages. FXIII-A deficiency is much more common than FXIII-B deficiency, for which there are only a few reported cases in the literature.<sup>228–230</sup> The gene coding for FXIII-A is on chromosome 6p24–25 and over 100 mutations have been described so far.<sup>229</sup> FXIII deficiency type I results from decreased synthesis of the protein and type II describes a qualitative defect of a normal concentration of defective FXIII-A.<sup>231</sup>

### Clinical manifestations

Factor XIII activity levels correlate well with bleeding symptoms experienced.<sup>195</sup> The deficiency is considered severe when activity levels are <5%, moderate if 5–10%, and mild when >10%.<sup>228</sup> The first and most clinically characteristic bleeding symptom experienced is bleeding from the umbilical cord days after birth.<sup>228–230</sup> Easy bruising/subcutaneous hematomas, intramuscular bleeds, hemarthroses, delayed bleeding after surgery or trauma, and ICH (the most common cause of disability or death) have all been reported. FXIII deficiency also has associated nonbleeding symptoms including recurrent spontaneous abortions and impaired wound healing/scar formation.<sup>228,229</sup> Individuals with mild and moderate deficiency may only have mucocutaneous bleeding or might be completely asymptomatic.<sup>195</sup>

### Diagnosis

Standard coagulation screening labs of PT, aPTT, thrombin time (TT), and fibrinogen are all normal in FXIII deficiency. The following algorithm has been recommended for the diagnosis of FXIII deficiency:<sup>231</sup>

- 1 First-line screening to detect all forms of FXIII deficiency should be obtained with a quantitative function FXIII activity assay, either by the measurement of ammonia released during the transglutaminase reaction or by the measurement of labeled amine incorporated into a protein substrate.
- 2 A. If the FXIII quantitative screen is abnormal, then
  - measure FXIII-A<sub>2</sub>B<sub>2</sub> antigen—if decreased, measure FXIII-A and FXIII-B antigens;
  - measure FXIII activity and FXIII-A antigen in the platelet lysate.
- B. If FXIII quantitative screen is normal, then
  - perform mixing study to evaluate for neutralizing antibodies;
  - if high suspicion of FXIII deficiency, consider type II defect.
- 3 Perform molecular genetic studies and use SDS-PAGE to evaluate fibrin crosslinking.

The urea clot solubility test has been traditionally used to screen for FXIII deficiency, but it can only detect individuals with severe deficiency so this screening test is no longer routinely recommended.<sup>231</sup>

### Management

Due to the clinical severity of the bleeding in FXIII deficiency, once factor activity of <1% is confirmed, prophylactic factor replacement therapy is the standard of care.<sup>231</sup> Prophylactic therapy should also be considered in individuals with factor activity <4–5% with severe bleeding phenotypes.<sup>232</sup> Treatment decisions should take into account that activity levels of 3–5% are usually sufficient to prevent spontaneous bleeding and the  $t_{1/2}$  of plasma FXIII is 11–14 days, meaning a monthly dosing schedule should be sufficient.<sup>228</sup>

FFP and cryoprecipitate are easily available sources of FXIII, providing 1 and 3 units/mL of FXIII, respectively, that can be used in the management of FXIII deficiency. FFP is dosed at 15–20 mL/kg and cryoprecipitate is 1 unit per 10 kg of body weight every 20–30 days. Plasma-derived pasteurized FXIII (pdFXIII) concentrate (Corifact, CSL Behring, USA) is preferred over FFP and cryoprecipitate because of the higher concentration of FXIII and lower risk of blood born virus transmission.<sup>228</sup> Prophylactic dosing of pdFXIII is recommended at 10–35 units/kg every 4–6 weeks.<sup>228,229,231</sup> For major surgery, FXIII activity levels should be maintained at >5% until wound healing is complete. Prophylactic FXIII therapy should be ideally started before 5–6 weeks of gestation in pregnancy to prevent spontaneous abortions and miscarriages.<sup>228</sup>

A recombinant FXIII (rFXIII) product (Tretten, Novo Nordisk, Denmark) has been approved for prophylactic therapy in the United States. It has been shown to be both safe and effective at preventing bleeding episodes in children and adults with congenital FXIII-A deficiency. Although about 10% of patients developed non-neutralizing antibodies to FXIII, none of these patients had bleeds that required treatment and these antibodies eventually became undetectable despite further rFXIII exposure.<sup>233</sup> It is important to note that this product is not effective for the rare case of FXIII subunit B deficiency.

### Fibrinogen disorders

Fibrinogen is the soluble glycoprotein precursor to insoluble fibrin. It is synthesized in the liver and consists of two sets of three polypeptide chains.<sup>234</sup> The three chains ( $\alpha$ ,  $\beta$ , and  $\gamma$ ) of fibrinogen are coded by different genes located in a 50-kb region on chromosome 4.<sup>235,236</sup> Normal circulating plasma fibrinogen concentration is about 150–350 mg/dL and it is constitutively secreted into circulation where it has a  $t_{1/2}$  of about four days. Fibrinogen levels of about 100 mg/dL are associated with adequate hemostasis.<sup>210,234</sup> Fibrinogen is converted into fibrin in three phases: (1) thrombin cleaves fibrinogen to produce fibrin monomers; (2) an organized polymeric structure forms from self-assembly of fibrin units; (3) FXIIIa covalently crosslinks fibrin.<sup>234</sup> Along with fibrin clot formation, fibrinogen also has a role in nonsubstrate thrombin binding, platelet aggregation, and fibrinolysis.<sup>235,236</sup>

Congenital fibrinogen deficiency is a rare bleeding disorder that affects the quantity of fibrinogen (afibrinogenemia or hypofibrinogenemia), the quality/activity (dysfibrinogenemia), or both (hypodysfibrinogenemia).<sup>210,234,236</sup> Clinical manifestations vary according to the type of deficiency and a strong association exists between clinical bleeding severity and fibrinogen levels.<sup>195,236</sup>

### Afibrinogenemia

Afibrinogenemia is a rare autosomal recessive disorder with a reported prevalence of 1 in 1,000,000 and a higher incidence in consanguineous marriages.<sup>234</sup> Over 80 distinct mutations, with a majority in the  $\alpha$  chain, have been identified in afibrinogenemia and individuals who are homozygotes or compound heterozygotes.<sup>195</sup> It is characterized by an undetectable plasma fibrinogen level.

Many individuals are diagnosed in the neonatal period as up to 85% of cases of afibrinogenemia present with umbilical stump bleeding. Some present later in life following a significant bleeding challenge. Mucocutaneous bleeding, muscle hematomas, oral cavity bleeding, prolonged bleeding after venous puncture, GI bleeding, and hemarthroses have all been reported in afibrinogenemia. ICH is a major cause of death in this population.<sup>234</sup> Afibrinogenemic women have gynecologic complications including menorrhagia, spontaneous recurrent abortions, as well as ante and postpartum

hemorrhage.<sup>210,234</sup> Issues with wound healing and wound dehiscence have also been reported.<sup>235</sup> Importantly, both arterial and venous thromboembolic events have been reported in afibrinogenemia both before and after replacement therapy, so close monitoring and high clinical suspicion are warranted.<sup>210,234,235</sup>

### Hypofibrinogenemia

Hypofibrinogenemia is inherited in an autosomal fashion and is associated with heterozygous fibrinogen gene mutations, thus is more prevalent than afibrinogenemia.<sup>234,236</sup> Hypofibrinogenemia is characterized by a fibrinogen level <100 mg/dL. Patients are often asymptomatic, but may have a mild bleeding phenotype. Many are only diagnosed after a major hemostatic challenge. Bleeding after trauma, hematomas, menorrhagia, and GI bleeding are the most frequently reported bleeding symptoms and wound healing can also be an issue.<sup>195,234,235</sup>

### Dysfibrinogenemia and hypodysfibrinogenemia

Dysfibrinogenemia and hypodysfibrinogenemia are rare autosomal dominant disorders caused by heterozygous missense mutations in one of the three fibrinogen genes, making them more prevalent than type 1 disorders.<sup>234</sup> Patients are frequently asymptomatic, but can present with a bleeding diathesis (usually bleeding after trauma/surgery or postpartum) or thrombosis.<sup>210,234,235</sup> Women can suffer from spontaneous abortions, stillbirths, and postpartum thrombosis.<sup>234,235</sup>

### Diagnosis

Any test that depends on fibrin as the end point (PT, aPTT, and TT) will be prolonged in hypofibrinogenemia or afibrinogenemia.<sup>234,235</sup> Erythrocyte sedimentation rates are determined mainly by fibrinogen and thus will be low. Absence of immunoreactive fibrinogen must be demonstrated to diagnose afibrinogenemia, while a proportional decrease in functional and immunoreactive fibrinogen is required to diagnose hypofibrinogenemia.<sup>234</sup>

For dysfibrinogenemia, screening should include a TT, reptilase time, as well as an immunologic and functional fibrinogen assay. Classically, TT will be prolonged while the immunologic fibrinogen assay will be normal and the functional fibrinogen assay will be low.<sup>234,235</sup> With normal functional fibrinogen present, a prolonged reptilase time is consistent with dysfibrinogenemia. Hypodysfibrinogenemia will show both a qualitative defect as well as a quantitative defect with fibrinogen levels of 50–120 mg/dL.<sup>235</sup> Mutation analysis should be obtained if possible as it can provide useful information for carrier testing and prenatal diagnosis.

### Management

Fibrinogen levels of 100–150 mg/dL are generally considered to be sufficient for hemostasis, so <100 mg/dL is typically used as the trigger for fibrinogen replacement.<sup>237</sup> FFP, cryoprecipitate, and fibrinogen concentrates are all available for fibrinogen replacement. Since the  $t_{1/2}$  of fibrinogen is so long, every other day replacement is usually sufficient for prolonged courses of treatment.

Plasma-derived fibrinogen concentrates have been approved for the management of acute bleeding events in adults and children with hypofibrinogenemia and afibrinogenemia only (RiaSTAP, CSL Behring, USA; Fibryga, Octapharma, USA).<sup>238,239</sup> Therapeutic doses can be administered in relatively small volumes with a minimal risk of bloodborne viral transmission. The risk of thrombosis with fibrinogen concentrates is low, and these agents have been shown to have a better clinical efficacy profile than FFP.<sup>237</sup> Initial dosing should be 70 mg/kg with a goal fibrinogen level of 100 mg/dL.<sup>237,240</sup>

Life-threatening bleeds and surgical procedures may require higher initial doses as well as more frequent dosing to maintain higher fibrinogen levels.<sup>240</sup>

FFP dosed at ~15 mL/kg can be used for fibrinogen replacement, noting an average fibrinogen concentration of 2.5 g/L although with significant variations.<sup>237</sup> Cryoprecipitate contains about 15 g/L of fibrinogen, and one unit of cryoprecipitate per 5–10 kg of body weight should increase the fibrinogen concentration by 50–100 mg/dL. Again, these products do share similar limitations due to risks of fluid overload, exposure to blood born viruses, and thrombosis.

Weekly prophylactic fibrinogen replacement may be appropriate in certain situations. Primary prophylaxis to prevent bleeding episodes should be considered in patients with afibrinogenemia. Secondary prophylaxis could be considered in individuals with recurrent severe bleeding, such as hemarthroses and hematomas, or after a life-threatening bleed (ICH). Prophylaxis plans should be individualized due to the associated potential thrombotic risk.<sup>236</sup>

Antifibrinolytic therapy may also be helpful in certain situations. Particularly, it may be useful following dental procedures or to treat mucosal bleeding. Fibrin glue is another option to aid in the treatment of superficial wounds.<sup>234</sup>

Women with congenital afibrinogenemia can conceive, but pregnancies usually end in spontaneous abortion by 5–8 weeks.<sup>234</sup>

It is recommended that fibrinogen levels should be maintained at >50 mg/dL during the first two trimesters, >100 mg/dL during the third trimester, and >150 mg/dL during labor.<sup>241</sup>

## CHAPTER 38

# Coagulation factor concentrates and pharmacologic therapies for acquired bleeding disorders

Natalie Bavli<sup>1</sup> & Ravi Sarode<sup>1,2</sup>

<sup>1</sup>Department of Internal Medicine (Hematology/Oncology), University of Texas Southwestern, Dallas, TX, USA

<sup>2</sup>Director of Transfusion Medicine and Hemostasis, Department of Pathology, University of Texas Southwestern, Dallas, TX, USA

## Introduction

Acquired bleeding disorders are much more common than congenital bleeding disorders and may occur in association with specific clinical conditions or may arise spontaneously in otherwise healthy patients. Unlike inherited bleeding disorders, acquired bleeding disorders are often diagnosed in adults, where they may present at any age. Bleeding symptoms can vary from mild bruising and mucosal bleeding to prolonged postoperative bleeding and severe hemorrhage. Management of bleeding in patients with acquired coagulation disorders requires prompt recognition of the underlying disorder to guide therapy.

Under physiologic conditions, hemostasis is achieved through the constriction of damaged vessels, activation of primary hemostasis leading to the formation of a platelet plug, and activation of secondary hemostasis, resulting in a stabilized fibrin clot at the site of bleeding. Parallel to this, the fibrinolytic system is activated to control clot formation and propagation and dissolve the unnecessary (and potentially dangerous) clots after hemostasis is achieved. Specific and nonspecific hemostatic and prothrombotic agents exploit these physiologic pathways to tip the balance toward forming and maintaining clots, thereby reducing bleeding. In this chapter, the coagulation factor concentrates, both recombinant and human-derived, and the pharmacologic agents utilized to manage acquired bleeding disorders are reviewed.

## Prothrombin complex concentrate

### Nonactivated prothrombin complex concentrate

#### Overview

Prothrombin complex concentrates (PCCs) contain vitamin-K-dependent coagulation factors (VKDFs) and are available as activated and nonactivated concentrates. Nonactivated three-factor PCC (3F-PCC) contains variable concentrations of factors II, IX, and X, while four-factor PCC (4F-PCC) also contains a sufficient amount of factor VII (and proteins C and S) (Table 38.1).

### Manufacturing and storage

PCCs are plasma derivatives prepared from pooled human plasma purified from either DEAE cellulose adsorption (e.g., Profilnine SD) or ion exchange chromatography (e.g., Kcentra). Viral inactivation is performed with either vapor heat (e.g., Kcentra) or solvent detergent (e.g., Profilnine SD). Clotting factors remain inactivated through the addition of heparin or antithrombin, or adjusting the pH. PCCs are stored at room temperature as a lyophilized powder and can be reconstituted rapidly with a small diluent volume, which allows for rapid administration.

### Indications

Most PCCs are approved for prophylaxis and treatment of factor IX deficiency in patients with hemophilia B. However, with the advent of high purity plasma-derived factor IX concentrates and recombinant factor IX products, PCCs are no longer used for this indication.

The main approved indication for 4F-PCC is the urgent reversal of vitamin K antagonists (VKA), where they constitute the first line of treatment (Table 38.2).<sup>1,2,3</sup> PCCs contain concentrated VKDFs that are approximately 25 times higher than in normal plasma, which allows for a smaller infusion volume compared to FFP and decreased risk of transfusion-associated circulatory overload.<sup>4</sup> Advantages of PCC over plasma also include rapid administration, lack of required ABO blood typing, and lower risks of allergic reactions, transfusion-associated lung injury, and viral transmission. Additionally, vitamin K should be administered along with PCCs due to the relatively short half-lives of VKDFs in the PCCs.

In a large phase IIIb study comparing 4F-PCC and plasma for urgent VKA reversal in patients with major bleeding, 4F-PCC achieved rapid INR reduction in 62.2% of patients compared with 9.6% of patients receiving plasma (difference 52.6%; 95% confidence interval [CI], 39.4–65.9%). Additionally, 4F-PCC was non-inferior in achieving effective hemostasis in 72.4% of treated patients versus 65.4% of patients transfused with plasma (difference 7.1%; 95% CI, 5.8–19.9%).<sup>5</sup> However, for visible bleeding,

**Table 38.1** Prothrombin Complex Concentrates

Products	Factor Levels (IU/mL)			
	II	VII	IX	X
Available in the USA				
<b>Four-factor PCC</b>				
Kcentra (CSL Behring)	17–40	10–25	20–31	25–51
<b>Three-factor PCC</b>				
Profilnine SD (Grifols)	≤150	≤35	≤100	≤100
Bebulin VH (Baxter)	24–38	<5	24–38	24–38
Available outside the USA				
<b>Four-factor PCC</b>				
Beriplex (CSL Behring) <sup>a</sup>	20–48	10–25	20–31	22–60
Octaplex (Octapharma) <sup>b</sup>	14–38	9–24	25	18–30
Cofact (Sanquin) <sup>c</sup>	14–35	7–20	25	14–35
Prothromplex T (Baxter) <sup>d</sup>	30	25	30	30
PPSB-Th <sup>e</sup>	20	20	20	20
<b>Three-factor PCC</b>				
Prothromplex HT (Baxter) <sup>f</sup>	30	–	30	130

The values given are the number of units per 100 factor IX units (IU/mL) in each 20 mL vial.

**Table 38.2** Guidelines for Management of Elevated INR in Patients on Vitamin K Antagonists. Based on Recommendations from the 2012 ACCP 9th Edition Guidelines<sup>17</sup> and ASH 2018 Guidelines<sup>18</sup>

Clinical Setting	INR	Management
Absent bleeding	>4.5 but <10	Temporary cessation of VKA alone without the use of vitamin K
Absent bleeding	>10	Temporary cessation of VKA with or without the addition of oral vitamin K
Life-threatening bleeding	Elevated INR	4F-PCC and vitamin K (5–10 mg by slow intravenous infusion) in addition to cessation of VKA

4F-PCC was superior to plasma.<sup>6</sup> In another phase IIIb study comparing PCC with plasma for urgent surgery, 4F-PCC was superior to plasma for rapid INR correction, shorter wait time for surgery, and blood loss.<sup>7</sup>

4F-PCCs have not been compared head to head with 3F-PCCs for the treatment of VKAs, but 3F-PCCs are thought to be inferior due to nontherapeutic levels of factor VII and lack of proteins C and S. If 4F-PCC is unavailable, a 3F-PCC can be given, often with a small amount of plasma and intravenous vitamin K to provide factor VII.

These PCCs have also been used off-label for the reversal of factor Xa inhibitors, apixaban and rivaroxaban, although there is limited data to support their use since evaluations have been limited to single-arm observational studies. A recent systematic review of a case series including 340 patients who received PCC to treat direct FXa inhibitor-related major bleeding showed a pooled proportion of patients with effective hemostasis of 69% (95% CI, 61–76%) or 77% (95% CI, 63–92%), depending on the criteria used, and a thromboembolism rate of 4% (95% CI, 1–8%).<sup>8</sup> Given the low certainty of this evidence, PCC is generally considered second-line therapy if Andexanet alfa (see later) is not available for the reversal of factor Xa inhibitors.<sup>9,10</sup>

## Dosing

PCCs are standardized according to factor IX content, and dosing is often based on units of factor IX per kg of body weight. The concentrations of VKDF factors in PCCs vary by the manufacturers and lot numbers and are listed on the vial. In patients with INR prolongation due to VKA, dosing is either based on body weight and degree of INR prolongation (as per package insert) or fixed dosing based on real-life experience publications. If weight-based dosing is given, repeated dosing is not recommended because it does not increase efficacy and may inadvertently increase the risk of thromboembolic complications. To date, fixed versus weight-based dosing has not been compared in a randomized trial. Vitamin K should be given in addition to PCC for the treatment of VKA reversal.

## Adverse reactions

The most common serious adverse reactions are thromboembolic events (TEEs), although the overall risk is low. Most TEEs are due to delay in re-anticoagulation following a major bleed in patients with an underlying hypercoagulable state. In a meta-analysis of 27 studies, including 1032 patients, the incidence of TEE was 1.4% (95% CI, 0.8–2.1).<sup>11</sup> Recognized adverse effects also include allergic reactions. Additionally, there is a theoretical risk of heparin-induced thrombocytopenia in heparin-containing PCC products. However, since there are no reported HIT-related cases from PCC therapy, this risk is considered theoretical, especially in a bleeding patient.

## Activated prothrombin complex concentrate Overview

Activated PCCs (APCCs) are PCCs that contain some activated factors. The only available APCC in the United States is FEIBA (factor VIII inhibitor bypassing agent), which consists of mainly activated factor VII, likely activated FX (because FEIBA is given every 8–12 hours and FVIIa has a  $t_{1/2}$  of 2 hours), and nonactivated II and IX.

## Manufacturing and storage

FEIBA is purified from pooled human plasma by DEAE-Sephadex adsorption, and viral transmission is reduced through nanofiltration and vapor heat treatment. FEIBA is stored as a lyophilized powder in single-use vials containing 500, 1000, or 2500 units per vial.

## Indications

APCC is approved in patients with hemophilia A or B with inhibitors to control and prevent bleeding, as well as to manage perioperative bleeding.<sup>12</sup> It is not indicated in hemophilia A or B patients without inhibitors. It is often the first line of therapy for patients with acquired hemophilia A due to autoantibodies who present with bleeding. Acquired hemophilia is a rare condition with a bimodal presentation affecting young women during the postpartum period and the elderly (>70 years). Most bleeds are in soft or fatty tissues (abdominal wall, buttocks, breast, etc.) rather than joint bleeding.

Generally, nonactivated 4F-PCC is preferred over APCC for the urgent reversal of VKAs due to the theoretical prothrombotic risks associated with the presence of activated FVII/Xa in APCC. APCC has also been used off-label for direct Xa anticoagulant reversal, although no high-quality randomized studies support its use. If idarucizumab is not available, APCC may be considered for reversing the dabigatran effect in life-threatening bleeding, although only a few small retrospective case series and observational studies support its use.<sup>13–16</sup>

## Dosing

For the treatment of bleeding in patients with acquired hemophilia, dosage and frequency depends on the type and extent of bleeding but is typically dosed as 50–100 IU/kg intravenously every 8–12 hours until clinical response, with a maximum of 100 IU/kg for a single dose and a maximum daily dose of 200 IU/kg. In the event that idarucizumab is unavailable, a single dose of APCC at 50 IU/kg may be given to manage bleeding due to dabigatran.

## Adverse reactions

Due to the presence of activated factor VII (and FXa), APCC increases the risk of both arterial and venous thromboembolic events and should be used with caution in patients with high thrombotic risk. Furthermore, APCC is contraindicated in the setting of disseminated intravascular coagulation or acute thrombosis. All acquired hemophilia patients receiving more than a few days of APCC should be monitored for DIC development.

## Recombinant activated factor VII

### Overview

Recombinant activated factor VII (rFVIIa) is a vitamin-K-dependent glycoprotein that initiates the tissue factor pathway of the coagulation cascade. At physiologic concentration, rFVIIa complexes with tissue factor (TF) at the site of vascular injury, forming the TF-FVIIa complex (a tenase). This complex is a key initiator of the coagulation cascade. It activates FX, which in turn combines with factor Va to form a prothrombinase complex, and it is this complex that activates prothrombin to thrombin. The resulting small burst of thrombin catalyzes a series of reactions on the platelet membrane essential for a larger thrombin burst, but also activates tissue factor pathway inhibitor (TFPI) to shut down the tissue factor pathway. At pharmacologic doses, rFVIIa can bind to activated platelets, which concentrates factor X activation to tissue injury sites and subsequently activates thrombin (bypassing the intrinsic pathway factors), or may also generate more thrombin by overwhelming TFPI.

### Manufacturing and storage

There are two FDA-approved recombinant factor VIIa products in the United States, NovoSeven RT and SevenFact, which have different properties, dosing, and approved indications. NovoSeven is a recombinant glycoprotein that is cloned and expressed in baby hamster kidney cells (BHK cells) followed by a chromatographic purification process during which the single-chain protein is proteolytically converted by autocatalysis to its active two-chain form. NovoSeven is available as a lyophilized powder in single-use vials of 1, 2, 5, or 8 mg which are stored at room temperature and need to be reconstituted before administration. After reconstitution, the solution may be stored at room temperature or refrigerated for up to three hours.

SevenFact is produced using genetically modified transgenic rabbits. Human factor VII is expressed in the rabbit mammary gland, secreted into the milk, and converted to its activated form during purification. SevenFact is stored as a lyophilized powder in single-use vials containing 1 or 5 mg, and is reconstituted in single-dose prefilled glass syringes. After reconstitution, the dose must be given within four hours.

### Indications

NovoSeven and SevenFact have different approved indications. Both products are approved in the United States to manage hemophilia A or B with inhibitors (SevenFact is only approved for

individuals ≥12 years of age). NovoSeven is also approved for the treatment of patients with acquired hemophilia, congenital factor VII deficiency, and Glanzmann's thrombasthenia with refractoriness to platelet transfusions.

There is growing use of rFVIIa for off-label indications. In fact, the vast majority of patients given rFVIIa in the United States receive it for off-label indications despite the questionable clinical benefit and lack of established dosing in this context.<sup>19,20</sup> The most common off-label uses of rFVIIa include cardiovascular surgery, trauma, and liver disease. Some clinical studies have shown reduced blood product utilization, but have not demonstrated improvements in more clinically relevant outcomes like reduced morbidity or mortality when rFVIIa is used for cardiovascular surgery,<sup>21,22</sup> traumatic coagulopathy,<sup>23,24</sup> or intracerebral hemorrhage.<sup>25</sup> There have also been reports of rFVIIa usage in the treatment of patients receiving anticoagulants, although specific reversal agents are preferred, with recent neurocritical guidelines recommending against the use of rFVIIa for VKA reversal in patients with intracranial hemorrhage.<sup>26–28</sup> The use of rFVIIa in off-label indications has also raised safety concerns with increased TEE.<sup>29,30</sup> Therefore, off-label uses of rFVIIa should be approached with caution, especially in patients at high risk for venous thromboembolism, and only given in life-threatening bleeding that has failed to respond to conventional therapies.

### Dosing

In patients with congenital hemophilia A or B with inhibitors, the typical dose of NovoSeven is 90–120 µg/kg administered as an intravenous bolus. Due to the short half-life of NovoSeven ( $t_{1/2}$  is about 2–3 hours), NovoSeven is typically given every 2–3 hours based on clinical response. SevenFact is dosed either as an initial bolus of 75 or 225 µg/kg, depending on the bleed severity. Since the half-life of SevenFact is similarly short ( $t_{1/2}$  is about 1.4–1.7 hours), the timing of subsequent doses depends on the initial bolus dose and the severity of the bleed.

Slightly lower doses of NovoSeven are given in acquired hemophilia, typically 70–90 µg/kg every 2–3 hours until hemostasis is achieved. In Glanzmann's thrombasthenia, dosing is typically 90 µg/kg every 2–6 hours until hemostasis is achieved. In patients with congenital factor VII deficiency, lower doses are administered, typically 15–30 µg/kg/dose every 4–6 hours, since the goal is to maintain hemostatic levels of FVII rather than bypass the intrinsic pathway factors. There is no established laboratory monitoring to guide the response to rFVIIa, so repeated administration should be based on clinical responses.<sup>31</sup> Dosing for off-label indications is not well established.

### Adverse reactions

rFVIIa carries a US boxed warning for arterial and venous thrombotic events. However, the rate of serious arterial and venous thrombotic events is low when rFVIIa is used for the four approved indications: hemophilia A or B with inhibitors, acquired hemophilia, congenital Factor VII deficiency, and Glanzmann's thrombasthenia.<sup>32,33</sup> Risk factors for thrombosis in these populations include older age, cardiac and cardiovascular disease, and concomitant use of APCC. rFVIIa should also be used with caution in patients with increased tissue factor expression, such as those with crush injury, septicemia, and disseminated intravascular coagulation.

As noted above, safety concerns have arisen when rFVIIa is used for off-label indications with increased TEE reported.<sup>34–36</sup> A large comprehensive review of 35 placebo-controlled trials of rFVIIa

demonstrated a high overall increased risk of arterial but not venous thromboembolic rates, especially among the elderly.<sup>37</sup>

Neutralizing alloantibodies to endogenous factor VII following exposure to rFVIIa have been reported in patients with severe congenital factor VII deficiency<sup>38</sup> but have not been reported in patients receiving rFVIIa for other indications.<sup>39</sup> rFVIIa is also associated with hypersensitivity reactions related to the manufacturing process. SevenFact is contraindicated in patients with an allergy to rabbit or rabbit proteins due to the risk of severe hypersensitivity reactions.

## Vitamin K

### Overview

Vitamin K is a fat-soluble vitamin that occurs in two bioactive forms. Vitamin K<sub>1</sub> (phylloquinones) is synthesized by plants and is the major dietary source of vitamin K. Vitamin K<sub>2</sub> (menaquinones) is produced by intestinal bacteria, and is also found in animal and soy protein products, but has limited bioavailability. Vitamin K has a major role in hemostasis as it is a required cofactor in hepatic cells for making coagulation factors II, VII, IX, and X, and the natural anticoagulant proteins C, S, and Z functional. The vitamin-K-dependent  $\gamma$ -carboxylation of glutamic acid residues to  $\gamma$ -carboxylated glutamyl at the N-terminal regions of the VKDF provides Ca<sup>2+</sup>-binding sites that are necessary for binding to anionic phospholipids at the sites of tissue injury. Vitamin K is a cofactor in the  $\gamma$ -carboxylation reactions and is subsequently reduced to an inactive vitamin K epoxide. Vitamin K epoxide reductase (VKOR) recycles vitamin K epoxide to reduce vitamin K to be reused. Warfarin and other VKAs produce their antithrombotic effects by blocking the action of VKOR and thus inhibiting the cyclic regeneration of active vitamin K. In conditions of vitamin K deficiency, there is diminished functionality of noncarboxylated proteins (also known as “proteins induced in vitamin K absence” or PIVKAs) that cannot bind to the phospholipid membrane and Ca<sup>2+</sup>, impairing hemostasis.

The daily dietary requirement of vitamin K is small (100–200  $\mu$ g/day), and vitamin K can easily be recycled, so vitamin K deficiency is rare in an otherwise healthy child or adult. However, acquired vitamin K deficiency can occur from inadequate intake or in patients with fat malabsorption syndromes, including celiac disease, sprue, inflammatory bowel disease, pancreatic insufficiency, cystic fibrosis, extensive small bowel resection, and severe biliary stasis, as well as ingestion of overdoses of vitamin E or salicylates. Antibiotic therapy contributes to vitamin K deficiency by inhibiting the synthetic capacity of vitamin-K-producing bacteria.<sup>40</sup> Certain antibiotics, such as cephalosporins, contain an N-methylthiotetrazol ring that directly interferes with VKOR and prevents the recycling of vitamin K. The combination of inadequate dietary intake of vitamin K and the use of broad-spectrum antibiotics is an insidious cause of vitamin K deficiency in hospitalized patients.

### Manufacturing and storage

Both vitamin K<sub>1</sub> and K<sub>2</sub> are biologically active, but only vitamin K<sub>1</sub> is available for use. It is available as an oral capsule or tablet, and also as an injectable emulsion that can be administered intravenously, intramuscularly, or subcutaneously. Due to the poor water solubility of vitamin K, a small amount of solvent or emulsifier (e.g., polyoxyethylated fatty acid derivative) is added to dissolve the vita-

min K into liquid form. The solution has a concentration of 1 mg/0.5 mL or 10 mg/mL. If a patient cannot swallow tablets, the parenteral form can also be administered in small oral doses.<sup>41</sup>

### Indications

The FDA-approved indications of vitamin K<sub>1</sub> include the treatment of coagulation disorders due to vitamin K deficiency, management of excessive anticoagulation due to VKAs, and VKDF deficiency secondary to other drugs or malabsorption factors limiting absorption, synthesis, or metabolism of vitamin K.

Vitamin K<sub>1</sub> is important in the treatment of accidental or surreptitious ingestion of superwarfarin rodenticides. After growing resistance to warfarin rodenticide among rodent populations, superwarfarin rodenticides, most commonly brodifacoum, were developed which are remarkably potent VKOR antagonists with exceedingly long half-lives (weeks to months) relative to warfarin.<sup>42</sup> Ingestion of these superwarfarin rodenticides can result in life-threatening bleeding, and treatment requires large doses of vitamin K<sub>1</sub> for up to 6–9 months.

Vitamin K<sub>1</sub> is also FDA approved for the prevention and treatment of vitamin K deficiency bleeding (VKDB), previously known as hemorrhagic disease of the newborn, which is a rare hemorrhagic disease in newborns that can cause life-threatening bleeding. Newborns have a physiologic deficiency of vitamin K due to several factors: the immature liver that does not effectively utilize vitamin K, the sterile gut, the poor placental transfer of vitamin K, and the low concentration of vitamin K in breast milk. The risk of VKDB can be further increased by prematurity, intestinal malabsorption defects, liver disease, and maternal exposure to warfarin, anticonvulsant drugs, or antituberculosis drugs. Prophylactic administration of vitamin K<sub>1</sub> to newborns diminishes the transient decrease in vitamin-K-dependent factors and prevents VKDB.<sup>43</sup> This practice is mandated by law in many countries, which accounts for the rarity of the disorder in the developed world.

The off-label use of vitamin K<sub>1</sub> in liver disease is common practice, but there is a lack of high-quality evidence to support this indication. There is an impaired synthesis of clotting factors from hepatic dysfunction in liver disease, leading to a prolonged prothrombin time (PT). Vitamin K<sub>1</sub> supplementation rarely improves coagulation parameters in patients with liver disease,<sup>44</sup> and there is a lack of randomized studies to support the use of vitamin K<sub>1</sub> in this population.<sup>45</sup>

### Dosing

The dose and route of vitamin K<sub>1</sub> depends on the severity of the clinical manifestations and the underlying cause. The intravenous route results in a more rapid reduction of the INR compared to subcutaneous or oral administration, but bears the risk of extremely rare anaphylactic reactions.<sup>46,47</sup> The rate of intravenous administration should not exceed 1 mg/minute to minimize the risk of this and other infusion reactions. Subcutaneous administration of vitamin K<sub>1</sub> is associated with an unpredictable response, particularly in patients with anasarca, and is, therefore, generally not recommended.<sup>48,49</sup> Intramuscular administration can cause hemorrhage, so this route should also be avoided aside from prophylaxis against VKDB.

Management of excessive anticoagulation from VKA should be guided by the degree of INR prolongation and the presence or absence of clinical bleeding (Table 38.2).<sup>50,51</sup> Minor or moderate elevation of the INR (above the therapeutic range but less than 10) in the absence of bleeding can generally be managed safely by

decreasing or omitting several warfarin doses or giving low-dose vitamin K<sub>1</sub>. Significant elevation of the INR (greater than 10), even in the absence of clinically evident bleeding, is generally treated by temporary discontinuation of warfarin and administration of vitamin K<sub>1</sub> (5–10 mg orally). If there is major or life-threatening bleeding from warfarin, then 10 mg of intravenous vitamin K<sub>1</sub> should be administered due to the faster onset of action in addition to cessation of VKA and administration of 4F-PCC. In cases of ingestion of superwarfarin rodenticides, vitamin K<sub>1</sub> doses in excess of 100 mg orally daily may be required because of the potency and extremely long biological half-lives of these poisons.<sup>52</sup>

For the treatment of vitamin K deficiency, typically 10 mg of vitamin K<sub>1</sub> restores adequate levels of vitamin-K-dependent coagulation factors within 24 hours. The dose can be repeated in 48–72 hours if the PT remains prolonged.

To prevent VKDB, all newborns should receive a single, intramuscular dose of 0.5–1 mg of vitamin K<sub>1</sub>.<sup>53</sup> If parents decline the intramuscular route, an alternative option is repeated doses of 2 mg oral vitamin K<sub>1</sub>.<sup>54</sup>

### Adverse reactions

Parental vitamin K<sub>1</sub> has a boxed warning for hypersensitivity reactions at an incidence of 3 per 10,000 doses of intravenous vitamin K<sub>1</sub>.<sup>55</sup> The reactions are consistent with an anaphylactoid reaction, may be related to the solubilizer, and can lead to severe hypotension, bradycardia or tachycardia, bronchospasm, and death. Risk factors may include faster administration rate, higher doses, and inadequate dilution. Less severe reactions may occur, including local site reaction, flushing, dizziness, and dysgeusia.

## Antifibrinolytic agents

### Overview

Fibrinolysis is responsible for clot resorption and requires the conversion of plasminogen to active plasmin on the surface of the fibrin clot by tissue plasminogen activator or urokinase. Plasmin cleaves fibrin into fibrin degradation products. The antifibrinolytic agents tranexamic acid (TXA) and  $\epsilon$ -aminocaproic acid (EACA) are synthetic lysine analogs that competitively block the lysine binding sites on plasminogen, inhibiting its ability to interact with the lysine residues on the fibrin surface and subsequent activation to plasmin. The main difference between TXA and EACA is that TXA is 7–10 times more potent, so lower doses are required to achieve the same effect as EACA.<sup>56</sup>

### Manufacturing and storage

TXA is available in intravenous and oral tablet form. An oral solution can also be compounded for topical applications. EACA is available as an intravenous solution, oral tablet, and oral solution.

### Indications

Antifibrinolytic agents are useful in the management of mucosal bleeding where high fibrinolytic activity can occur. EACA is FDA approved for the treatment of bleeding due to high fibrinolytic activity and the treatment of traumatic hyphema. TXA is only FDA approved for menstrual bleeding<sup>57</sup> and short-term treatment and prevention of bleeding in hemophilia during and following tooth extractions.<sup>58</sup> Both TXA and EACA have been successfully employed in numerous off-label clinical settings and have generally been safe and effective, as detailed below.

Antifibrinolytic agents have demonstrated efficacy with reduced blood loss and transfusion requirement in numerous elective and emergency surgical settings. The most widely studied are cardiothoracic<sup>59</sup> and orthopedic surgeries<sup>60–62</sup> with smaller studies in other surgical fields such as urology, vascular, thoracic, neurosurgery and otorhinolaryngology. A large meta-analysis showed that TXA reduces blood loss in surgical patients by one-third compared to placebo.<sup>63</sup> A 2011 Cochrane systemic review similarly showed that TXA decreases the need for a perioperative blood transfusion by 39% compared to placebo (RR 0.61, 95% CI, 0.53–0.7).<sup>64</sup> EACA also reduced the need for a perioperative blood transfusion by 19% (RR 0.81; 95% CI, 0.67–0.99). Neither agent increased the risk of deep vein thrombosis, pulmonary embolism, myocardial infarction, or stroke.

Antifibrinolytics are also safe and effective in reducing bleeding and mortality in trauma, with TXA being the most well-studied antifibrinolytic agent in this setting. The CRASH-2 trial randomized over 20,000 trauma patients to receive TXA or placebo and showed reduced mortality with early administration of TXA.<sup>65</sup> Empiric TXA reduced both all-cause mortality (14.5% vs. 16%;  $p = 0.004$ ) and bleeding-related mortality (4.9% vs. 5.7%;  $p = 0.0077$ ) without increasing thromboembolic events. There have been numerous criticisms of the CRASH-2 trial, including (1) the small difference in mortality of less than 1% that may not be clinically relevant, (2) the greatest efficacy occurred if TXA was administered within three hours of injury (with increased risk of death observed if TXA was administered after three hours), and (3) only half of the patients received a blood transfusion or emergent surgery. The MATTERs study, a retrospective review of the military experience, similarly showed improved survival with the use of TXA following combat injury but raised the concern of increased thromboembolic events (although this was the only study that showed increased thrombosis rates with TXA).<sup>66</sup> The CRASH-3 trial randomized over 12,000 adults with traumatic brain injury and found early administration of TXA within three hours of injury reduces head-injury-related death.<sup>67</sup> The use of early administration of antifibrinolytics is likely to be the most beneficial in trauma patients with hyperfibrinolysis guided by viscoelastic measurements.

TXA also reduces blood loss during cesarean section<sup>68</sup> and vaginal delivery. The WOMAN study showed early administration of TXA decreased bleeding-related mortality among women with postpartum hemorrhage (PPH) (1.5% vs. 1.9%,  $p = 0.045$ ) with no increase in thromboembolic events.<sup>69</sup> Accordingly, the 2012 WHO recommendations include the use of TXA for the treatment of PPH.<sup>70</sup> Evidence to support prophylactic administration of TXA in vaginal deliveries to prevent postpartum hemorrhage is less robust, with a large randomized trial showing no effect.<sup>71</sup>

Antifibrinolytics are commonly used prophylactically as an adjunct therapy in patients with hematologic malignancy, but there is a lack of clearly established benefit. A 2016 Cochrane review included only 86 patients with hematological disorders and severe thrombocytopenia and showed no significant reduction of bleeding with antifibrinolytics.<sup>72</sup> The a-Treat trial randomized over 300 patients with hematologic malignancy and therapy-induced thrombocytopenia to TXA or placebo in addition to routine platelet transfusions; this study found no difference in WHO Grade 2+ bleeding.<sup>73</sup>

Antifibrinolytics have also been used in off-label settings including dental procedures for patients on oral anticoagulation,<sup>74</sup> gastrointestinal bleeding,<sup>75</sup> epistaxis, hemoptysis, and surgical-related bleeding in patients with hereditary bleeding disorders like von

Willebrand disease or hereditary thrombocytopathies.<sup>76,77</sup> In some cases, it may be beneficial to reconstitute TXA as an oral solution and apply it topically to improve hemostasis.<sup>78</sup>

### Dosing

Dosing regimens and routes of TXA and EACA vary significantly in individual studies and depend on the clinical indication. TXA is typically administered at 10 mg/kg intravenously three times daily for 2–8 days. Oral TXA is available as 650 mg tablets and can be given as 1300 mg three times daily for a maximum of five days during menses. EACA is usually dosed as 50–100 mg/kg followed by 50 mg/kg every six hours with a maximum of 24 g in 24 hours. Because of high bioavailability, the same dose of EACA is given intravenously or orally. Given the predominant renal excretion (95% for TXA and 65% for EACA), dose adjustments should be made in the setting of renal insufficiency. Generally, EACA is preferred over TXA in the setting of renal insufficiency.

### Adverse reactions

It must be remembered that antifibrinolytic agents stabilize a pre-formed clot—they do not promote thrombosis per se. Thus, despite the theoretical risk of thrombosis associated with antifibrinolytics, numerous studies have shown that these agents are generally safe without an increase in TEE. Nonetheless, antifibrinolytics are generally contraindicated in patients with active thrombosis. In disseminated intravascular coagulation (DIC), antifibrinolytics should be used with caution due to the risk of impairing fibrinolysis and potentiating severe thrombosis. However, antifibrinolytics may have a role in patients with hyperfibrinolytic DIC. Antifibrinolytics are contraindicated in patients with upper urinary tract bleeding due to the risk of glomerular capillary thrombosis and intrarenal and intraureteral obstruction.

Both EACA and TXA are generally well tolerated; however, the long-term use of EACA has been associated with skeletal muscle weakness and rhabdomyolysis.<sup>79</sup> TXA can cause mild headaches, muscle weakness, and visual disturbances. It has also been associated with seizures, particularly with higher doses or in patients with underlying renal dysfunction, which is thought to be from dose-dependent CNS hyperexcitability. Rapid infusions of TXA can cause hypotension, so infusion rates should not exceed 1 mL/minute.

## Desmopressin

### Overview

Desmopressin (1-deamino-8-d-arginine vasopressin, DDAVP) is a synthetic analog of vasopressin that induces the release of von Willebrand factor (VWF) and factor VIII from storage sites within the endothelial cells. Compared to the natural hormone vasopressin, which activates both V<sub>1</sub> and V<sub>2</sub> receptors, DDAVP has no appreciable pressor activity due to decreased affinity for V<sub>2</sub> receptors and has enhanced diuretic potency due to increased affinity for the V<sub>1</sub> receptors.<sup>80</sup> Tissue plasminogen activator (tPA) is also released from Weibel-Palade bodies by DDAVP, but the excess plasmin is mostly complexed to α<sub>2</sub>-antiplasmin and does not contribute to fibrinolysis.<sup>81</sup> The mechanism of improved hemostasis following DDAVP administration in patients with platelet defects is unclear; it is likely independent of the increase of high-molecular-weight VWF multimers,<sup>82</sup> and may be mediated by enhanced interaction with the vascular subendothelium<sup>83</sup> and possibly increased platelet membrane glycoprotein expression.<sup>84</sup>

### Manufacturing and storage

DDAVP is available in intravenous, subcutaneous, and intranasal formulations. The intravenous formulation is available as a 4 µg/mL solution stored at 2–8 °C. In July 2020, there was a worldwide recall of DDAVP nasal sprays because of superpotency, and it is expected to remain off the market until mid-2023.

### Indications

The response to DDAVP varies depending on the underlying hemostatic abnormality, so it is generally useful to perform a DDAVP challenge to confirm responsiveness before clinical use. DDAVP is typically effective short term in patients with mild to moderate hemophilia A and type 1 von Willebrand disease (VWD) for minor bleeding, as well as for brief minor invasive procedures or dental work. Off-label use in type 2A VWD can be considered, although the response is variable. DDAVP is contraindicated in type 3 VWD due to a lack of efficacy and in type 2B VWD due to increased platelet binding leading to worsening thrombocytopenia and possibly bleeding. In patients with acquired von Willebrand syndrome (AVWS), DDAVP has about a 30% response rate, and the half-life of released VWF tends to be shorter.<sup>85</sup>

DDAVP is efficacious in certain conditions with normal factor VIII and VWF levels, including some patients with inherited platelet dysfunction,<sup>86</sup> antiplatelet-induced thrombocytopeny, uremic thrombocytopeny,<sup>87,88</sup> and cardiopulmonary bypass.<sup>89,90</sup> With the exception of perioperative blood loss after aspirin use, most of the studies evaluating DDAVP in these indications have only observed shortened bleeding times, and it remains unclear whether there is a reduction in more clinically significant bleeding. Additionally, with the increasing use of erythropoietin and resultant correction of the hemostatic defect in patients with chronic renal insufficiency,<sup>91</sup> there is a decreased frequency of uremic bleeding and the need for DDAVP in this population.

DDAVP does not seem to be effective in patients with liver cirrhosis. Early studies did demonstrate shortened bleeding time with DDAVP<sup>92,93</sup> but subsequent studies showed a lack of improvement in laboratory indices of primary hemostasis<sup>94</sup> and no benefit of DDAVP in variceal bleeding<sup>95</sup> or hepatectomy.<sup>96</sup>

### Dosing

Although DDAVP is available subcutaneously, it is predominantly administered intravenously or intranasally. Peak activity levels occur about 30 minutes after intravenous administration and 90–120 minutes after intranasal or subcutaneous administration. The half-life is 2–4 hours, although the half-life can be prolonged to nine hours in severe renal impairment. Typical intravenous dosing is 0.3 µg/kg diluted in 50–100 mL saline infused slowly over 30 minutes to avoid hypotension. The maximum single dose is 20–30 µg. Intranasal dosing is 150 or 300 µg depending on if the patient's weight is less than or greater than 50 kg, respectively. Doses may be repeated after 8–12 hours and then once daily thereafter. Tachyphylaxis can occur with more frequent dosing or after several days of DDAVP, so use should be limited to 2–3 days.

### Adverse reactions

Due to the antidiuretic effect, symptomatic hyponatremia and volume overload can occur. To minimize this risk, fluid restriction and electrolyte monitoring is recommended for 24 hours after use. Administration of DDAVP in children under the age of two years is contraindicated because of the risk of hyponatremic seizures. DDAVP has vasodilator properties caused by release of nitric oxide, leading to hypotension, tachycardia, and facial flushing.<sup>97</sup> The

intranasal formulation can also cause abnormal lacrimation, conjunctivitis, ocular edema, and rhinitis. Tachyphylaxis occurs with repeated dosing, possibly from depleted factor VIII and VWF stores. Mannucci *et al.*<sup>98</sup> showed an average decrease of 30% with the second dose of DDAVP compared with the initial dose, but there were no further reductions with the third or fourth dose. Given the predominant renal excretion, DDAVP is generally contraindicated in renal impairment with a creatinine clearance less than 50 mL/min, although it has been used off-label in patients with renal failure experiencing uremic bleeding.<sup>99</sup>

DDAVP should be used cautiously in patients with active cardiovascular disease because of reports of increased arterial thrombotic events, especially acute cerebrovascular thrombosis and myocardial infarction. A systemic review of 16 randomized trials evaluating the use of DDAVP to prevent perioperative blood loss in cardiac surgery showed a 2.4-fold increased risk of perioperative myocardial infarction with DDAVP compared to placebo (2.39; 95% CI, 1.02–5.6%).<sup>100</sup> However, a separate systemic review<sup>101</sup> and a meta-analysis<sup>102</sup> failed to show a statistically significant increased risk of arterial thrombosis with perioperative DDAVP.

## Protamine

### Overview

Protamine sulfate is a strongly basic, arginine-rich protein that binds to the negatively charged heparin molecules forming an inactive salt, neutralizing heparin's anticoagulant effect within minutes. The electrostatic binding of the cationic protamine sulfate with the anionic heparin results in a stable complex and displaces the antithrombin/heparin complex, allowing antithrombin to recover its activity.<sup>103</sup> Protamine also has intrinsic anticoagulant effects in the absence of heparin, including reducing platelet activity and aggregation, inhibition of coagulation factors (Va and Xa), and enhanced fibrinolysis. This activity can produce paradoxical increases in bleeding if protamine is overdosed. These anticoagulant effects are not detected by routine coagulation tests except in rotational elastometry (ROTEM). Heptem clotting time is typically more prolonged than Intem clotting time after cardiac bypass surgery, where a higher amount of protamine is given than needed for heparin neutralization.

### Manufacturing and storage

Protamine sulfate was initially derived from salmon fish sperm, but it is now increasingly produced with recombinant biotechnology. It is supplied as a solution with a concentration of 10 mg/mL.

### Indications

Protamine is indicated for the reversal of unfractionated heparin (UFH). Protamine can also be used in clinically significant bleeding with low-molecular-weight heparin (LMWH), but the anticoagulation effect is not fully reversed by protamine due to the smaller molecular size and reduced sulfate charge density of LMWH.<sup>104</sup> The low sulfate charge density of LMWH results in decreased protamine binding capacity with neutralization of anti-IIa activity, but variable neutralization of the anti-Xa activity of LMWH.<sup>105</sup>

### Dosing

Protamine sulfate has an immediate onset of action within minutes with a very short half-life (~7 minutes). Dosing is generally based on protamine-to-heparin ratios, with 1 mg of protamine sulfate neutralizing 80–100 units of heparin with a maximum single dose of protamine of 50 mg and a maximum infusion rate of 5 mg/minute. Protamine is dosed based on the amount of UFH received over the preceding three hours, taking into account the half-life of intravenous UFH of about one hour (e.g., if a patient has been receiving UFH heparin at a rate of 1000 units/hour, then 17.5 mg of protamine sulfate will be needed to neutralize a total of 1750 units of UFH).

For the reversal of LMWH administered within the preceding eight hours, 1 mg of protamine is given for every 1 mg of enoxaparin. If clinically significant bleeding persists (or if enoxaparin is administered greater than eight hours prior), an additional 0.5 mg of protamine can be administered for every 1 mg of enoxaparin.<sup>106</sup> Given the anticoagulant properties of excessive protamine, overdosing should be avoided as excess protamine can lead to increased bleeding.

### Adverse reactions

Protamine can cause rare but serious hypersensitivity reactions with hypotension, pulmonary vasoconstriction, pulmonary hypertension, and bradycardia.<sup>107</sup> Risk factors for the anaphylactic reaction include allergies for fish proteins, history of vasectomy, and prior exposure to protamine-containing insulin, all of which can lead to preformed antibodies against protamine sulfate. Infusing protamine slowly can mitigate the risk of severe allergic reactions.<sup>108</sup>

## Andexanet alfa

### Overview

Andexanet alfa is a recombinant-modified inactive form of factor Xa approved for reversing the factor Xa inhibitors, apixaban and rivaroxaban (Table 38.3). It acts as a “decoy” to bind and

**Table 38.3** Specific Reversal Agents for Direct Oral Anticoagulants

Pharmacologic Agent	Andexanet alfa	Idarucizumab
Mechanism of action	Recombinant-modified factor Xa protein that binds and sequesters direct Xa inhibitors	Humanized monoclonal antibody fragment that binds dabigatran with high affinity
Dose	Low versus high dose depending on the dose and timing of the last direct Xa inhibitor*	5 g total dose (given as two separate 2.5 g doses) administered as an intravenous bolus
Onset	Rapid within minutes	Rapid within minutes
Half-life	~1 hour	~45 minutes
FDA-approved indications	Reversal of the anticoagulant effect of apixaban and rivaroxaban in patients with life-threatening or uncontrolled bleeding	Reversal of the anticoagulant effect of dabigatran in patients with life-threatening or uncontrolled bleeding or for emergency surgery or procedures
Serious adverse reactions	Arterial and venous thromboembolic events	Mostly venous thromboembolic events

\* High-dose of andexanet alfa should be given if the rivaroxaban or apixaban dose is 10 or 5 mg, respectively (or unknown dose), and less than eight hours has elapsed since the last dose was given; otherwise, the low-dose andexanet alfa should be given.

sequester factor Xa inhibitors. Additionally, andexanet alfa causes off-target inhibition of tissue factor pathway inhibitor (TFPI), which can lead to increased thrombin generation and thromboembolic events.

### Manufacturing and storage

Andexanet alfa is stored as a lyophilized powder in single-use vials of 100 or 200 mg of recombinant factor Xa.

### Indications

Andexanet alfa is FDA approved for the reversal of anticoagulation with rivaroxaban or apixaban in patients with life-threatening or uncontrolled bleeding. While andexanet alfa is currently only FDA approved for the reversal of apixaban and rivaroxaban, it also has neutralizing activity against other direct and indirect factor Xa inhibitors. Approval for andexanet alfa was based on a single-arm open-labeled trial (ANNEXA-4) of 352 patients with acute major bleeding within 18 hours of receiving a factor Xa inhibitor (although nearly 30% of patients were excluded from the efficacy analysis due to levels less than 75 ng/mL).<sup>109,110</sup> Excellent or good hemostatic efficacy at 12 hours was obtained in 82% of patients (204 of 249 patients). During the 30-day follow-up period, thrombotic events occurred in 10% of patients (34 of 352 patients), which were mainly arterial. Because of its very short  $t_{1/2}$ , it is not approved for patients requiring emergent surgery while on factor Xa inhibitors. There are no randomized studies comparing andexanet alfa with PCC and no compelling data to choose one over the other for the reversal of factor Xa inhibitors for bleeding patients. However, for urgent surgery, PCC is preferred due to its longer duration of effect.

### Dosing

Dosing of andexanet alfa is based on the specific factor Xa inhibitor (e.g., apixaban or rivaroxaban) and the dose and time of last administration of that inhibitor. Andexanet alfa is administered as an initial bolus over 15–30 minutes, followed by a two-hour infusion. The initial bolus is either 400 or 800 mg followed by an infusion of 4 mg or 8 mg/minute for the low versus high dose of andexanet alfa, respectively. Given the high thromboembolic risks associated with andexanet alfa, it is essential to resume anticoagulation as soon as hemostasis is achieved and clinically appropriate.

### Adverse reactions

The most serious adverse events associated with andexanet alfa include arterial and venous thromboembolic events, ischemic events including myocardial infarction and ischemic strokes, cardiac arrest, and sudden death. Other adverse drug reactions include infusion reactions, urinary tract infections, and pneumonia.

## Idarucizumab

### Overview

Idarucizumab is a humanized monoclonal Fab antibody fragment that binds dabigatran with a 350-fold higher affinity than thrombin, neutralizing its activity and reversing the anticoagulant effect within minutes (Table 38.3).<sup>111</sup>

### Manufacturing and storage

Idarucizumab is packaged in ready-to-use vials of 2.5 g.

### Indications

Idarucizumab is indicated for the reversal of the anticoagulant effect of dabigatran in patients with life-threatening or uncontrolled bleeding or for emergency surgeries. FDA approval was based on the single-arm prospective cohort study, Reversal Effects of Idarucizumab on Active Dabigatran (RE-VERSE AD).<sup>112,113</sup> Idarucizumab was administered in 503 patients taking dabigatran with either uncontrolled bleeding (301 patients) or patients requiring an urgent procedure (202 patients), with nearly all patients achieving normalization of the diluted thrombin time within four hours. Of the 203 evaluable patients with uncontrolled bleeding, 134 patients (67.7%) had confirmed bleeding cessation. Among the patients receiving idarucizumab before a procedure, periprocedural hemostasis was normal in 93.4% of patients. The thrombotic event rate was 4.8% at 30 days and 6.8% at 90 days. Notably, all of the thrombotic events that occurred within 72 hours of idarucizumab administration failed to reinitiate anticoagulation.

### Dosing

Idarucizumab is dosed as 5 g intravenously and administered as two separate 2.5 g doses no more than 15 minutes apart. Repeated doses are generally not given but can be considered if there is persistent bleeding with evidence of the dabigatran effect. Case reports have shown incomplete reversal of dabigatran with idarucizumab; repeat doses of idarucizumab may be required in patients with massive dabigatran accumulation with evidence of re-elevation of coagulation parameters.<sup>114</sup>

### Adverse reactions

The most common side effects include headaches, nausea, and constipation. Since patients on anticoagulation therapy have underlying hypercoagulable states, the cessation of dabigatran and administration of idarucizumab may increase the thrombotic risk, so anticoagulation should be resumed as soon as clinically indicated.

## Clinical settings

### Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) is always secondary to an underlying condition, most commonly infection/sepsis, followed by obstetrical catastrophes, trauma, malignancy, and intravascular hemolysis. Increased expression of tissue factor on various cells (monocytes/macrophages, tumor cells, etc.) is characteristic of DIC and leads to pathologic activation of the coagulation system, resulting in widespread microvascular thromboses with ischemic tissue injury. Life-threatening hemorrhage can also occur from consumption of coagulation factors and platelets, as well as accelerated fibrinolysis. DIC is a clinicopathological syndrome, with a highly variable presentation that may manifest as acute or chronic, localized or systemic, and hemorrhagic or thrombotic (and sometimes both). There is no single diagnostic test for DIC, and, therefore, a careful assessment of hemostasis tests is essential. Because of the consumption of coagulation factors, various tests become abnormal depending upon the severity of DIC and synthetic function of the liver and bone marrow. Thus, in an acute DIC scenario, generally, there is a prolongation of PT and aPTT, decreased fibrinogen, increased d-dimers, and moderate to severe thrombocytopenia. These are accompanied by reduced levels of procoagulant factors (e.g., factors II, VII, X, and V) and natural

anticoagulants (e.g., antithrombin, protein C, and protein S). The International Society on Thrombosis and Hemostasis developed a simple scoring system based on the underlying condition associated with DIC and routine coagulation tests that include platelet count and fibrin-related markers (e.g., D-dimer), PT, and fibrinogen.<sup>115</sup> Prospective validation demonstrated a sensitivity of 91% and a specificity of 97%.<sup>116</sup>

Identification and treatment of the underlying cause is essential in the management of DIC. Supportive management should be tailored to the individual patient, underlying condition, laboratory studies, and presence and severity of bleeding and thrombotic complications. It is important to remember that many patients who have definitive laboratory evidence of DIC may not have clinically significant thrombosis or hemorrhage. Such patients typically do not require any specific therapy other than the treatment of the underlying process. In contrast, patients with active bleeding or impending procedures, as well as laboratory evidence of severe consumption of fibrinogen (fibrinogen level less than 100 mg/dL), coagulation factors (PT greater than 1.5 × control value), or thrombocytopenia (platelets <50,000/µL), should be treated by transfusion of cryoprecipitate, plasma (10–15 mL/kg), and/or platelets. In the absence of bleeding or a planned procedure, platelet transfusions should be avoided as long as the platelet count is maintained above 10,000–20,000/µL.<sup>117–119</sup> A restrictive blood component transfusion approach is based on the fact that there is no clear evidence that a liberal transfusion approach improves bleeding complications and may increase thrombotic complications because of adding fuel to the fire effect.

Low-dose unfractionated heparin may help inhibit the activation of coagulation in DIC and slow the consumptive process.<sup>120</sup> However, the use of heparin in DIC remains controversial, and the overall impact on clinically relevant outcomes has not been definitively demonstrated in clinical trials.<sup>121,122</sup> Low doses of heparin can be considered in patients without thrombosis, typically at a continuous infusion rate of 5–10 U/kg/hour (~300 U/hour), and therapeutic anticoagulation is indicated in patients with overt thrombosis.

When bleeding associated with DIC is refractory to heparin and transfusion therapy, antifibrinolytic agents are occasionally used, although they are generally contraindicated. In addition to stabilizing clots, antifibrinolytic agents also reduce FDP production. However, inhibition of fibrinolysis has the potential to exacerbate fibrin deposition, resulting in severe thrombotic complications. Therefore, antifibrinolytic agents should be reserved for life-threatening hemorrhage and should be considered for use only in conjunction with heparin in the setting of DIC.

There is conflicting evidence on the use of antithrombin in patients with DIC. A large randomized controlled trial, KyberSept, failed to show a survival benefit with the use of high-dose antithrombin in patients with sepsis.<sup>123</sup> Additionally, there was increased bleeding when antithrombin was administered with heparin. While a post hoc analysis showed a significant mortality reduction in septic patients with DIC,<sup>124</sup> this benefit was not replicated in a meta-analysis<sup>125</sup> and has not been validated prospectively. Despite initial promising data with activated protein C in patients with severe sepsis and DIC, subsequent evaluation likewise failed to demonstrate improved survival. Furthermore, this therapy showed an increased risk of bleeding, prompting the withdrawal of activated protein C (drotrecogin alfa) from the market.<sup>126–128</sup>

## Chronic liver disease

Chronic liver disease results in complex changes in the hemostatic system. Alterations in pro- and antihemostatic pathways lead to a delicately “rebalanced” hemostasis that may predispose to both bleeding and thrombotic complications. Primary hemostasis is affected by decreased platelet number (from splenic sequestration, decreased thrombopoietin, and bone marrow suppression) and function.<sup>129,130</sup> However, the effect of thrombocytopenia is rebalanced by very high von Willebrand factor (VWF) levels (endothelium-derived) and increased function due to reduced levels of the VWF cleaving protease ADAMTS-13.<sup>131</sup> Secondary hemostasis is altered, with reduced levels of all procoagulant factors synthesized by the liver; however, thrombin generation is rebalanced by a simultaneous reduction in natural anticoagulants and elevated FVIII (from endothelium).<sup>132</sup> Enhanced fibrinolysis can result from increased tissue-type plasminogen-activator (t-PA) relative to increased levels of plasminogen activator inhibitor 1 (PAI-1) and decreased levels of alpha-2-antiplasmin.<sup>133</sup> Therefore, significant liver dysfunction can lead to both bleeding and thrombosis from multiple factors, including impaired biosynthesis of multiple hemostatic factors, failed clearance of inhibitory factors, and fibrinolysis.

Conventional coagulation tests may be abnormal in cirrhosis with prolonged PT, and sometimes aPTT, and decreased fibrinogen levels (in approximately 30–50%). However, these levels are misleading and do not reflect the complex “rebalanced” hemostasis or predict the risk for bleeding.

Given that functional hemostasis remains intact despite abnormal laboratory studies of hemostasis, routine prophylactic transfusions or administration of prohemostatic agents should generally be avoided in patients with cirrhosis. The exception is vitamin K, which can be administered to patients with liver disease who may be deficient, but it is often poorly effective, and bleeding may persist even if the PT is shortened.<sup>134,135</sup> There is a lack of high-quality evidence to show the clinical benefit of prophylactic plasma or platelet transfusions prior to procedures in cirrhotics.<sup>136,137</sup> Moreover, variceal bleeding, which commonly occurs in patients with cirrhosis, is due to elevated portal pressures rather than hemostatic failure; the transfusion of blood products further increases portal and central venous pressures and, thus, promotes further bleeding.<sup>138</sup> Thrombopoietin receptor antagonists, avatrombopag and lusutrombopag, are approved to raise platelet count in patients with chronic liver disease undergoing intermediate or high-risk procedures; however, the clinical benefit is unknown due to concurrent elevation of VWF.<sup>139,140</sup> Fibrinogen levels are seldom decreased enough from liver dysfunction to cause major bleeding. However, severe hypofibrinogenemia (fibrinogen level <100 mg/mL) in a patient with active bleeding or requiring surgery should be treated with cryoprecipitate (VWF levels are already too high for the use of DDAVP). Large epidemiological studies have shown that cirrhotics have twice the incidence of venous thromboembolism than the general population. Therefore, thromboprophylaxis should not be withheld based on the prolongation of PT and aPTT in hospitalized patients with cirrhosis.<sup>141</sup>

## Acquired von Willebrand syndrome

Acquired von Willebrand syndrome (AVWS) is a rare bleeding disorder that results in structural and functional alterations of VWF. Generally, it occurs in association with an underlying disorder, including myeloproliferative neoplasms, lymphoproliferative disorders, solid malignancies, autoimmune disorders, and cardiovascular

disorders with increased shear stress.<sup>142</sup> The pathophysiology of AVWS may involve several different mechanisms, such as autoantibodies that cause functional interference or rapid clearance of VWF from the plasma, adsorption of VWF to malignant cells, or high shear stress causing increased proteolysis of high molecular weight multimers. The clinical features and laboratory abnormalities are similar to congenital VWD. However, unlike congenital VWD, AVWS occurs in patients with no personal or family history of bleeding disorders. Symptoms can vary from mild mucocutaneous bleeding (ecchymosis, epistaxis, gingival hemorrhage, or menorrhagia) to severe, life-threatening hemorrhage.

Laboratory studies may be notable for a prolonged closure time on platelet function analyzer (PFA-100). aPTT may also be prolonged. Levels of VWF activity (ristocetin cofactor activity and collagen-binding activity), VWF antigen, and factor VIII are often depressed. Selective loss of high-molecular-weight multimers of VWF can be seen in AVWS associated with cardiovascular diseases with increased shear stress, and in this setting it may resemble type 2A VWD. The inhibitors cause rapid clearance of VWF from the circulation, so inhibitory activity often cannot be demonstrated in the plasma by mixing studies.

If possible, the underlying disorder associated with AVWS should be treated, which may lead to long-term remission (e.g., treatment with cytoreductive therapy in myeloproliferative neoplasms or corrective cardiac surgery in aortic valve stenosis). In patients with acute bleeding, therapeutic options include DDAVP, infusion of intermediate purity factor VIII concentrates containing large quantities of VWF or recombinant VWF. Cryoprecipitate may be given as a source of VWF if the above products are unavailable, but one must remember to give a very high dose of cryoprecipitate (30–50 units). Responses to DDAVP and replacement therapy depend on the cause of AVWF and may be only transiently effective because of the short half-life of VWF caused by excessive clearance from the circulation.<sup>143</sup> Antifibrinolytic agents may be beneficial, particularly in patients with mucosal bleeding. In therapy-resistant life-threatening bleeding, rFVIIa can be considered, although the safety has not been well established.<sup>144</sup> Administration of high-dose intravenous immune globulin (1 g/kg for two days or 0.4 g/kg for five days) can sometimes be effective in patients with AVWF, and repeated administration of intravenous

immune globulin every three weeks may control chronic bleeding. AVWS can also be seen in patients with myeloproliferative disorders who manifest extreme thrombocytosis ( $>1000 \times 10^9/L$ ). In this setting, large VWFs are adsorbed to GPIb on platelets leading to decreased VWF in the plasma and bleeding symptoms. Such patients often benefit from plateletpheresis to lower platelet count of  $<500 \times 10^9/L$ .

## Background

Anemia, thrombocytopenia, and derangements in coagulation parameters are common in the perioperative setting.<sup>1–4</sup> Historically, concerns for surgical hemorrhage associated with adverse patient outcomes have driven liberal transfusion practices in these surgical populations. However, a growing body of evidence supports more conservative transfusion practices.<sup>5,6</sup> These sentiments are largely based upon accumulating evidence suggesting a lack of efficacy with liberal transfusion practices,<sup>6,7</sup> increased awareness regarding the risks of transfusion therapies,<sup>8–10</sup> and an increased appreciation of blood components as a valuable health-care resource—both in terms of supply limitations and associated costs.<sup>11,12</sup> In light of these findings, dedicated patient blood management (PBM) programs have been implemented, aiming to cultivate more evidence-based transfusion practices.<sup>13</sup> Despite these advances, the literature continues to describe the liberal and highly variable utilization of transfusion therapies in surgical populations.<sup>14,15</sup> Examples include red blood cell (RBC) administration for the correction of stable asymptomatic anemia and plasma administration for the correction of abnormal coagulation parameters in the absence of bleeding.<sup>16–19</sup>

Although the risk for hemorrhage must be considered in all patients undergoing invasive procedures, it is important to recognize that our ability to accurately predict bleeding risk remains disappointingly limited.<sup>15,19,20</sup> Likewise, the determinants of when to transfuse RBCs to a bleeding surgical patient remain poorly defined. Moreover, it must also be acknowledged that the practice of the prophylactic administration of either plasma products or platelet components with the intention of modifying bleeding risk is largely devoid of evidence and may be potentially harmful.<sup>21–23</sup>

This leaves us with challenging questions. What is the best way to assess a patient's risk of perioperative bleeding? What is the best approach to mitigating this bleeding risk? How should perioperative anemia be managed? What options are there to avoid or minimize allogeneic blood transfusions? What clinical and laboratory information helps to guide transfusion decision-making? What is the role of transfusion therapy in special circumstance for surgical patients? In this chapter, we discuss anemia, its impact on surgical outcomes, and preoperative anemia optimization; the impact of RBC transfusions on surgical patient outcomes; the utility of preoperative hemostatic

testing; the management of perioperative anticoagulation and antiplatelet therapies; conservative versus liberal transfusion practices; blood avoidance techniques; topical hemostatic therapies; perioperative transfusion guidelines; the role of plasma transfusion in special circumstances; and the role of platelet transfusion in special circumstances.

## Anemia and surgery

In a physiological sense, anemia is a state of inadequate red cell mass to support tissue oxygen requirements. However, given the difficulties of accurately assessing red cell mass or tissue oxygen needs at the patient level, anemia is more commonly defined by hemoglobin (Hb) concentrations (i.e., mass of hemoglobin per given blood volume) or hematocrit (Hct) values (i.e., proportion of whole blood volume comprised by red cells) falling below normative reference values. In the mid-1900s, the World Health Organization (WHO) assigned reference Hb ranges to define anemia, including: <11.0 g/dL for children 0.5–5 years, <11.5 g/dL for children 5–12 years, <12.0 g/dL for children 12–15 years and nonpregnant women ≥15 years, <11.0 g/dL for pregnant women, and <13.0 g/dL for men ≥15 years.<sup>24</sup> It should be noted that these definitions were assigned based upon observed distributions of hemoglobin in a limited number of population-based studies rather than by the physiological significance of Hb concentrations themselves. In any case, employing these definitions, anemia is extraordinarily common, affecting approximately 25% of the world's population,<sup>25</sup> though the prevalence and burden of anemia are highest in low- and middle-income countries. Not surprisingly, anemia, as defined by these criteria, is the most common preoperative hematologic abnormality encountered in surgical patients.<sup>26</sup> Estimates of the prevalence of preoperative anemia generally range from 25% to 40%,<sup>1,27–31</sup> though prevalence varies substantially by surgery type, approaching 75% in those with advanced colon cancer.<sup>32</sup> Rather than representing a distinct disease process itself, anemia is often a sign of underlying diseases or conditions that could negatively impact surgical outcomes. Such negative consequences are not restricted to those with severe anemia, which is typically defined by Hb concentrations <8–9 g/dL. Adverse outcomes such as renal injury, stroke, and even death have been shown

to be associated with surgical patients categorized as having mild or moderate anemia.<sup>27,28,33,34</sup> Further, recent research in cardiac surgical patients suggests increasing risk for adverse perioperative outcomes for every 1 g/dL decrease in preoperative Hb below 13 g/dL in females and 14 g/dL in males.<sup>35</sup> Importantly, anemia represents a potentially modifiable risk factor for adverse perioperative outcomes, and there is growing recognition of the importance of appropriate optimization throughout the spectrum of perioperative care.<sup>36</sup>

### **Impact of anemia on surgical outcomes**

There is now abundant literature regarding the relationships between preoperative anemia and surgical outcomes. For example, in a study of more than 200,000 adults undergoing major noncardiac surgery, with data obtained from the American College of Surgeons' National Surgical Quality Improvement Program (ACS NSQIP) database derived from 211 hospitals worldwide, more than 30% of patients presented to surgery with mild (Hct >29% but <39% in men and <36% in women) or moderate-to-severe (<29% in men and women) preoperative anemia.<sup>27</sup> In multivariable regression analyses, the odds of 30-day postoperative mortality were higher in patients with anemia compared to those without (odds ratio [OR] 1.42, 95% confidence interval [CI], 1.31–1.54), with similar relationships noted for mild (OR 1.41, 95% CI, 1.30–1.53) and moderate-to-severe anemia (OR 1.44, 95% CI, 1.29–1.60). Similar findings were observed for 30-day composite postoperative morbidity (cardiac, central nervous system, respiratory, sepsis, urinary tract, venous thromboembolism, and wound complications; OR 1.35, 95% CI, 1.30–1.40 for any anemia, OR 1.31, 95% CI, 1.26–1.36 for mild anemia, and OR 1.56, 95% CI, 1.47–1.66 for moderate-to-severe anemia).

Numerous additional investigations have also noted similar relationships between preoperative anemia status and adverse perioperative outcomes in noncardiac surgery,<sup>37–40</sup> such that there is no longer any uncertainty regarding the relationship between preoperative anemia and surgical outcomes. For example, in an analysis of more than 300,000 veterans >65 years of age undergoing noncardiac surgery, preoperative Hct was inversely correlated with both cardiac events and mortality.<sup>37</sup> Specifically, there was a 10% increase in adverse events with mild anemia (Hct 36.0–38.9) and a greater than 50% increase with more severe anemia (Hct 18.0–20.9). In the European Surgical Outcomes Study including data from nearly 40,000 patients, preoperative anemia was associated with both postoperative morbidity and mortality.<sup>41</sup> Outcomes were progressively worse with greater severity of preoperative anemia. Similar relationships between anemia and adverse outcomes, including mortality, have been confirmed in other patient groups.<sup>38</sup> In a study of nearly 2000 adult patients who refused blood transfusion,<sup>42</sup> decreasing preoperative Hb concentrations were associated with increased risk for 30-day mortality, especially for patients with Hb of 6 g/dL or lower. The risk of mortality was particularly high in patients with preexisting cardiovascular disease who had a preoperative Hb of 10 g/dL or less.

Like noncardiac surgery, there is also abundant literature on preoperative anemia and outcomes in cardiac surgery. In a cohort of 7738 adults undergoing cardiac surgery between 2003 and 2009, preoperative anemia was an independent predictor of mortality (OR 1.44, 95% CI, 1.02–2.03), postoperative renal dysfunction (OR 1.73, 95% CI, 1.43–2.1), and prolonged hospital length of stay (OR 1.3, 95% CI, 1.15–1.47 for >7-day length of stay).<sup>43</sup> Similarly, in a multicenter study of nearly 5000 adults undergoing coronary bypass

surgery, preoperative anemia was associated with both renal and cerebrovascular adverse events.<sup>34</sup> More recently, in a study of more than 4000 adults undergoing elective cardiac surgery, progressively lower Hb concentrations were associated with adverse postoperative outcomes such as acute kidney injury and prolonged hospitalizations.<sup>35</sup> Importantly, the relationships between Hb concentrations and outcomes were not uniform across sexes, with differential thresholds identified for increasing perioperative risk in men (14 g/dL) and women (13 g/dL). This result suggests that reliance on WHO definitions of anemia may not be ideally suited for identifying Hb concentrations associated with the greatest risk of adverse perioperative outcomes.

While most published literature on preoperative anemia and surgical outcomes is focused on adults, there is also substantial evidence that preoperative anemia is similarly detrimental in children. In a study of more than 50,000 children between ages 1 and 18 years in the ACS NSQIP database, approximately one quarter were anemic at the time of surgery.<sup>44</sup> Preoperative anemia was associated with increased in-hospital mortality after multivariable adjustment, with an odds ratio of 1.75 (95% CI, 1.15–2.65) compared to propensity-matched nonanemic patients. Like in adults, preoperative anemia is also an independent risk factor for perioperative RBC transfusion and prolonged hospitalization in children.<sup>45</sup>

Beyond preoperative anemia, postoperative anemia is also extremely common, occurring in up to 90% of patients.<sup>46</sup> Anemia after surgery is most often related to inadequately optimized preoperative red cell mass, perioperative blood loss, prolonged inflammatory states, diagnostic phlebotomy, and impaired nutritional status. In noncardiac patients that received intraoperative red cell transfusion, severe anemia immediately postoperatively (i.e., initial postoperative Hb <7.5 g/dL) was associated with increased odds for acute kidney injury, cerebral ischemia, and mortality.<sup>47</sup> Similarly, several studies have assessed the relationships between postoperative Hb concentrations and clinical outcomes in patients that declined RBC transfusion.<sup>48,49</sup> In those studies, mortality rates were low with nadir postoperative Hb concentrations between 7.1 and 8.0 g/dL (range 0–1.5%), though composite morbidity/mortality rates were higher, ranging between 9% and 23%. Most importantly, every 1 g/dL decrease in postoperative Hb was associated with progressive increases in morbidity and mortality, with outcomes markedly inferior in those with nadir Hb concentrations less than 5 g/dL.

### **Preoperative anemia optimization**

Given the detrimental impact of anemia on perioperative outcomes, there is increasing recognition of the importance of evaluating and treating anemia prior to surgery. Formal preoperative anemia programs or clinics have been created to fill this niche,<sup>50</sup> though these are far from ubiquitous in modern medical practice despite numerous benefits. Preoperative anemia programs are tasked with identifying anemia in advance of surgery, determining the underlying cause(s) of anemia which may include further diagnostic testing (e.g., endoscopy, referral to a hematologist), prescribing appropriate targeted treatments, and ensuring optimal hemoglobin recovery prior to surgery.<sup>36</sup> Diagnostic evaluation usually entails thorough medical history and medical record review to identify likely sources of anemia (e.g., blood loss, nutritional deficiencies, hemolysis, chemotherapy, thalassemias, sickle cell anemia, and end-stage renal disease) followed by laboratory testing to assess iron status (i.e., transferrin saturation, ferritin,

and reticulocyte hemoglobin content) and noniron nutritional status (i.e., B12 and folate levels). Additionally, labs are typically assessed to exclude anemia secondary to hemolysis or severe renal dysfunction.<sup>36</sup>

Iron deficiency is the leading cause of preoperative anemia and can be treated with either oral or intravenous (IV) iron replacement. The advantages of IV iron are related to quicker resolution of iron deficits, faster hemoglobin recovery, and the avoidance of gastrointestinal side effects that are commonly encountered with oral therapy. As such, IV iron may be considered first-line therapy for preoperative iron deficiency anemia, particularly in those with surgery occurring within 4–6 weeks of preoperative evaluation and in those with severe anemia. Fortunately, current IV iron formulations have an excellent safety profile,<sup>36</sup> though costs associated with IV therapy are much greater than over-the-counter oral iron supplements. Anemia of inflammation is another common cause of preoperative anemia, which is typically a diagnosis of exclusion in patients without other obvious etiologies of anemia and with evidence of chronic illness or inflammatory conditions. These patients typically show an abrupt hemoglobin response with erythropoietic stimulation after ensuring optimization of iron stores.

Numerous observational studies and several randomized clinical trials have evaluated the efficacy and safety of preoperative anemia programs on hemoglobin concentrations, perioperative red cell transfusion utilization, and patient outcomes. For those with iron deficiency anemia, clinical trials have shown that targeted therapy with IV iron or the combination of IV iron and low-dose erythropoietin results in successful augmentation of hemoglobin concentrations and reductions in perioperative red cell transfusions.<sup>51,52</sup> While anemia treatments should optimally be tailored to the underlying cause(s) of anemia, even in those with anemia not exclusively related to iron deficiency, IV iron improves hemoglobin recovery through six months postoperatively after major abdominal surgery and reduces readmission rates for the management of postoperative complications.<sup>53</sup> Additionally, the utilization of a “kitchen-sink” approach to anemia management including a combination of IV iron, erythropoietin, vitamin B12, and folic acid administered only one day prior to cardiac surgery resulted in improved hemoglobin recovery and reduced perioperative transfusion utilization. In addition to finding similar improvements in hemoglobin concentrations and transfusion reductions with preoperative anemia programs, observational data support substantial reductions in hospital costs and reductions in hospital lengths of stay following the implementation of formal preoperative efforts to address anemia.<sup>54</sup> Given these findings, preoperative anemia programs appear to be a clear win for both patients and healthcare systems.<sup>55</sup> Further, it is important to provide the same vigilance for anemia throughout the perioperative spectrum of care.<sup>36</sup>

It is logical to ask whether preoperative transfusion of RBCs to increase red cell mass in anemic patients positively impacts perioperative clinical outcomes. While formal studies of RBC transfusion for anemia correction before surgery are lacking, the overwhelming evidence from observational data and transfusion trials in other clinical settings, as detailed in the following section, suggest that RBCs are unlikely beneficial and may be harmful in this context. Briefly, allogeneic RBCs are associated with substantial risk, do not address the underlying causes of anemia, and do not reliably improve tissue oxygenation except in those with the most critical hemoglobin deficits (i.e., hemoglobin <5–6 g/dL).<sup>56</sup> Preoperative

anemia optimization efforts should, therefore, be focused on addressing underlying causes of anemia whenever possible with nontransfusion-based modalities.

## Impact of RBC transfusions on surgical patient outcomes

Red blood cell transfusions are widely utilized in the perioperative setting. Earlier studies around the year 2000 showed that 40–70% of all RBC transfusions are given in association with surgical procedures.<sup>57–59</sup> A decade later, the 2011 AABB National Blood Collection and Utilization Survey (NBCUS) documented that surgical departments used 19.8% of all RBCs distributed.<sup>60</sup> This decrease in surgical blood use over a decade, consistent with other recent evaluations demonstrating overall reductions in RBC utilization,<sup>61</sup> is likely due to the emerging emphasis on patient blood management initiatives over the same time period, at least in part.<sup>62</sup>

The rationale underpinning RBC transfusion is to enhance oxygen delivery ( $\text{DO}_2$ ) in patients with a decreased red cell mass, as inferred by the presence of a low Hb. This is particularly relevant in patients in whom impaired compensatory mechanisms, such as coexisting cardiovascular disease, mean their expected tolerance for such a state is diminished.<sup>63</sup> In the surgical arena, decisions to transfuse may be guided by amount of ongoing blood loss, evidence of evolving coagulopathy, hemodynamic signs of anemia, and recent hemoglobin values. Ultimately, the decision-making process necessitates weighing the risk of transfusion against the risk of anemia. As described above, historical studies have shown an association between anemia and morbidity and mortality in surgical patients. However, until recently, it has been difficult and impractical to determine specific thresholds at which RBC administration to correct anemia results in improved outcomes. In the absence of strong data to support superior surgical outcomes with more liberal transfusion practices, and with increased appreciation for the cost, resource utilization,<sup>64</sup> and potential risks associated with transfusion,<sup>65–67</sup> restrictive transfusion practices have been advocated by patient blood management programs. For example, in 2019, Will *et al.*<sup>47</sup> proposed transfusing to a target postoperative hemoglobin value between 7.5–11.5 g/dL to achieve superior outcomes, as determined by hospital free days.

The influence of RBC transfusions on outcomes in surgical patients has been assessed in multiple studies. A recent study evaluated postoperative morbidity, in-hospital mortality, and long-term survival of Jehovah’s Witness patients who underwent cardiac surgery compared to a similarly matched group of cardiac surgery patients who received RBC transfusions.<sup>68</sup> Between 1 January 1983 and 1 January 2011, 322 Jehovah’s Witness cardiac surgery patients were compared with 87,453 non-Jehovah’s Witness patients who also underwent cardiac surgery. Transfusions were given to 48,986 of the non-Jehovah’s Witness patients. When compared to matched patients who received transfusions, Jehovah’s Witnesses had better outcomes for the following:

- Myocardial infarction, 0.31% versus 2.8% ( $p = 0.01$ ).
- Additional operation for bleeding, 3.7% versus 7.1% ( $p = 0.03$ ).
- Prolonged ventilation, 6% versus 16% ( $p < 0.001$ ).
- Intensive care unit length of stay (15th, 50th, and 85th percentiles), 24, 25, and 72 hours versus 24, 48, and 162 hours ( $p < 0.001$ ).
- Hospital length of stay (15th, 50th, and 85th percentiles), 5, 7, and 11 hours versus 6, 8, and 16 days ( $p < 0.001$ ).

The 95% one-year survival in Jehovah's Witness patients was significantly higher than the 89% one-year survival of transfused patients ( $p = 0.007$ ). In contrast, 20-year survival was similar (34% vs. 32%;  $p = 0.90$ ). The results of this study suggest that nontransfused cardiac surgery patients are not at increased risk for morbidity or mortality compared to similar patients who receive perioperative transfusions.

Carson *et al.*<sup>69</sup> studied the impact of RBC transfusions on 30-day and 90-day postoperative mortality in a retrospective cohort study of 8787 consecutive patients, 60 years of age or older, who underwent surgery for the repair of hip fractures at 20 hospitals between 1983 and 1993. The "trigger" Hb for transfused patients was defined as lowest value prior to the first transfusion, and this was compared to the lowest Hb in nontransfused patients. The overall mortality rates were 4.6% ( $n = 402$ ) at 30 days and 9.0% ( $n = 788$ ) at 90 days. Postoperative transfusions were given to 3699 (42%) patients. Transfusions were given to 55.6% of patients with an Hb between 8.0 and 10 g/dL and to 90.5% of patients with an Hb less than 8.0 g/dL. After adjustment for trigger Hb, cardiovascular disease, and other risk factors for death, the odds ratios for 30-day (0.96; 95% CI, 0.74–1.26) and 90-day mortality (1.08; 95% CI, 0.90–1.29) showed no influence of postoperative RBC transfusions on mortality. There was also no difference in 30-day postoperative mortality when patients who received preoperative RBC transfusions were compared to those who did not (adjusted OR, 1.23; 95% CI, 0.81–1.89). It was concluded that perioperative RBC transfusions at an Hb transfusion trigger of 8.0 g/dL or higher in this elderly patient population did not influence 30-day or 90-day mortality. Assessment of the influence of RBC transfusions on mortality at an Hb transfusion trigger of less than 8.0 g/dL in this population could not be made because 90.5% of patients received RBC transfusions.

The Transfusion Requirements in Critical Care (TRICC) trial is an important randomized clinical trial designed to assess RBC transfusion-related outcomes in critically ill patients.<sup>70</sup> In this trial, 838 critically ill, normovolemic patients with an Hb of less than 9 g/dL within 72 hours of admission to an intensive care unit were randomized to either restrictive or liberal RBC transfusion strategies. There were 408 patients in the restrictive group and 420 patients in the liberal group. RBC transfusions were administered to restrictive-group patients for an Hb less than 7 g/dL in order to maintain the Hb between 7 and 9 g/dL. RBCs were administered to liberal-group patients for an Hb less than 10 g/dL in order to maintain the Hb between 10 and 12 g/dL. Thirty-day mortality was not statistically different between the restrictive and liberal RBC transfusion groups, although the raw mortality rate was lower in the restrictive group (18.7% vs. 23.3%,  $p = 0.11$ ). The mortality rates were also lower in the restrictive transfusion group (8.7% in the restrictive group vs. 16.1% in the liberal group,  $p = 0.03$ ) when less acutely ill patients (Acute Physiology and Chronic Health Evaluation II score of  $\leq 20$ ) as well as when patients younger than 55 years of age (5.7% in the restrictive group vs. 13.0% in the liberal group,  $p = 0.02$ ) were compared. The restrictive strategy group also had lower rates of myocardial infarction (0.07% vs. 2.9%,  $p = 0.02$ ), pulmonary edema (5.3% vs. 10.7%,  $p < 0.01$ ), and mortality during hospitalization (22.3% vs. 28.1%,  $p = 0.05$ ). The restrictive and liberal groups had similar mortality rates for patients with a primary or secondary diagnosis of cardiac disease (20.5% vs. 22.9%,  $p = 0.69$ ). The average Hb and the number of RBC units transfused were significantly lower in the restrictive group. It was concluded that the restrictive RBC transfusion strategy with a transfusion trigger of 7 g/dL was at least as effective as, and possibly superior to, a trigger of 10.0 g/dL

in critically ill patients, with the possible exception of patients with acute MI and unstable angina.

In a large study designed to determine the optimal perioperative RBC transfusion threshold, the Transfusion Trigger Trial for Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair (FOCUS) studied 2016 patients with known cardiovascular disease or cardiovascular risk factors who were randomized to restrictive or liberal postoperative RBC transfusion groups following surgical repair of hip fractures.<sup>7</sup> All study patients were at least 50 years of age (mean age, 82 years), and all had a postoperative Hb less than 10 g/dL. Patients in the liberal RBC transfusion group received one RBC transfusion immediately after enrollment and additional RBC transfusions to maintain the Hb higher than 10 g/dL. Patients in the restrictive RBC transfusion group received RBCs if they developed symptoms warranting RBC transfusions or when the postoperative Hb dropped below 8 g/dL (even in the absence of symptoms). Symptoms triggering RBC transfusions were chest pain believed to be cardiac in nature, orthostatic hypotension or tachycardia unresponsive to fluid challenge, or congestive heart failure. The primary study outcome was mortality or the inability to walk 10 feet across a room without assistance at the 60-day evaluation point. Also evaluated was a combined outcome score comprising death, in-hospital MI, or unstable angina. Another secondary outcome was death beyond the 60-day evaluation point for any reason. For the primary study outcome, similar rates were observed for the liberal and restrictive RBC transfusion groups (35.2% vs. 34.7%, OR 1.01, 95% CI, 0.84–1.22). Similar rates for the liberal and restrictive groups were also found for the composite end point of death, in-hospital MI, or unstable angina (4.3% vs. 5.2%, OR 0.82, 99% CI, 0.48–1.42). When evaluated individually, the rate of MI was higher (although not statistically significant) in the restrictive group (3.8% vs. 2.3%, relative risk [RR] 1.65, 95% CI, 0.99–2.75). The death rates for the liberal and restrictive groups at 60 days were similar (7.6% vs. 6.6%, OR 1.17, 99% CI, 0.75–1.83). The FOCUS trial demonstrated that, when compared to a liberal postoperative RBC transfusion strategy at a threshold of 10 g/dL, a restrictive RBC transfusion strategy (threshold of 8 g/dL or for symptoms) was not associated with worse outcomes in hip fracture repair patients with cardiovascular disease or cardiovascular risk factors. The only exception to this conclusion might be related to the risk for MI where there was a marginally increased rate in the restrictive RBC transfusion group. The results of this trial, therefore, support the concept that, for patients with a postoperative Hb of 8.0 g/dL or higher, RBC transfusion decisions can be guided by symptoms rather than a higher Hb threshold.

Two landmark studies in cardiac surgery patients provide support for the concept that an Hb of 8 g/dL is a safe RBC transfusion trigger.<sup>71,72</sup> In the first study, 428 consecutive coronary artery bypass graft (CABG) patients were assigned to one of two postoperative RBC transfusion groups.<sup>71</sup> One group was transfused with RBCs for an Hb <8 g/dL, whereas the other group was transfused for an Hb <9.0 g/dL. No between-group differences in mortality or morbidity were seen. The restrictive group, however, received fewer RBC transfusions (0.9 vs. 1.4 RBC units/patient), which resulted in a reduction of 500 RBC transfusions per 1000 CABG procedures.

In the second cardiac surgery trial, 502 consecutive patients were randomized to liberal or restrictive RBC transfusion strategies.<sup>72</sup> Patients in the liberal strategy were transfused to maintain the Hct at or above 30% throughout surgery and the postoperative period. Patients in the restrictive strategy were transfused to maintain the

Hct at or above 24% throughout surgery and postoperative period. The combination of 30-day all-cause mortality, acute renal injury requiring dialysis or hemofiltration, acute respiratory distress syndrome (ARDS), and cardiogenic shock was chosen as the composite primary outcome. No difference in the rates of the composite end points was observed (liberal group 10% vs. restrictive group 11%). Overall, regardless of restrictive or liberal RBC transfusion strategy, the number of RBC transfusions was correlated with death and other clinical complications (HR 1.2 per transfused RBC unit). These two trials support a restrictive RBC transfusion approach (i.e., Hb or Hct transfusion triggers of 8 g/dL or 24%) in cardiac surgery patients.

A recent Cochrane review evaluated strategies for guiding allogeneic RBC transfusion decisions.<sup>73</sup> Nineteen randomized trials comparing lower (restrictive) versus higher (liberal) RBC transfusion thresholds involving a total of 6264 medical and surgical patients were identified. Most of the studies assessed outcomes in patients transfused at Hb thresholds between 7 and 10 g/dL, although specific thresholds differed between trials. The analysis showed that, when compared to liberal RBC transfusion strategies, restrictive transfusion strategies resulted in the following:

- A lower rate of receiving RBC transfusions (46% vs. 84%, RR 0.61, 95% CI, 0.52–0.72).
- 1.19 fewer RBC units transfused per patient.
- Trends suggesting lower 30-day mortality (RR 0.85, 95% CI, 0.70–1.03) and overall infection rates (RR 0.81, 95% CI, 0.66–1.00) (no differences seen in pneumonia rates, however).
- No differences in functional recovery, hospital length of stay, or intensive care length of stay.
- No differences in MI risk when all trials were evaluated (RR 0.88, 95% CI, 0.38–2.04).

The two largest studies included in the Cochrane analysis, the TRICC trial and the FOCUS trial, however, showed different results pertaining to the risk of MI associated with a restrictive RBC transfusion strategy.<sup>7,70</sup> The TRICC trial documented a lower risk of MI in the restrictive group (0.7% vs. 2.9%, RR 0.25, 95% CI, 0.07–0.88), and the FOCUS trial showed a higher (although not statistically significant) risk in the restrictive group (3.8% vs. 2.3%, RR 1.65, 95% CI, 0.99–2.75). Though some ambiguity in the literature exists regarding the best way to manage patients considered to be high risk for major perioperative cardiovascular events,<sup>72,74–76</sup> conservative approaches remain advocated, with careful attention to individual signs of end organ ischemia.

Regarding RBC transfusion decisions in patients with active bleeding, in a single center trial, 921 patients with acute upper GI bleeding were randomized to a restrictive (threshold Hb 7 g/dL) or a liberal (threshold Hb 9 g/dL) RBC transfusion strategy.<sup>6</sup> Excluded from the study were patients with acute coronary syndrome, massive bleeding, a history of peripheral vascular disease, a history of stroke, or an Hb more than 12 g/dL. Emergent upper endoscopy was performed on all patients, and endoscopic therapy was provided, as necessary. The patients in the restrictive RBC transfusion group as compared to the liberal group had the following symptoms:

- Lower percent of patients receiving RBC transfusions (49% vs. 86%).
- Fewer number of RBC units transfused (mean 1.5 units vs. 3.7 units).
- Fewer complications (40% vs. 48%).
- Lower percent of patients having subsequent bleeding (10% vs. 16%, hazard ratio [HR] 0.62, 95% CI, 0.43–0.91).

- Lower mortality due to uncontrolled bleeding (0.7% vs. 3.1%).
- Lower all-cause mortality (5% vs. 9%, HR 0.55, 95% CI, 0.33–0.92).

The results of this study suggest that a restrictive RBC transfusion strategy might be safe and associated with improved outcomes in actively bleeding, hemodynamically stable patients when there are no additional comorbidities that impart risk such as unstable coronary artery disease and when surgical intervention is promptly available. Similar findings in the TRIGGER study support this approach.<sup>77</sup>

## The utility of preoperative hemostatic testing

Preoperative hemostatic assessment is important to ensure that patients at-risk for abnormal procedure-related bleeding are identified, evaluated, and managed appropriately to minimize this risk. The components of this assessment include a clinical bleeding history, a physical examination, and often laboratory tests of hemostasis. Ideally, the preoperative hemostatic assessment utilizes an individual patient's clinical history and physical examination findings in the context of the bleeding risk associated with a planned procedure to guide whether preoperative laboratory screening is necessary, and if so, the extent of such testing. In many cases, however, the clinical history and physical examination do not reveal evidence of an increased perioperative bleeding risk. The performance of preoperative hemostatic testing in the absence of evidence from the history and physical examination assumes that the results have predictive value regarding the risk of perioperative bleeding and allow for measures to be taken to prevent or respond to bleeding should it arises. The question to be considered is whether this is a valid assumption, and therefore, a valuable approach when it comes to preoperative patient management. A 1983 review of preoperative hemostatic evaluation considered the question of whether clinical history alone is sufficient to determine perioperative bleeding risk.<sup>78</sup> The author presented four reasons in support of the performance of laboratory tests in addition to the clinical history:

- Testing “may protect against the doctor who fails to take an adequate history” (i.e., inadequate information is obtained to accurately assess perioperative bleeding risk).
- “Some patients give an unreliable history” (i.e., some patients do not know they bled excessively in association with previous surgery or trauma).
- Some patients have hemostatic abnormalities but have not been exposed to hemostatic challenges serious enough to reveal their presence (e.g., factor XI deficiency).
- Some patients who have “withstood surgery without abnormal bleeding may later acquire a hemostatic defect” (e.g., thrombocytopenia that developed after prior surgical interventions that has remained asymptomatic and has not been subjected to significant hemostatic challenges).

Although these arguments in favor of performing preoperative hemostatic screening tests seem to reflect common sense, the critical question that remains is: do the results of screening tests of hemostasis in the absence of clinical information suggestive of an increased bleeding risk provide relevant information regarding the likelihood of perioperative bleeding?

## Performance characteristic of the common coagulation screening tests

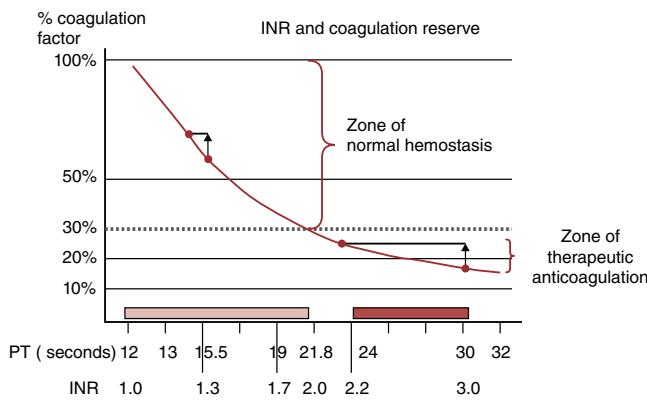

The international normalized ratio (INR) determined from the prothrombin time (PT) and the activated partial thromboplastin time (aPTT) are frequently used to guide hemostatic interventions,

including in the perioperative setting. Indeed, several societal guidelines specify INR values that may warrant treatment.<sup>22,79,80</sup> However, the interpretation of coagulation test results is fraught with challenges. Coagulation test result interpretation is hampered by a lack of clarity regarding the relationship of INR or aPTT values with in vivo coagulation factor concentrations and clinical hemostasis.<sup>20,23</sup> This uncertainty regarding the clinical significance of INR and aPTT results as gauges of true bleeding risk almost certainly contributes to the well-documented inappropriate use of plasma products.<sup>81,82</sup> To this point, it has been demonstrated in a variety of clinical settings that the INR and aPTT are poorly predictive of clinically significant hemostatic defects or periprocedural bleeding.<sup>83</sup> Furthermore, the administration of plasma often fails to produce an effective and sustained correction in coagulation factor content. Indeed, for mild-to-moderate prolongations of the INR (1.1–1.85), plasma administration frequently fails to “normalize” the coagulation test result.<sup>15,17</sup> The poor correlation between coagulation screening tests, in vivo coagulation factor levels, and clinical hemostatic dysfunction is perhaps best explained by the nonlinear relationship between the INR and serum coagulation factor levels<sup>84</sup> (Figure 39.1).

As noted in the Figure 39.1 legend, the curve is a generalized view that will vary for individual patients, which further affects the utility of the INR in evaluating the bleeding risk of a given individual patient. In settings such as liver disease or vitamin K depletion, when multiple mild coagulation factor deficiencies exist, the INR and the aPTT have been shown to overestimate the extent of coagulation defects.<sup>85</sup> This phenomenon was demonstrated by Burns *et al.*,<sup>86</sup> who observed that an in vitro plasma mixture containing a single coagulation factor at 75% activity and all the remaining factors at 100% activity produced normal INR and aPTT results. In contrast, an in vitro plasma mixture containing two coagulation factors at 75% activity and all the remaining factors at 100% activity resulted in prolonged INR and aPTT values.

### Clinical utility of preoperative hemostatic testing

Early publications proposed that preoperative assessment with the PT and the aPTT was a worthwhile effort to identify patients at-risk for bleeding.<sup>87,88</sup> Subsequent studies, however, have not provided

**Figure 39.1** The nonlinear relationship between the concentration of coagulation factors and coagulation test results. The concentration of factors (y-axis) is shown as a function of the international normalized ratio (INR) or prothrombin time (PT, in seconds). In general, a concentration of 30% is adequate for biologic hemostasis. Note that when starting at an elevated INR, a small increase in the concentration of factors will have a large impact on the measured INR. In contrast, an equivalent rise in the concentration of factors will have a negligible effect on mildly elevated INR values. The curve is a generalized view and will vary for individual patients.

strong evidence in support of preoperative hemostatic testing as a significant benefit to patient care.

A study of 480 patients with no evidence of abnormal bleeding and 139 patients with evidence of an increased risk of bleeding (by history and physical examination) evaluated the performance of the PT and aPTT done prior to surgery.<sup>89</sup> Abnormal results were obtained in 13 (2.7%) patients with no evidence of a bleeding risk and in 25 (18.0%) patients with evidence of an increased risk. One of the thirteen patients without evidence of a bleeding risk had to return to the operating room for arterial bleeding. The authors stated that the prolonged PT or aPTT was of “no apparent clinical importance” in the remaining 12 patients, and the value of preoperative coagulation testing is obscured by a high incidence of apparently false positive results. Furthermore, the authors stated that 2.28% of the healthy population would be expected to have a prolonged PT or aPTT if the reference range extended to two standard deviations above the mean normal value. Therefore, the 2.7% incidence of abnormal PT and aPTT results obtained in patients with no prior evidence of bleeding in this study could be explained by random variation in healthy subjects.

The usefulness of a protocol for the selective ordering of 12 preoperative tests was evaluated in 3866 consecutive surgery patients during a one-year period.<sup>90</sup> Test selection was based upon patient clinical status and the type of procedure planned. Based upon the protocol, the aPTT, PT, platelet count, and bleeding time were not ordered for 75%, 76%, 92%, and 99% of the patients. The value of the omitted tests was assessed relative to the occurrence of intraoperative and postoperative events. Of the nonordered tests, 0.4% were considered “potentially useful” and 0.2% “truly useful” according to the opinion of the anesthetists. Only in one case it was determined that a nonordered test (platelet count) would have been “truly useful” for patient care. This protocol for selective performance of preoperative testing was believed to have minimal adverse patient consequences, while significantly reducing test utilization.

Two prospective studies that evaluated whether preoperative hemostatic testing was justified in major surgery patients without an abnormal bleeding history were described in a single publication.<sup>91</sup> In the first study, a preoperative platelet count, bleeding time, PT, and aPTT were performed in 111 patients without an abnormal bleeding history. Mild thrombocytopenia was detected in one patient (platelet count:  $130 \times 10^9/L$ ), and eight additional patients had a prolonged aPTT. None of these patients experienced abnormal perioperative bleeding. The second study identified 49 of 1872 patients with higher than anticipated perioperative transfusion requirements over a four-month period. None of these patients had demonstrable hemostatic abnormalities, and the transfusions were given to address technical problems. The authors concluded that, in the absence of history and physical findings suggestive of a bleeding problem, preoperative testing for hemostatic testing appears unnecessary. Many similar clinical studies have reached consistent conclusions that routine preoperative hemostatic testing in the absence of clinical information suggestive of an increased bleeding risk is not useful.<sup>92-99</sup>

A systemic review of routine preoperative hemostatic testing disclosed incidences of abnormal results for the bleeding time, the PT, and the aPTT of 3.8%, 4.8%, and 15.6%, respectively.<sup>100</sup> The abnormal test results rarely led to changes in patient management. The authors concluded that the evidence did not support a policy of routine preoperative hemostatic testing for all patients. Another systemic review reported on the predictive value of the patient bleeding history and unselected coagulation testing for abnormal

perioperative bleeding.<sup>101</sup> The PT and aPTT were found to be poor predictors of bleeding. It was recommended that a bleeding history be performed in all preoperative patients, and if that history is negative, then coagulation testing is not required. If the bleeding history is positive or if clinical conditions that clearly impart an increased risk of perioperative bleeding are present (e.g., liver disease), then a comprehensive hemostasis assessment should be performed prior to surgery.

One preoperative laboratory screen that may be of use is a platelet count. A recent observational cohort study of adult elective surgery patients assessed the clinical significance of preoperative thrombocytopenia.<sup>26</sup> Preoperative thrombocytopenia was associated with significantly increased odds for intraoperative transfusions in anemic (odds ratio 2.60;  $p < 0.001$ ) and nonanemic patients (odds ratio 3.39;  $p < 0.001$ ). Preoperative thrombocytopenia, therefore, seems to correlate with intraoperative transfusion requirements.

In addition to routinely available tests such as the PT, aPTT, and platelet count, other assays have been evaluated for predicting the risks of perioperative bleeding. In the absence of a history suggestive of a bleeding tendency, the bleeding time has not been shown to be useful as a preoperative screening test (normal and abnormal results have poor predictive value) and it has not been recommended to serve in this capacity.<sup>102,103</sup> Although fairly rapid tests have been developed to measure native and drug-induced platelet dysfunction (e.g., PFA-100, Plateletworks<sup>®</sup>), because of questionable abilities to predict bleeding,<sup>104</sup> these assays are likewise not recommended as screening tests for perioperative bleeding risk.

Consistent with the above literature, the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation has concluded that routine preoperative tests (tests intended to detect a potentially significant abnormality in an asymptomatic patient) do not provide an important contribution to the perioperative assessment and management of the patient.<sup>105</sup> Preoperative laboratory testing, including coagulation testing, should be ordered only as necessary based upon information obtained from the medical record review and the patient history and physical examination in the context of the types of procedure and anesthesia planned for an individual patient.

In conclusion, based upon the evidence currently available, with the possible exception of knowing a patient's preoperative platelet count, it seems reasonable to conclude that preoperative screening with hemostatic tests should be restricted to patients with a family history of an inherited bleeding disorder (in conjunction with a hemostasis consult with perioperative recommendations for management), a history of abnormal bleeding or a family history of abnormal bleeding (such patients should undergo a comprehensive preoperative hemostatic evaluation), and those with underlying conditions associated with an increased risk of bleeding such as chronic liver disease.

### **Point-of-care viscoelastic assays instead of preoperative hemostatic testing**

With growing concern regarding the ability of PT/INR, aPTT, and platelet function tests to predict bleeding events, in addition to their frequently unacceptable turnaround times for results, recent focus has shifted toward the use of modern viscoelastic assays such as thromboelastography (TEG) and rotational thromboelastometry (ROTEM).<sup>106–109</sup> These tests appear able to provide a more accurate and timely point-of-care assessment of thrombus formation in whole blood.<sup>110</sup> Although used most extensively in cardiac surgery

and liver transplantation, early data suggest that these tools may better guide individual transfusion decisions and reduce overall blood product exposure.<sup>111,112</sup> Indeed in 2011, Görlinger *et al.*<sup>113</sup> found that the use of ROTEM in cardiac surgical patients resulted in increased utilization of specific factor concentrates, while simultaneously producing an overall reduction in blood product transfusions, without any associated increase in morbidity or mortality. The use of test systems, such as point-of-care viscoelastic assays, to monitor and manage hemostatic status in surgical patients, deserves further investigation as a potentially useful adjunct or alternative to preoperative hemostatic testing.

### **Intraoperative use of the activated clotting time (ACT)**

The activated clotting time (ACT) is the preferred test for intraoperative monitoring of anticoagulation because it has a rapid turnaround time and a reportable range for patients receiving high-dose heparin during cardiopulmonary bypass. Although sensitive to factors in the intrinsic coagulation cascade and unfractionated heparin, the ACT can also be affected by antithrombin and fibrinogen levels, low platelet or red cell counts, quantitative platelet abnormalities, hypothermia, lupus anticoagulants, and antiglycoprotein IIb/IIIa medications.<sup>114–116</sup>

Several ACT devices are currently approved in the United States and each is unique regarding sample type, activator used, and clot detection mechanism.<sup>114</sup> Several studies have demonstrated that the ACT values obtained with these various devices are not interchangeable.<sup>114,117–119</sup> In one study, the Hemochron ACT and the i-STAT ACT were directly compared, and the mean difference between the two methods was  $24 \pm 101$  seconds.<sup>120</sup> This study suggested, for anticoagulation monitoring during cardiopulmonary bypass, a Hemochron ACT of  $>480$  was correlated with an i-STAT ACT of  $>400$  seconds. Similarly, Maslow *et al.* compared the i-STAT ACT to the Hemochron ACT and found that the i-STAT consistently had lower values when the ACT was  $>180$  seconds, and this difference grew as heparin levels increased.<sup>121</sup> In contrast, Lewandrowski *et al.* compared the iSTAT ACT to the Medtronic ACT Plus and found a correlation coefficient of 0.94.<sup>122</sup> Additionally, Carroll *et al.* recently demonstrated a complete lack of correlation of the Hemochron ACT with Anti-Xa levels after heparinization for cardiopulmonary bypass.<sup>123</sup>

With such wide variation in response to high-dose anticoagulation, it seems prudent for each practice to develop a well-validated testing strategy and anticoagulation goals for each perioperative need. The most recent guidelines from the Society of Thoracic Surgeons, The Society of Cardiovascular Anesthesiologists, and The American Society of ExtraCorporeal Technology on anticoagulation for cardiopulmonary bypass suggest a target ACT of  $>480$  seconds, while specifically highlighting the need to incorporate instrument bias and technology into this target.<sup>124</sup>

### **Management of perioperative anticoagulation and antiplatelet therapies**

Management of anticoagulation in the perioperative period can be challenging. Clinicians must weigh the risk of thromboembolic complications versus procedural bleeding and determine the best overall strategy for optimizing outcomes (e.g., passive anticoagulant interruption, versus active reversal with vitamin K or coagulation factor replacement, versus bridging with heparin therapy and/or IVC filter placement). Currently, there is little strong evidence in

the literature from randomized clinical trials to provide definitive recommendations, and many of the existing guidelines are based upon expert opinion. In clinical practice, thromboembolic and bleeding risks depend upon both patient and procedural characteristics. Therefore, determining the optimal management strategies will depend upon specific individual risk factors and procedural details. For patients with mechanical heart valves, the risk of thromboembolism is highest in the first three months after valve surgery, particularly when considering the mitral valve.<sup>125</sup> In this instance, simple measures such as avoiding elective surgery during this time frame can help to prevent unnecessary interruptions in anticoagulation that would place the patient at greatest risk of thromboembolic complications.

In 2012, the American College of Chest Physicians (ACCP) recommended careful planning of elective procedures with cessation of warfarin seven days before surgery thus allowing INR to gradually normalize. This approach avoids the need for vitamin K administration that may prolong achievement of an effective antithrombotic state with warfarin.<sup>126</sup> This guideline also stressed the importance of regular INR checks during this time to allow for initiation of bridging anticoagulation (either with heparin or low-molecular-weight heparin) until the time of surgery. An INR check is specifically endorsed on the day prior to surgery to allow for low-dose oral vitamin K supplementation if clinically indicated.

For patients with atrial fibrillation (AF), the risk of thromboembolism may be best characterized using existing risk stratification scores such as the CHADS2 or CHADS2-VASc.<sup>127</sup> However, it must be recognized that these scores have not been specifically validated for predicting risk of thromboembolism in the postoperative period. Of note, the Randomized Evaluation of Long-Term Anticoagulant Therapy (RE-LY) trial recently evaluated thromboembolic risk in patients with nonvalvular AF.<sup>128</sup> This investigation found a rate of thromboembolic complications (including stroke, pulmonary embolus, or cardiovascular death) of 1.2%, with the greatest risk seen in patients undergoing urgent surgery.

Finally, for patients whose indication for anticoagulation is thromboembolic disease, risk of subsequent thromboembolism with anticoagulant interruption is believed dependent on the time from the initial thromboembolic event. Where feasible, deferring surgery and accompanying anticoagulation interruption may be of benefit.<sup>129,130</sup> If emergency surgery is required, bridging with heparin is often endorsed.<sup>131</sup> However, further randomized trials are warranted in this area to determine the optimal perioperative management of anticoagulation in this setting.

For patients taking direct oral anticoagulants (DOACs) including factor Xa inhibitors such as rivaroxaban and apixaban, or direct thrombin inhibitors such as dabigatran, evidence guiding perioperative interruption is more limited. Based on their elimination half-lives (7–11 hours for factor Xa inhibitors and 12–14 hours for thrombin inhibitors in patients with normal renal function),<sup>132</sup> these agents are typically stopped 2–3 days ahead of elective surgery to minimize surgical bleeding.<sup>133,134</sup> This interval may be extended in particularly high-risk operations or shortened in particularly low-risk procedures.

Importantly, coagulation studies are not routinely indicated in DOAC-treated patients. For example, while the aPTT has been advocated to assess coagulation status in patients treated with direct thrombin inhibitors,<sup>135</sup> this method lacks sufficient evidence to make strong recommendations for its use. Indeed, for the most part, the INR and aPTT have not been validated for the assessment of coagulation status in patients treated with any DOAC.<sup>136</sup>

Nonetheless, for emergent operations or in patients presenting with a bleeding episode, assessment of coagulation status may be desired. Specific factor Xa activity assays, if available, may help to guide management of factor Xa inhibitors.<sup>137</sup> If factor Xa assays are not available, the PT may show prolongation in patients taking factor Xa inhibitors; however, significant interassay variability exists so PT and/or INR measurements are not strongly advocated in this setting.<sup>136</sup> If available, ROTEM can be used to assess coagulation status as factor Xa inhibitors will produce a dose-dependent prolongation of R and K time with no change in maximal amplitude.<sup>137</sup> At present, dabigatran anticoagulation may be best measured using the thrombin time or dilute thrombin time.<sup>138</sup> Overall, while prolonged coagulation times may point to residual anticoagulation effect in a patient treated with DOACs, normal coagulation test results cannot be considered evidence of normal coagulation; therefore, treatment should not be delayed awaiting the results coagulation testing.

If rapid correction of anticoagulation with rivaroxaban is required, prothrombin complex concentrates (PCCs) may be effective.<sup>139,140</sup> Furthermore, a specific reversal agent for factor Xa inhibitors (andexanet alfa) has recently been approved for the management of life-threatening bleeding.<sup>141</sup> Similarly, idarucizumab is a monoclonal antibody that can be used for emergency reversal of dabigatran.<sup>142</sup> Each of these reversal agents, however, carries the risk of thrombosis.<sup>143</sup> Alternatively, in the setting of acute bleeding, dabigatran may be successfully filtered by hemodialysis,<sup>144</sup> offering a unique method for reversing anticoagulation. Additionally, the use of oral activated charcoal may be considered for recently ingested oral anticoagulants, while antifibrinolytics, such as tranexamic acid, may also be effective. Ongoing randomized clinical trials are needed to determine the best way to reverse DOACs.<sup>145</sup> As with warfarin, decision-making regarding interruption of anticoagulation should weigh the risk of thrombosis versus the risk of bleeding for each individual patient and procedure. Due to the rapid onset of action of these agents relative to warfarin, bridging with heparin is often not required when reinitiating DOAC therapy postoperatively.

With an aging population, the use of antiplatelet agents, such as aspirin and clopidogrel, is widespread to manage the risk of major cardiac and vascular thromboembolic events. As with anticoagulants, similar risk to benefit assessments must be made ahead of elective surgery.<sup>146</sup> Both aspirin's and clopidogrel's antiplatelet properties last for the lifespan of the platelet due to their irreversible inhibition of cyclooxygenase 1/2 and the platelet adenosine diphosphate (ADP) P2Y12 receptor, respectively.<sup>147</sup> Due to concern for increased perioperative bleeding,<sup>148–150</sup> antiplatelet agents have historically been withheld for 7–10 days preoperatively. Most recently, this notion was supported by findings from the Perioperative Ischemic Evaluation (POISE-2) randomized controlled trial in which aspirin administration was not associated in any significant decrease in risk of death or nonfatal myocardial infarctions; however, major perioperative bleeding was increased.<sup>151</sup> Of note, patients with recent coronary stents and those taking thienopyridines or Ticagrelor were excluded from this study, raising concern about the generalizability of these findings. Moreover, prior observational studies have suggested that early perioperative aspirin use may reduce both death and ischemic complications in patients undergoing cardiac surgery.<sup>152,153</sup> Similarly, Biondi-Zoccali *et al.*<sup>146</sup> noted a threefold increase in thrombotic complications in moderate- to high-risk patients in whom aspirin was withheld perioperatively. This controversy has led to a re-exploration of the risks and benefits of antiplatelet therapies in the perioperative setting. Indeed

the 2012 ACP Guidelines suggest continuing aspirin around non-cardiac surgery in those deemed to be at moderate to high risk of cardiovascular events (with aspirin cessation for 7–10 days in those at low risk).<sup>126</sup> Of note, these guidelines were published ahead of the POISE-2 trial findings becoming publicly available.

Considering the ongoing equipoise, individual assessments of risk-to-benefit ratios are required for each patient. In general, currently accepted evidence is in favor of withholding antiplatelet agents when prescribed only for primary prevention (low thrombotic risk) and/or when bleeding risk may be life threatening, for example with intracranial or ophthalmic surgery. Conversely, patients with bare metal stent placement within six weeks, or drug eluting stent within six months, should not routinely discontinue antiplatelet therapy for elective surgery. For those patients requiring urgent surgery with an intermediate or high risk of bleeding, options include discontinuation of clopidogrel with continuation of aspirin or discontinuation of both agents with bridging therapy around the time of surgery.

### **Conservative versus liberal transfusion practices**

Historically, blood products have been administered to treat patients with both life-threatening hemorrhage and those with mild derangements in laboratory parameters. For the latter, the assumption has been that the normalization of these laboratory abnormalities would improve patient outcomes. Indeed, in the middle of the last century, it was recommended that RBCs be transfused to maintain an Hb concentration >10 g/dL based upon the assumption that increasing the patient's Hb would improve tissue oxygenation.<sup>154</sup> This became a longstanding, accepted standard of practice for surgical patients for many years. Similarly, even now, plasma is often administered to correct modest abnormalities in the INR in the absence of active bleeding.<sup>17,21,155–158</sup> Importantly, the perioperative setting remains a leading environment for the administration of blood component therapies. This makes the perioperative environment a prime setting to improve blood product utilization moving forward. Additionally, recent evidence suggests that massive transfusion protocol activations are more common in the perioperative setting than in any other area of care delivery.<sup>159</sup>

A substantial body of literature is now available evaluating RBC transfusion practices in various clinical situations. As outlined above, multiple RBC transfusion studies have demonstrated the safety and effectiveness of more restrictive transfusion practices.<sup>6,7,70,160–163</sup> A more restrictive approach has been shown safe in the setting of liver resection<sup>160</sup> as well as in patients with sepsis,<sup>161</sup> gastrointestinal bleeding,<sup>6</sup> and traumatic brain injury.<sup>162</sup> A growing body of literature also suggests safety in the setting of cardiac surgery<sup>163</sup> and acute coronary syndrome.<sup>164</sup> Additionally, Yu *et al.*<sup>165</sup> identified a positive dose-response relationship between the number of blood products transfused and risk of adverse outcomes in patients undergoing cardiac surgery. In aggregate, the prevailing conclusion of available clinical trial literature suggests that liberal RBC transfusion practices do not offer a morbidity or mortality advantage in stable, nonhemorrhaging patients. To the contrary, most observational research studies have suggested that restrictive transfusion practices may be associated with a higher probability of survival and fewer complications such as infection, acute respiratory distress syndrome, cardiogenic shock, acute kidney injury, and multiorgan dysfunction.<sup>166–168</sup>

Despite the growing evidence supporting restrictive RBC transfusion strategies, widespread implementation of conservative transfusion practices in the operating room environment has not been without challenges. Although many societal guidelines and patient blood management programs now advocate restrictive transfusion strategies,<sup>169–174</sup> transfusions continue to be frequently administered outside of published guidelines. In an effort to improve the intraoperative transfusion practice, the American Society of Anesthesiologists' (ASA) practice guidelines recommend (1) periodic visual assessment of the surgical field and communication with the surgical team, (2) continuous monitoring for evidence of inadequate perfusion and oxygenation of vital organs, (3) use of standard methods for quantitative measurement of blood loss, including checking suction canisters, surgical sponges, and surgical drains, and (4) implementation of a blood management protocol with the determination of whether hemoglobin concentrations between 6 and 10 g/dL justify or require red blood cell transfusion based on potential or actual ongoing bleeding (rate and magnitude), intravascular volume status, signs of organ ischemia, and adequacy of cardiopulmonary reserve.<sup>171</sup> Furthermore, these guidelines endorse the use of blood recovery techniques and permissive hypotension to decrease blood loss, when appropriate. Outside of massive transfusion protocols, it is also recommended that RBC transfusions occur one unit at a time, with subsequent evaluation of the clinical response before determining the need for additional RBC transfusions.<sup>171</sup>

### **Blood avoidance techniques**

Considering the potential for transfusion-related adverse events, the limited supply of blood components, and the occasional religious objection to blood transfusion, the avoidance of transfusion, in some situations, may represent a more safe, cost-effective, and morally acceptable option. Although blood transfusion is not always avoidable, several interventions may be employed to facilitate the avoidance of blood component therapies. Prior to elective surgery, phlebotomy should be limited to only tests essential for clinical decision making.<sup>175</sup> The rationale for limiting phlebotomy is based on a growing body of data outlining the prevalence and severity of iatrogenic hospital-acquired anemia (HAA) and its effect on patient outcomes.

A large observational study by Koch *et al.*<sup>176</sup> describes an incidence of HAA of 74%. Although felt to be multifactorial, phlebotomy has been highly correlated with HAA. Data suggest a decrease in Hb of 0.08 g/dL for every 1 mL of blood drawn<sup>177</sup> or an 18% increased risk of developing moderate-to-severe HAA with every 50 mL of blood drawn.<sup>178</sup> Equally, if not more important, HAA has been associated with increased hospital length of stay, hospitalization costs, and in-hospital mortality.<sup>176</sup> Minimizing phlebotomy volumes has been previously demonstrated to reduce transfusion requirements in critically ill patients and should be a standard measure employed as part of blood avoidance.<sup>179</sup> Postoperatively, iatrogenic anemia can likewise be minimized through the judicious use of phlebotomy.

In certain populations, particularly patients with preexisting anemia, and in those who refuse transfusion, erythropoietin and iron supplementation should be considered, especially if preoperative autologous blood donation will take place.<sup>180</sup> In one study, preoperative IV iron therapy prior to major abdominal surgery was associated with fewer blood transfusions, a shorter hospital stay, increased iron stores, and a higher mean hemoglobin four weeks

after surgery.<sup>52</sup> If safe to do so, cessation or avoidance of blood thinning drugs—including nonsteroidal anti-inflammatory drugs, anti-platelet agents, and anticoagulants—is also prudent.<sup>181</sup>

Intraoperatively, there should be meticulous attention to hemostasis and rapid control of hemorrhage.<sup>176</sup> Permissive hypotension may be considered as a method to minimize precipitous blood loss.<sup>182,183</sup> To this end, a recent randomized trial evaluating resuscitation of trauma patients demonstrated that patients resuscitated to a mean arterial pressure (MAP) of 50 mmHg required significantly fewer blood products and reduced crystalloid resuscitation volumes compared with those resuscitated to an MAP goal of 65 mmHg.<sup>182</sup> These patients also had a lower early postoperative mortality and experienced coagulopathy less frequently and with a lesser severity. A subsequent meta-analysis of 1158 patients from five RCTs in adult trauma demonstrated a small survival benefit (OR 0.7, 95% CI, 0.53–0.92), fewer transfused blood products, and lower estimated blood loss in permissive hypotension; however, the studies were rated as low to moderate quality and were in general under-powered.<sup>184</sup> More robust evidence is needed before recommending this as a viable practice in critically ill patients.

Other measures to minimize intraoperative blood loss include the avoidance of hypothermia,<sup>185,186</sup> and when possible, cell salvage mechanisms should be utilized to facilitate rapid autologous transfusion. Although it has been well established that coagulation worsens with hypothermia, there is ongoing enthusiasm and controversy regarding targeted temperature management to improve neurologic outcomes after cardiac arrest.<sup>187</sup> Although this remains controversial, transfusion experts should be aware of its continued use as it may conflict with the goal of maintaining normothermia to promote hemostasis.

Modern cell salvage technologies are unique in their ability to provide rapid, large volumes of blood to patients without the need for preoperative donation or hemodilution that may be limited by patient tolerance and hemodynamic reserve. These methods have been most extensively used in hepatic,<sup>188,189</sup> cardiac,<sup>190–192</sup> obstetrics,<sup>193,194</sup> and orthopedic<sup>195</sup> surgeries and have been shown to be cost-effective and safe. In recent decades, the use of cell salvage in patients with active malignancy and bacteremia has been questioned due to the concern of hematogenous spread.<sup>196,197</sup> Despite a recent meta-analysis of 4354 patients from nine RCTs in a variety of cancers showing no differences in five-year survival, five-year disease-free survival, or five-year recurrence rates,<sup>198</sup> there is no consensus on cell salvage in surgical oncology and its use should likely be considered a relative contraindication.

Although not broadly utilized, acute normovolemic hemodilution (ANH) remains a viable option for many types of surgery by minimizing the loss of red cell mass through dilution and sequestering coagulation factors and platelets until after surgical hemostasis is achieved.<sup>199–201</sup> A recent meta-analysis in cardiac surgery including 2439 patients from 29 RCTs demonstrated that the use of ANH was associated with fewer red cell transfusions and less post-operative blood loss;<sup>202</sup> however, a detailed assessment of the effects of ANH vs. controls on coagulation parameters after cardiac surgery was modest at best.<sup>203</sup> Regardless, ANH may be considered as a component of a comprehensive patient blood management protocol.

Although aprotinin is no longer approved for use by the US Food and Drug Administration, lysine analogs such as  $\epsilon$ -aminocaproic acid and tranexamic acid are advocated by some, including the Society of Thoracic Surgeons and Society of Cardiovascular

Anesthesiologists (STS/SCA), to minimize total blood loss.<sup>204</sup> Efficacy for these agents is most robust in the settings of cardiac surgery, orthopedic surgery, trauma resuscitation, and in postpartum hemorrhage, particularly when used in the first few hours of resuscitation.<sup>205,206</sup> In addition, topical hemostatic agents may be utilized (see below).

Over the past several decades, there has been a growing emphasis placed on blood conservation and transfusion avoidance techniques due to the association with improved patient outcomes and lower complication rates.<sup>207</sup> This emphasis has recently been amplified due to recent crisis-related blood shortages due to disasters and the COVID-19 pandemic. Consequently, multiple international societies have recommended PBM campaigns as a component of best practice to address these situations.<sup>208</sup>

## Topical hemostatic therapies

Topical hemostatic therapies offer a variety of options to manage localized bleeding that could prevent the need for transfusion. While suture ligation of a damaged vessel remains the single most effective method for hemostasis, this is not always technically feasible. In this situation, the use of electrocautery, sclerosing agents, argon laser beam coagulation, and direct packing and compression are common practices.<sup>209</sup> Topical hemostatic therapies provide additional options to achieve local hemostatic control of bleeding sites during surgery. There are two general categories of topical hemostatic therapies: physical agents, which provide an environment where hemostasis can occur, and biologically active agents, which actively enhance hemostatic mechanisms at bleeding sites. They are used to treat bleeding in many locations including the following:<sup>210</sup>

- Areas close to nerves
- Vital structure regions that should not sustain cautery-induced injury
- Suture holes in vessels or grafts
- Cut surfaces of bone
- Pleural or peritoneal surfaces
- Cut surfaces of solid organs<sup>211–213</sup>
- The nose<sup>214,215</sup>
- Dental extractions<sup>216</sup>

## Physical agents

Physical agents consist of materials that foster hemostasis through activation of platelets and the extrinsic coagulation pathway while also serving as the structural foundation for thrombus deposition. As the thrombus grows at the site of physical agent placement, pressure is exerted locally, which can tamponade bleeding vessels. There are a number of physical hemostatic agents that can be used topically including the following:

- Bone wax
- Ostene
- Gelatin preparations
- Microfibrillar collagen
- Microporous polysaccharide spheres
- Oxidized regenerated cellulose
- Hydrophobic light-activated adhesive (investigational)

Bone wax and Ostene can be used to control bleeding from cut surfaces of medullary bone, which can occur during neurosurgery and orthopedic procedures and after median sternotomy. Bone wax stops bleeding by physically occluding blood vessels within bone.

Bone wax has been implicated as a risk factor for surgical site infections and in the generation of granulomas, resulting in interference with bone healing.<sup>217,218</sup> Ostene also occludes blood vessels within bone; however, it does not remain in the wound for long term and persist as a foreign body. Ostene has been reported to be associated with better bone healing in comparison to bone wax.<sup>219,220</sup>

Gelatin (e.g., Gelfoam and Surgifoam) preparations provide a meshwork that entraps platelets and coagulation factors, thus providing an environment that fosters clot formation.<sup>221,222</sup> Gelatin sponge preparations can absorb a significant volume of blood or fluid (40–45 times its weight) and they can expand in size by up to 200%. This creates a tamponade effect that also helps to achieve hemostasis. Pressure is maintained (often for several minutes) on the gelatin sponge after placement to secure hemostasis. The sponges can be left in place as they completely resorb in four to six weeks. However, gelatin use has been associated with granulomas, fibrosis, increased incidence of infection, and clot disruption from sponge removal.<sup>221,223</sup>

Microfibrillar collagen (e.g., Avitene) serves as a scaffold for the activation of platelets and subsequent clot formation. Microfibrillar collagen can be applied to sites of bleeding as a powder or as a foam sheet, and it will fully resorb within three months.<sup>210</sup> Indications for use of microfibrillar collagen include neurosurgery, urology, and vascular surgery. Microfibrillar collagen should not be allowed to enter cell salvage systems because the filters do not effectively block their passage; therefore, the fibers can be reinfused into the patient along with the salvaged product and pose a risk for embolization and DIC.

Microporous polysaccharide spheres (MPS) (e.g., Arista) absorb water, which serves to regionally concentrate platelets and coagulation factors, promoting clot formation. MPS are available as a powder. The powder is generously dispersed over bleeding sites following pressure with a dry surgical sponge, which is used to achieve as dry a surface as possible. After distribution of the spheres, pressure is again applied with a surgical sponge to achieve hemostasis. MPS rapidly absorb within 48 hours and they do not promote infections or cause foreign body responses.<sup>224</sup> The spheres are approved for use in neurosurgery, and they have also been used in cosmetic surgery. MPS can be used in patients undergoing cell salvage procedures that utilize cell washing and 40-μm infusion filters.

Oxidized regenerated cellulose (ORC) is sterile, dry mesh (e.g., Surgicel) that can be directly applied to sites of bleeding. ORC is typically used to control bleeding at the cut surfaces of solid organs, at vascular anastomoses, and at pelvic and retroperitoneal surfaces after lymphadenectomy. It is pliable and can be delivered to bleeding sites laparoscopically.<sup>225,226</sup> Full absorption of a single sheet of ORC is expected to occur in approximately 14 days.<sup>223</sup> Adhesions and infections, however, have occurred in association with residual ORC. Unabsorbed ORC was identified as a risk factor in a study of 360 patients with postoperative pelvic abscesses.<sup>227</sup> In some of these patients, nonresorbed ORC was identified during laparotomy more than 1 year after application.

Hydrophobic light-activated adhesive (HLAA) is a topical hemostatic agent that is being investigated.<sup>228</sup> It is a prepolymer that is mixed with a substance that can be photoactivated. HLAA is applied to bleeding sites as a liquid and, upon exposure to ultraviolet light, the material develops crosslinks and converts into a tissue glue that resists dissolution in the presence of blood or other fluid environments.

## **Biologically active agents**

Biologically active topical hemostatic agents enhance hemostasis at the site of application. Agents of this type include the following:<sup>210</sup>

- Topical thrombin
- Fibrin sealant
- Tranexamic acid

Topical thrombin is available as a lyophilized powder that requires reconstitution prior to use.

In diffuse bleeding, such as when large portions of pleural and peritoneal surfaces are oozing, topical thrombin can be delivered via a sprayer. When bleeding is more localized, it can be delivered to the site with a needle and syringe. Topical thrombin in combination with gelatin preparations (sponge or granules) takes advantage of the combination of the biological hemostasis enhancement properties of thrombin with the physical configuration of the gelatin, which serves as a scaffold for clot formation.<sup>229,230</sup> This combination has been effective in achieving hemostatic control of suture holes in vascular grafting procedures. Hemostatic control may be more rapid when thrombin is used in combination with gelatin granules (e.g., FloSeal, Surgiflo) as opposed to thrombin-soaked gelatin foam.

Currently, bovine, human, and recombinant thrombins are available. The use of bovine-derived thrombin has been associated, in a minority of patients, with the development of antibodies directed against bovine coagulation proteins in the preparation.<sup>231</sup> These antibodies include factor V antibodies and thrombin antibodies. In some patients, these antibodies can crossreact with human coagulation proteins, resulting in the development of a coagulation inhibitor. In some of these patients, the inhibitor can be clinically significant and represents a serious adverse effect of bovine thrombin. Because human-derived and recombinant preparations of topical thrombin are now widely available, the necessity to use of bovine thrombin for hemostatic control has significantly decreased.<sup>232</sup>

Fibrin sealant preparations typically consist of two separate solutions, one containing fibrinogen and factor XIII and the other thrombin and calcium.<sup>233</sup> A fibrin clot forms when these two solutions are applied simultaneously. The fibrin sealants are applied as a liquid, spray, or dressing, and they facilitate the control of bleeding from cut tissue surfaces and vascular anastomoses.<sup>234–236</sup>

Tranexamic acid is an antifibrinolytic agent that competitively blocks the binding of lysine to lysine binding sites on plasminogen molecules, resulting in the inhibition of the conversion of plasminogen to plasmin.<sup>237</sup> Topical use of tranexamic acid to achieve local hemostatic control of bleeding surfaces has been used in settings such as breast, cardiac, head and neck, and orthopedic surgery.<sup>238–242</sup> Evidence regarding the safety and efficacy of topical tranexamic acid is still rather preliminary, and more data will be required to better define its role in the management of surgical bleeding.

## **Topical hemostatic selection**

The selection of a particular topical hemostatic is affected by the site and extent of bleeding, the local availability of the various agents, the usage experience and preferences of practitioners, and cost.<sup>243</sup> In general, compared to nonbiologically active physical topical agents, biologically active agents such as thrombin or fibrin sealant tend to be more effective for more rapid bleeding and when a coagulopathy and/or defibrinated fluids are present.

## Perioperative transfusion guidelines

### Red blood cells: indications, threshold, and dose

Evidence-based indications for RBC transfusion in nonbleeding, hemodynamically stable patients have been revised and subsequently reaffirmed many times in recent decades.<sup>173,174,244</sup> Unfortunately, few of these investigations provide meaningful guidance for surgical populations, particularly when clinically significant active bleeding is encountered.<sup>170,171,204</sup> In this specific clinical circumstance, the unwavering take home message is that appropriate RBC transfusion practices require more than an arbitrary hemoglobin-based transfusion trigger. Rather, the decision to transfuse RBCs in this context should be based upon patient-specific symptoms (e.g., hemodynamic instability or evidence of tissue hypoxia) and details relating to the surgical course (e.g., expected ongoing blood loss).<sup>170,171,204</sup> To this point, the most compelling indication for intraoperative RBC transfusion remains acute hemorrhage with associated hemodynamic instability or evidence of inadequate oxygen delivery. In contrast, generalized mucosal oozing, gradual blood loss over a prolonged period of time, and asymptomatic anemia related to chronic disease or hemodilution are perhaps more frequent clinical scenarios that prompt difficult decisions regarding the appropriateness of intraoperative RBC administration. In 2006, the ASA's taskforce on perioperative blood transfusion was among the first to encourage more conservative transfusion practices for surgical populations.<sup>22</sup> The authors appropriately noted that the literature was insufficient to define a transfusion trigger in surgical patients with substantial blood loss. They concluded that the decision to transfuse should be based upon regular assessment of the surgical field, communication with the surgical team, estimated blood loss, Hb concentration, and an assessment of organ perfusion. Assessment of organ perfusion includes heart rate, blood pressure, urine output, evidence of ischemia, and, where appropriate, mixed venous oxygen saturations and echocardiography. All members of the panel agreed that RBCs should be administered when the Hb is <6 g/dL and that transfusion is rarely necessary when the Hb >10 g/dL.<sup>22</sup> These guidelines were updated in 2015, reinforcing the use of a restrictive red blood cell transfusion strategy for most clinically stable surgical patients.<sup>171</sup>

Beyond the setting of acute hemorrhage, available guidelines generally support conservative transfusion practices, considering individual patients' need for RBC transfusion only when the Hb falls below 7 g/dL.<sup>173,174,244</sup> This recommendation was also endorsed by the Society of Critical Care Medicine and the Eastern Association of Surgery for Trauma's 2009 joint clinical practice guidelines.<sup>169</sup> Specifically, this guideline intended to address indications for RBC transfusion in the critically ill, those presenting with trauma, requiring mechanical ventilation or with known stable coronary disease. Although there remains a degree of equipoise regarding optimal transfusion thresholds in patients with coronary artery disease,<sup>75,245</sup> recent clinical trials suggest safety with more restrictive approaches to RBC transfusion in these populations as well.<sup>163,164</sup> Although recommendations similar to these were re-emphasized in the AABB 2016 clinical practice guidelines, a more modest Hb threshold of 8 g/dL was suggested for patients with stable coronary disease and for those undergoing cardiac or orthopedic procedures.<sup>173</sup> This slightly higher threshold of 8 g/dL was predominantly chosen based upon findings of the FOCUS trial in which liberal (Hb < 10 g/dL) transfusion strategies were compared to a more restrictive approach (Hb < 8 g/dL or symptomatic) in surgical patients with known stable cardiovascular disease.<sup>246</sup> As the restrictive threshold chosen for this trial was 8 g/dL rather than 7 g/dL,

AABB has endorsed this slightly higher threshold acknowledging that 7 g/dL may also be safe but has not been formally studied in these specific patient populations.

The primary goal of perioperative RBC transfusion is to maintain tissue oxygenation. Although improved oxygen carrying capacity is certainly achieved with RBC transfusion, the association between RBC transfusion and improved tissue oxygenation remains much more controversial.<sup>247–250</sup> Multiple studies have attempted to address this very question and while oxygen delivery consistently improves following RBC transfusion, very few studies have been able to demonstrate an increase in tissue oxygen consumption.<sup>169,249</sup> Although the underlying mechanisms remain under investigation, it is hypothesized that this observation may be secondary to a diminished capillary diameter in critically ill or injured patients, or as a function of the many biochemical changes that occur in stored RBCs.<sup>250</sup>

In the absence of acute blood loss, the desired end points following perioperative RBC transfusion are less well defined. Available literature suggests that an individualized assessment for evidence of ischemia or hemodynamic stability with signs or symptoms suggestive of inadequate end-organ perfusion and oxygenation should guide decisions on RBC administration.<sup>170,171</sup> Where none of the above criteria are satisfied, further transfusion is unlikely to result in meaningful clinical benefit. However, respecting existing guidelines recommending RBC transfusion when the Hb falls below 7 g/dL, it would seem reasonable to transfuse patients to a target above this threshold.

In summary, modern perioperative RBC transfusion practice has seen a move toward more restrictive transfusion strategies. This substantial re-evaluation of our RBC transfusion practice has been largely driven by evolving evidence showing an association between liberal transfusion practices and adverse patient outcomes, including infection, acute respiratory distress syndrome, multiorgan dysfunction, and mortality. Although the association between liberal RBC transfusion practices and these adverse patient outcomes remains a matter of much debate, largely due to the observational nature of supporting literature, the absence of evidence suggesting the potential for harm with restrictive transfusion therapies would appear to support recommendations to avoid RBC transfusion in the majority of nonbleeding, hemodynamically stable patients when the Hb is >7 g/dL.

### Plasma: indications, threshold, and dose

It has been estimated that approximately one-third of plasma products are transfused for nonevidence-based indications.<sup>17–19</sup> In the United States, the most frequently cited rationale for deviation from published guidelines is to correct abnormal preprocedural coagulation screening tests in nonbleeding patients.<sup>84,158,251</sup> The rationale for transfusing plasma in this context is based on three basic assumptions: (1) an elevated INR reliably predicts bleeding complications, (2) administration of plasma will normalize the INR, and (3) administration of plasma will prevent bleeding complications. Importantly, all three assumptions rest on minimal evidentiary support, and when considering the growing body of evidence suggesting a poor correlation between coagulation screening test abnormalities and periprocedural bleeding complications alongside the increasingly appreciated risks of transfusion, such practice is strongly discouraged.<sup>20,84,252–256</sup>

It is important to note that, in the absence of massive transfusion or hemorrhagic shock, anticoagulant therapy, or consumptive disorders, such as disseminated intravascular coagulation,

coagulation factor depletion as an underlying cause of clinically significant bleeding is rare. Indeed, it is understood that adequate coagulation persists with approximately one-third of normal clotting factor concentrations and fibrinogen levels  $\geq 75$  mg/dL.<sup>155,257</sup> Although these abnormalities will result in derangements of laboratory coagulation parameters, thrombin generation is generally preserved, and clinical coagulopathy does not typically correlate with testing results. Accordingly, with improved understanding of in vivo coagulation, as well as the risks of transfusion therapies,<sup>66,67</sup> there have been notable changes in the clinical indications for perioperative plasma transfusion. Indeed, the historic use of plasma as a volume expander is now obsolete. At present, the strongest indication for plasma transfusion is for the treatment of active hemorrhage that is believed related to multiple coagulation factor deficiencies.<sup>155,171,258,259</sup> A substantial body of evidence supports the use of liberal plasma transfusion strategies (e.g., 1:1 RBC–plasma) in the setting of massive hemorrhage associated with military trauma in attempt to avoid trauma-induced coagulopathy.<sup>260–262</sup> The rationale for this more aggressive plasma resuscitation practice is that it may prevent subsequent persistent and unrelenting transfusion requirements resulting from delayed and/or inadequately dosed plasma transfusion. The absence of accurate and timely point-of-care laboratory tests reflecting the current coagulation status during active resuscitation, particularly in the setting of military trauma, has further supported this simplified approach to coagulation factor management in the setting of massive transfusion.<sup>263</sup>

Although such liberal approaches to plasma transfusion have been investigated in civilian trauma populations,<sup>264</sup> equipoise remains. Numerous studies have suggested that fixed-ratio plasma resuscitation strategies may reduce early transfusion requirements and potentially improve survival in civilian populations.<sup>264–266</sup> However, additional literature raises concern that such liberal approaches to plasma resuscitation may not translate well to civilian populations in whom there is often far greater prevalence of comorbid disease. The role of ratio-based resuscitation strategies is particularly unclear in circumstances not related to major trauma (e.g., obstetric, surgical, gastrointestinal bleeding).<sup>159,255,267,268</sup> Indeed, such populations may be at risk for adverse outcomes with more liberal plasma transfusion strategies.<sup>269–271</sup> Additionally, the issue of survival bias in the observational studies investigating hemostatic resuscitation strategies has also raised concern as to the true impact of these liberal transfusion practices on patient important outcomes.<sup>272–276</sup> Of note, the modern viscoelastic assays, TEG and ROTEM (discussed in the “The utility of preoperative hemostatic testing” section), may enable physicians to make point-of-care decisions regarding a patient’s ability to form thrombus and thereby offer a more individualized and evidence-based approach to plasma transfusion in a variety of civilian trauma or massive hemorrhage settings.<sup>277–280</sup> Indeed, a better understanding of the translatability of fixed-ratio plasma resuscitation strategies to civilian populations and a robust comparison of fixed-ratio plasma resuscitation strategies to strategies incorporating viscoelastic testing are highly anticipated areas of future research.

Beyond massive bleeding, indications for plasma transfusion are notably sparse. Specific examples of evidence-based indications for plasma transfusion include the following:

- Replacement of inherited single coagulation factor deficiencies for which no virus-safe fractionated product exists.<sup>258</sup>
  - Replacement of specific protein deficiencies.<sup>281</sup>
  - Replacement of multiple coagulation factor deficiencies with associated severe bleeding, massive transfusion, and/or disseminated intravascular coagulation.<sup>278,282</sup>
  - Replacement of fluid during plasma exchange in patients with TPP.<sup>283</sup>
  - Urgent reversal of warfarin anticoagulation when severe bleeding is present and PCCs are not available.<sup>284</sup>
- Notably, the frequently cited indication of  $\geq 1.5$ -fold prolongation of the PT and/or aPTT is particularly controversial based on the knowledge that elevated PT/INR or aPTT results do not necessarily correlate well with clinical coagulopathy.<sup>84</sup> Haas *et al.*<sup>83</sup> conducted a comprehensive review of the literature pertaining to the value of the PT/INR and aPTT in perioperative coagulopathy. Their study found that 6 of the 11 published guidelines for the management of perioperative bleeding continued to endorse the  $\geq 1.5$ -fold prolongation threshold; however, referenced evidence supporting this recommendation was generally from small, poor-quality studies and expert panel recommendations. Use of plasma for correction of abnormal coagulation tests prior to specific invasive procedures and in patients with liver disease is discussed elsewhere in this chapter.
- Specific contraindications to plasma transfusion include the presence of an isolated coagulation factor deficit when specific factor concentrates are available, reversal of oral anticoagulation therapy in the absence of bleeding, and treatment of hypovolemia. For patients who are anticoagulated with vitamin K antagonist therapies (e.g., warfarin), discontinuation of the oral anticoagulant therapy and supplementation with vitamin K are the primary therapeutic modalities when reversal is needed, and there is no evidence for active bleeding or requirements for emergent high-risk surgery. In the presence of clinically significant active bleeding, PCCs should be considered ahead of plasma transfusion due to their potential for more rapid reversal of the oral anticoagulant effect.<sup>278,285–287</sup> In addition, these agents are felt to carry a lower risk of transfusion-associated pulmonary and infectious complications. Finally, there is not a role for plasma transfusion as a strategy to mitigate bleeding associated with DOACs.
- In the absence of massive bleeding, plasma is typically dosed at 10–15 mL/kg predicted body weight with an expected increase in clotting factor levels of 25–30%.<sup>288</sup> This equates to approximately 1 L of plasma in a typical 70 kg patient. Importantly, however, studies have suggested that this dosing regimen may often result in an inadequate repletion of clotting factors.<sup>268,289</sup> Indeed, evidence suggests that upward of 30 mL/kg of plasma may be needed to reliably achieve desired coagulation factor levels, thereby ensuring adequate hemostasis.<sup>290</sup> However, a primary concern with this plasma dosing regimen is the potential for volume overload, particularly in those with baseline predisposing factors (e.g., congestive heart failure and advanced renal disease).
- As previously discussed, the evidence supporting plasma transfusion outside of massive hemorrhage is limited. Importantly, much of these data do not relate to patients with liver disease, casting yet more uncertainty over interpretation of PT/INR values with regard to bleeding risk. An in-depth evaluation of in vivo coagulation status in patients with liver disease by Lisman *et al.*<sup>291</sup> provided a comprehensive contemporary summary of “rebalanced hemostasis.” In this review, they summarize the evidence for the simultaneously enhanced procoagulant state (due to elevated von Willebrand factor and factor VIII, along with decreased ADAMTS-13, proteins C and S, antithrombin, and plasminogen) as well as an anticoagulant state (due to thrombocytopenia and platelet dysfunction; depletion of

factors II, V, VII, IX, X, XI and XIII; vitamin K deficiency; dysfibrinogenemia; along with elevated tissue plasminogen activator, nitric oxide, and prostacyclins).<sup>291</sup> In light of the complexity of hemostatic derangements in this patient population, traditional coagulation tests must be interpreted with particular caution and should not be the sole indication for plasma transfusion.<sup>292</sup>

Although a number of observational studies have attempted to examine the efficacy of plasma transfusion, no randomized trials have evaluated liberal versus conservative plasma transfusion strategies as has been performed with RBCs. This will be an important future step in refining current transfusion practice.

### Platelets: indications, threshold, and dose

As with other blood component therapies, platelet transfusion is generally considered appropriate in the presence of thrombocytopenia or abnormal platelet function with clinically significant active bleeding.<sup>293–297</sup> Recommendations for non-neuraxial surgery advocate single unit platelet transfusions with a target platelet count of  $\geq 50 \times 10^9/L$ .<sup>294,296,297</sup> In patients undergoing invasive neurologic or ophthalmologic procedures, a slightly higher threshold of  $100 \times 10^9/L$  has been recommended.<sup>296–298</sup> As with plasma transfusion, early military data suggest a potential role for early transfusion of platelets in order to avoid persistent bleeding following massive transfusion. Specifically, when the application of a 1:1:1 ratio of RBCs, plasma, and platelets was applied in military populations, improved survival was noted.<sup>260,262</sup> The pragmatic, randomized optimal platelets and plasma ratios (PROPPR) trial found that patients who received higher ratios of platelets and plasma to red blood cells were more likely to achieve hemostasis (86.1% vs. 78.1%,  $p = 0.006$ ) and experience fewer deaths due to exsanguination by 24 hours (9.2% vs. 14.6%).<sup>264</sup> These data may support a more liberal approach to platelet transfusion in the setting of trauma-related massive hemorrhage. However, the data supporting this strategy are not robust and clinical uncertainty persists. This again is an area in critical need of additional scientific study.

Current evidence suggests that the risk of bleeding due to thrombocytopenia is minimal when the platelet count is  $\geq 50 \times 10^9/L$ .<sup>296,297,299</sup> Importantly, however, this assumes that platelet function is normal. Frequently, there are clinical scenarios that may result in platelet dysfunction despite normal platelet counts (e.g., cardiopulmonary bypass, antiplatelet therapies, and congenital disorders). In these specific circumstances, the role of platelet transfusion is often unclear.<sup>294,296,297</sup> Indeed, recent recommendations from the AABB have highlighted these uncertainties.<sup>294</sup> Increasingly, thromboelastography, platelet aggregometry, and platelet mapping assays have been advocated to help inform clinical decisions in these specific settings.<sup>300</sup> As an example, a maximal amplitude of  $<54$  mm on TEG has been noted to represent abnormal platelet count and/or function with impaired whole blood clot formation.<sup>301</sup> Platelet aggregometry with an ADP-induced aggregation  $<31$  units has been shown to be independently associated with bleeding events and transfusion in cardiac surgery.<sup>302</sup> Similarly, platelet mapping provides an estimate of the degree of platelet inhibition due to aspirin or ADP-receptor antagonists and has been shown to correlate well with light transmission aggregometry.<sup>303</sup> Nonetheless, no well-validated guidelines currently exist with regard to platelet transfusion thresholds using these more advanced laboratory testing strategies and significant knowledge gaps remain, precluding broad endorsement of these testing strategies at this time.<sup>304,305</sup>

Aside from active bleeding, evidence-based guidelines suggest the administration of platelet components for platelet counts

$<10 \times 10^9/L$  to prevent spontaneous hemorrhage ( $<20 \times 10^9/L$  when fever, sepsis, heparin therapy, DIC, or other conditions leading to increased platelet consumption coexist).<sup>296,297</sup> These indications are mostly supported by a number of studies evaluating transfusion strategies in patients with leukemia and bone marrow failure and do not specifically focus on the needs of nonbleeding surgical populations.<sup>306</sup> Therefore, the optimal platelet count triggering platelet transfusion in the nonbleeding postoperative patient remains poorly defined and specific recommendations are largely lacking.

Following platelet transfusion, the expected increments in the platelet count for a typical 70 kg adult are  $5–10 \times 10^9/L$  per whole-blood-derived unit transfused and  $30–60 \times 10^9/L$  per apheresis platelet transfused.<sup>307</sup> These expected increments should be used to guide dosing with the aforementioned transfusion goals in mind. Platelet refractoriness can complicate the transfusion support of patients who require long-term platelet transfusion therapy.<sup>307</sup> Questions related to dosing and efficacy of platelet transfusion have been further examined by the PROPPR and platelet dose (PLADO) trials.<sup>264,308</sup> In the absence of massive hemorrhage, guidelines generally recommend the administration of up to a single apheresis unit or equivalent as greater doses are not more effective, and lower doses may be equally effective.<sup>294,297</sup>

### The role of plasma transfusion in special circumstances

#### Central venous catheter (CVC) insertion

Serious complications of CVC placement are rare and include pneumothorax, air embolus, and hemothorax. In fact, significant bleeding following subclavian vein catheterization occurs in patients with intact hemostasis and results from inadvertent injury of the subclavian artery, right atrium, and superior vena cava.<sup>309</sup> Among patients with advanced liver disease, the insertion of a central venous catheter for transvenous hepatic biopsy provides an excellent model to demonstrate the failure of abnormal coagulation tests to predict bleeding complications at the time of central line placement. Goldfarb and Lebrec<sup>310</sup> reported results of 1000 consecutive CVC placements in patients with liver disease, all of whom had abnormalities of laboratory coagulation tests. Only one patient experienced a significant hematoma despite 74 of 1000 also having inadvertent carotid artery puncture. Similarly, Foster *et al.*<sup>311</sup> performed central line insertions on 259 patients with advanced liver disease awaiting transplantation, all of whom had serious coagulation derangements. Importantly, no preprocedure products were given, and no important bleeding complications were observed.

Comparable results have been replicated in multiple subsequent studies. Petersen<sup>312</sup> compared bleeding complications in anticoagulated (aPTT of 1.5 times control) versus nonanticoagulated patients undergoing CVC placements. Of the 22 hematomas observed, 13 were found in anticoagulated patients and 9 were in nonanticoagulated patients. None of the patients with hematomas required treatment beyond topical care. Of note, among 22 episodes of inadvertent puncture of the carotid artery, the incidence of subcutaneous hematoma formation was the same in both the anticoagulated patients (4/12) and the nonanticoagulated patients (3/10). Another recent randomized clinical trial compared pretreating coagulopathic patients with FFP versus no transfusion prior to an invasive procedure (CVC placement, percutaneous tracheostomy, chest tube, or abscess drainage).<sup>313</sup> Although the overall numbers were

small, there was no difference in bleeding complications between the groups with the vast majority having no bleeding events at all.

Fisher and Mutimer<sup>314</sup> reported results of 658 subclavian and internal jugular cannulations in patients with advanced liver disease (median INR 2.4–2.7 and median platelet count 81–83 × 10<sup>9</sup>/L) in which no preprocedural plasma or platelets were given. INR values >5.0 and platelet counts <50 × 10<sup>9</sup>/L were associated with a higher incidence of superficial hematomas or site oozing; however, the strongest predictor (OR 8.0) of a procedure-related hematoma was a failed guide wire attempt. This paper underscored the fact that technical mishaps remain the dominant cause of hematoma formation and that bleeding complications other than skin hematoma or oozing are rare regardless of the coagulation test results.

A recent summary of available data was published by van de Weerd et al.<sup>315</sup> and included one RCT and 21 observational studies. Of 3150 patients with severe coagulopathy that remained uncorrected, the bleeding incidence ranged from 0% to 32%, and the risk of bleeding could not be predicted by the severity of coagulopathy on lab testing. Additionally, no study demonstrated a beneficial effect from prophylactic platelet or FFP transfusion.<sup>315</sup>

### Liver biopsy

Closed liver biopsy has generally been considered one of the higher risk bedside invasive procedures due to the fact that patients with liver disease often have multiple hemostatic test abnormalities and biopsies are performed without the aid of direct pressure on the wound sites. For these reasons, there is a strong desire to identify patients at increased risk for bleeding. In some instances, abnormalities in hemostasis screening tests sway providers to preferentially perform open surgical or laparoscopic biopsy over closed biopsies or a biopsy followed by Gelfoam plugging.<sup>316</sup>

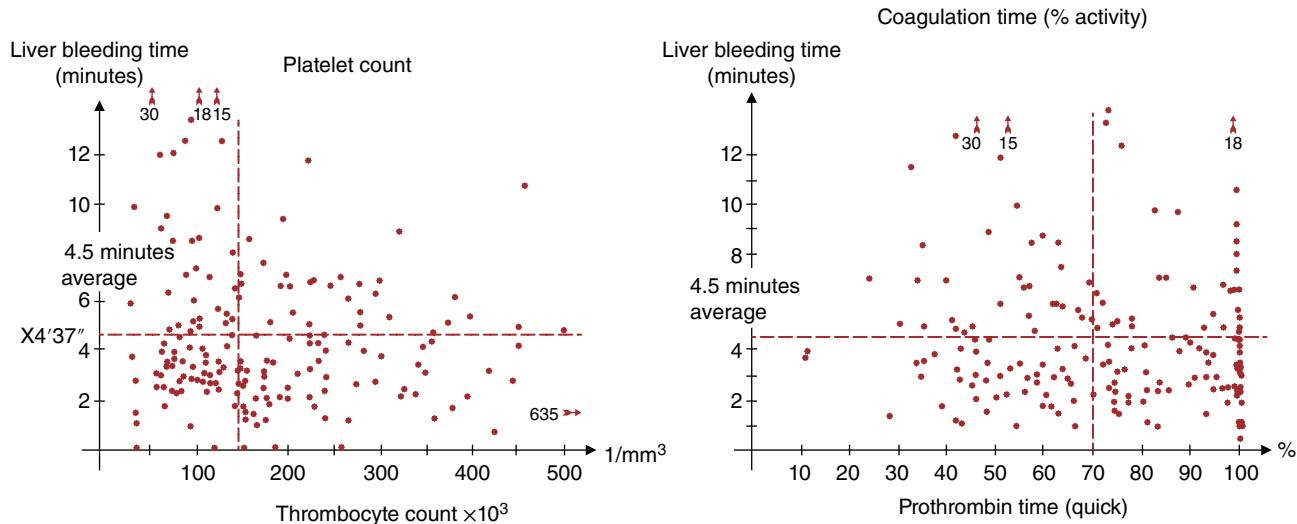

One of the earliest studies evaluating hemostasis in patients with liver disease found that among 200 patients with nonmalignant liver disorders undergoing laparoscopic liver biopsy, most patients had at least one abnormal coagulation test, but none were treated with blood components preprocedurely.<sup>317</sup> These

investigators found no correlation between the length of time the liver bled after puncture and the preprocedure laboratory values (Figure 39.2).

Similar findings have been duplicated by others, including Terjung et al.<sup>318</sup> In this study, patients undergoing percutaneous liver biopsies with at least one abnormality in preprocedural coagulation tests were evaluated for bleeding outcomes. The authors found no correlation between bleeding risk and mild-to-moderate abnormalities in the preprocedure INR, aPTT, platelet count, or bleeding time.

Given the strong (albeit unfounded) reliance on the INR as a key measure of hemostasis in liver disease, and the dependence of the INR test on factor VII, it is not surprising that investigators might explore the role of recombinant factor VIIa given before liver biopsy. Jeffers et al.<sup>319</sup> studied 71 patients who received recombinant factor VIIa in doses ranging from 5 to 120 µg/kg 10 minutes before laparoscopic liver biopsy. Although PT correction was fairly uniform, especially with the 20, 80, and 120 µg/kg doses, hemostasis at 10 minutes failed in 26% of patients, and an 80 µg/kg “rescue” dose of recombinant factor VIIa was administered. No toxicity was observed. This study unfortunately lacked a control group, and no follow-up testing for hematoma formation was performed. Although the ability of recombinant factor VIIa to improve the INR in patients with liver disease readily occurs, the fundamental question is whether preprocedure treatment with it is superior to treatment with FFP or to no treatment at all. This would be best answered in a prospective, randomized controlled clinical trial.

Similarly, in a recent report of 1321 transjugular liver biopsies in 932 patients, only 8 patients (0.6%) had an intraperitoneal hemorrhage, all of which were nonfatal.<sup>320</sup> When comparing the major and minor complication rates at three days and at one month, there was no association with the severity of coagulopathy (platelet count or PT/INR). Overall, these results continue to suggest that liver biopsy remains a relatively safe procedure with minimal bleeding complications that cannot be adequately predicted with preoperative coagulation studies or prevented with coagulation factor therapy.

**Figure 39.2** Lack of correlation between bleeding from the site of liver biopsy and preprocedure coagulation test or platelet count. The duration of bleeding from the site of puncture of the liver (y-axis) is plotted as a function of the preprocedure platelet count (left-hand panel) or the preprocedure coagulation test (expressed as % activity, right-hand panel). There is no correlation between preprocedure laboratory test results and the duration of bleeding. Source: Ewe (1981).<sup>317</sup> Reproduced with permission of Springer.

## Thoracentesis and paracentesis

Given the lack of evidence in favor of preprocedure transfusions for CVC placement or for closed liver biopsy, it is not surprising that published evidence also fails to support the use of preprocedure prophylaxis for less invasive procedures such as thoracentesis or paracentesis. McVay and Toy<sup>321</sup> reported a retrospective review of outcomes in 608 consecutive procedures. Patients were not transfused before the procedure, and no patient had serious bleeding. The proportion of procedures that were accompanied by a decline in Hb was comparable in the group with normal INR/aPTT/platelet values versus abnormal INR/aPTT/platelet values.

Similarly, a retrospective analysis of ultrasound-guided thoracenteses was performed comparing those with preprocedural correction of abnormal coagulation labs versus no correction.<sup>322</sup> Of 1009 procedures, there were only four hemorrhagic complications (0.4%), all of which occurred in those that received preprocedural platelet or FFP transfusion, suggesting that attempting to correct abnormal labs in this population is unlikely to yield any benefit.

Bleeding following paracentesis was also examined by Webster *et al.*<sup>323</sup> who reported a retrospective analysis of 179 outpatients. Four patients developed intraabdominal or abdominal wall bleeding that required a transfusion of RBCs. The INR values of these four were indistinguishable from those of the 175 patients who did not bleed.

In another retrospective study of ultrasound guided paracentesis, of 3116 patients (most with abnormal coagulation labs due to cirrhosis), 6 patients (0.19%) suffered a postprocedure hemorrhage and one of these patients required radiologic embolization.<sup>324</sup> No preprocedure testing results could be identified that predicted a bleeding complication, including abnormal PT/INR or platelet count, further suggesting the futility in transfusing to correct isolated abnormal lab values in the absence of bleeding.

## Procedures on the upper airway, bronchoscopy, and transbronchial lung biopsy

Special care to provide good hemostasis is prudent when procedures are being performed on the oropharynx, trachea, or bronchi, given that excessive bleeding can be rapidly fatal. Tonsillectomy was an early subject for studies assessing preoperative hemostatic screening. As with other surgical procedures, the predictive value of an isolated abnormal coagulation screening test for bleeding at tonsillectomy or adenoidectomy is very poor. The majority of patients who bleed during these procedures have normal presurgical tests.<sup>325</sup>

Tracheostomy is commonly performed in very ill patients in intensive care, many of whom may have abnormal laboratory tests for coagulation. Auzinger *et al.*<sup>326</sup> studied patients with severe liver disease undergoing percutaneous tracheotomy. In this study, all but two patients had derangements of laboratory coagulation tests or platelet count. Only one patient had excessive bleeding (defined as >150 mL), which was external (extratracheal). Similar findings have been confirmed in multiple small observational studies<sup>327,328</sup> and in critically ill patients on VV-ECMO.<sup>329</sup> In aggregate, these publications appear to refute the notion that mild-to-moderate prolongation of the INR or aPTT or mild-to-moderate thrombocytopenia represent absolute contraindications to safe tracheotomy.

In 1994, Kozak and Brath<sup>330</sup> reviewed 274 patients undergoing fiberoptic bronchoscopy and biopsy procedures. Abnormal coagulation screening tests were found in 10% ( $n = 28$ ) of patients. Overall, 35 patients bled, 32 of whom had normal preprocedure laboratory values. Three patients had severe bleeding, and each of them had normal preprocedure test results.

A larger retrospective review of bronchoscopies by Diette *et al.*<sup>331</sup> found that bleeding did not correlate with coagulation parameters or platelet count, and that performing a transbronchial biopsy did not independently increase the risk of bleeding. Such findings have now been replicated several times in both human and animal models.<sup>332,333</sup>

## Epidural anesthesia, diagnostic lumbar puncture, and neurosurgical procedures

Because bleeding in the closed space of the subarachnoid or epidural region can produce paraparesis or paraplegia following lumbar puncture (LP), avoiding preventable bleeding is more important for lumbar punctures and epidural anesthesia than for most invasive procedures. The chance of peridural hematoma appears to be increased among patients with full-dose anticoagulation who undergo placement or removal of an epidural catheter for spinal anesthesia. Ruff and Dougherty<sup>334</sup> reported five cases of paraplegia among 342 patients who received a diagnostic LP followed by administration of full-dose heparin. In addition, the introduction of low-molecular-weight heparin treatment in the United States was accompanied by an observed increase in reported spinal hematomas among patients with epidural catheters, estimated to occur at a rate of 1 in 10,000 patients.<sup>335</sup> In patients with low-dose anticoagulation undergoing vascular surgery, Rao and El-Etri<sup>336</sup> did not find evidence of epidural/peridural hematomas following placement of either an epidural catheter or a subarachnoid catheter. In a similar manner, low-dose heparin was not associated with spinal hematoma in over 5000 patients undergoing spinal or epidural anesthesia.<sup>337</sup>

The true incidence of epidural hematoma formation with epidural placement is not precisely known, especially in the setting of coagulopathy. The risk of hematoma appears greatest both at the time of epidural placement as well as when removed. A recent retrospective review of 11,600 epidurals identified 629 patients with associated abnormal coagulation studies when placed (278 patients) or removed (351 patients).<sup>338</sup> Of this coagulopathic cohort, only two epidural hematomas occurred for a combined incidence of 1 in 315 (95% CI, 1 in 87–2597).

Despite some institutions commonly transfusing FFP or platelets to patients with coagulopathy prior to neuraxial procedures, the practice remains controversial. Two recent attempted Cochrane reviews aimed to assess the efficacy of FFP<sup>339</sup> or platelet<sup>340</sup> transfusions before lumbar punctures or epidural placement; however, they were unable to find any completed or ongoing trials to include. They estimated that each intervention (platelets and FFP) would need 47,000 patients to detect a 1/1000 difference in epidural hematomas.

Interestingly, in 2001, Schramm *et al.*<sup>341</sup> reviewed outcomes among 1211 patients undergoing craniotomy, spinal surgery, or other neurosurgical procedures at the Royal Melbourne Hospital in Australia. The authors found that 17% of preoperative laboratory tests were abnormal, but neither prolongation of the INR nor depression of the platelet count predicted excessive surgical bleeding. Of note, procedure-related bleeding was associated with patients who demonstrated a prolonged aPTT and these prolonged aPTTs were predictable by history in most of these patients.

## Angiography

The increasing use of interventional radiology and cardiology has created a new cohort of patients at risk for arterial bleeding following angiography. Not surprisingly, there is little evidence that pre-procedure blood components are indicated for angiographic

procedures. Darcy *et al.*<sup>342</sup> prospectively studied 1000 consecutive patients undergoing femoral arterial puncture for diagnostic or therapeutic vascular procedures. Analysis was restricted to patients with INR values <1.5. The incidence of hematoma formation was the same in patients without any abnormality in preprocedural INR (9.7%) as those with abnormal results (8.1%). Neither the INR nor the aPTT was predictive of hematoma formation; however, hematoma formation was more common among patients with platelet counts <100 × 10<sup>9</sup>/L, with the use of catheters larger than 5 Fr, and among patients with a documented history of bleeding disorders.

### The role of platelet transfusion in special circumstances

The efficacy of prophylactic platelet transfusion remains a point of contention with somewhat limited experimental evidence to support its use in a wide variety of clinical scenarios. A platelet count of <10 × 10<sup>9</sup>/L is widely accepted as the threshold to transfuse platelets in order to prevent spontaneous hemorrhage. However, recent data demonstrates that prophylactic platelet transfusion at higher thresholds does not necessarily reduce bleeding complications or support improved outcomes in the critically ill,<sup>343</sup> surgical patients,<sup>344</sup> and those undergoing invasive interventional radiology procedures.<sup>345</sup> Indeed, the most recent Cochrane review concluded there was insufficient evidence to recommend prophylactic perioperative platelet transfusions.<sup>346</sup> In 2015, the AABB provided their recommendations for prophylactic platelet use in various clinical circumstances.<sup>294</sup> More recently, in 2020, the European Society of Intensive Care Medicine (ESICM) provided their recommendations for prophylactic transfusion in the critically ill.<sup>347</sup> Various clinical applications of these recommendations are summarized below.

#### Central venous catheter placement

Equipoise regarding the appropriate threshold with which to prophylactically transfuse platelets in patients undergoing invasive procedures was highlighted in 1997, when Ray and Shenoy<sup>348</sup> found no evidence of increased bleeding, infection, or thrombosis in a prospective study of 105 patients undergoing prophylactic platelet transfusion for central line placement. Further small studies and one randomized controlled trial subsequently noted increased bleeding and/or mortality in those receiving preprocedural platelet transfusions.<sup>349,350</sup> More recently, in 2017, Warner *et al.*<sup>345</sup> conducted a propensity matched analysis of adults undergoing vascular interventional radiology procedures, including central line placement, to assess the relationship between platelet transfusions and periprocedural RBC transfusion requirements. They concluded that prophylactic platelet transfusion did not result in a lower periprocedural RBC requirement in patients with a platelet count of at least 50 × 10<sup>9</sup>/L, suggesting that this intervention may indeed lack efficacy for this population. The AABB clinical practice guideline supports the use of prophylactic platelet transfusion in patients requiring elective central venous catheter placement with a platelet count of <20 × 10<sup>9</sup>/L.<sup>294</sup> In the same vein, the ESICM recommend against prophylactic platelet transfusion for platelet counts greater than 50 × 10<sup>9</sup>/L, but makes no recommendation regarding prophylactic platelets for counts between 10 and 50 × 10<sup>9</sup>/L.<sup>347</sup>

#### Liver biopsy

Sparse focused literature exists to definitively guide prophylactic platelet transfusion for liver biopsy. While various sources recommend threshold ranging from 50 to 100 × 10<sup>9</sup>/L, data from as far

back as 1981 have shown no correlation between degree of bleeding after liver biopsy and any laboratory measure of hemostasis.<sup>317</sup> However, conflicting data exist to suggest increased bleeding events at platelet counts below 60 × 10<sup>9</sup>/L.<sup>351</sup> Further, much of these data make no account for platelet function. Overall the risk of bleeding with either transjugular or percutaneous liver biopsy is believed to be <1%.<sup>351</sup> In 2003, a retrospective review of 51 patients with thrombocytopenia related to hematological malignancy undergoing transjugular liver biopsy found no hemorrhagic complications despite a mean platelet count of 38 × 10<sup>9</sup>/L.<sup>352</sup> In patients with liver disease, interpretation of bleeding risk for any given platelet count is further complicated by complex coexisting disturbances in both pro- and anticoagulant systems. Warner *et al.*<sup>345</sup> recently demonstrated that peri-procedural bleeding complications did not correlate with preprocedural platelet count in patients undergoing liver biopsy. In light of these data, the American Association for the Study of Liver Disease makes no specific threshold recommendation, but instead advocates for an individualized peri-procedural risk assessment including identification and correction of modifiable risk factors such as antithrombotic drug use, or concurrent acute kidney injury or systemic infection.<sup>353</sup>

Two TPO receptor agonists have been approved for the treatment of thrombocytopenia in patients with chronic liver disease. While each agent was superior to placebo at achieving a target platelet count of 50 × 10<sup>9</sup>/L, there were no statistically significant differences in bleeding complications; therefore, routine use is not recommended at this time.<sup>354,355</sup> Furthermore, because each of these agents require 2–8 days to be effective, they are unlikely to be useful for emergent liver biopsies.

#### Thoracentesis and paracentesis

Published evidence to guide the use of platelet transfusions in the setting of thoracentesis and paracentesis is scant. Though few focused studies exist, such patients have been included in both historical and contemporary evaluations of periprocedural bleeding risk, without clear evidence of benefit for prophylactic platelet transfusion.<sup>321,345</sup>

#### Procedures on the upper airway, bronchoscopy, and transbronchial lung biopsy

While careful attention to hemostasis in the airway is critical, available data do not support the use of prophylactic platelet transfusion below a threshold of 50 × 10<sup>9</sup>/L. The only available RCT to evaluate such practice was terminated early due to a low number of bleeding events and physician's unwillingness to transfuse prophylactic platelets to correct mild thrombocytopenia (threshold under investigation 40 × 10<sup>9</sup>/L).<sup>350</sup> Contemporary retrospective analyses have supported similar conclusions, with a lack of evidence that prophylactic platelets reduce periprocedural RBC requirements or mortality.<sup>345</sup> In 2016, Nandagopal *et al.*<sup>356</sup> found that overall there was a very low incidence of bleeding complications in patients undergoing bronchoscopy (with or without lavage), none of which were considered to be clinically significant, even in patients with platelet counts below 30 × 10<sup>9</sup>/L. They concluded that such procedures could be safely performed with severe thrombocytopenia. The AABB makes no formal recommendations regarding this clinical scenario, while the ESICM maintains that, in the absence of clear benefit, prophylactic platelet transfusions are not recommended for bronchoscopy patients with a platelet count of >50 × 10<sup>9</sup>/L.<sup>347</sup>

## Epidural anesthesia, diagnostic lumbar puncture, and neurosurgical procedures

As with other clinical scenarios already described, limited data exist to support the use of platelet transfusions for bedside procedures such as epidural anesthesia and lumbar puncture (LP). Several studies provide evidence that thrombocytopenia is not a major contraindication to diagnostic LP. Howard *et al.*<sup>357,358</sup> reported an extensive experience with >5000 LP procedures performed in 958 children with leukemia. Despite the fact that platelets in these children may have been dysfunctional due to leukemia or antibiotics in addition to the varying degrees of thrombocytopenia observed ( $10\text{--}100 \times 10^9/\text{L}$ ), no patient developed spinal hematoma or a clinical bleeding complication. The authors noted that the likelihood of finding >500 red cells/ $\mu\text{L}$  in the spinal fluid was slightly higher in patients with platelet counts  $<100 \times 10^9/\text{L}$  compared to those with counts  $>100 \times 10^9/\text{L}$ . However, among patients with counts  $<100 \times 10^9/\text{L}$ , the likelihood of an LP with >500 red cells/ $\mu\text{L}$  did not increase as the platelet count declined to levels as low as  $10 \times 10^9/\text{L}$ ; thus, the authors concluded that a platelet count of  $10 \times 10^9/\text{L}$  was adequate to perform a routine LP for administration of intrathecal chemotherapy. Similar findings have subsequently been confirmed in adult populations,<sup>359,360</sup> although the authors recommended prophylactic transfusions be given if the platelet counts were  $<20 \times 10^9/\text{L}$ .<sup>359</sup> These studies provide evidence that LPs that are critically important for patient care should not be delayed or withheld because of thrombocytopenia.

In 2016, Warner *et al.*<sup>344</sup> described the impact of preoperative platelet transfusions on perioperative RBC transfusion needs in almost 14,000 thrombocytopenic patients (threshold  $<100 \times 10^9/\text{L}$ ) undergoing noncardiac surgery, including neurological and spinal surgery. They noted that preoperative prophylactic platelet transfusion did not appear to attenuate perioperative RBC requirements; however, it was associated with an increased ICU admission rate and prolonged hospital stay, suggesting that a more conservative approach may be warranted. Though evidence is weak, for patients undergoing neurosurgical procedures a platelet count  $<100 \times 10^9/\text{L}$  is believed to be associated with an increased risk of hemorrhagic complications.<sup>361</sup> While this is the threshold often cited for the management of these patients, acuity and magnitude of the drop in platelet count likely impacts individual risk and should be considered when deciding to transfuse platelets.

Current AABB guidelines support the use of prophylactic platelet transfusions in patients requiring elective lumbar puncture with platelet counts  $<50 \times 10^9/\text{L}$ . They do note that evidence is weak, and some sources advocate for a lower thresholds of  $10\text{--}20 \times 10^9/\text{L}$  in patients with hematological malignancies and immune thrombocytopenia.<sup>359,362</sup> The AABB makes no specific comment on epidural catheter placement; however, a threshold of  $80 \times 10^9/\text{L}$  is often cited in the absence of stronger data to support lower thresholds.<sup>363</sup> Similarly, no specific recommendations are provided for neurological surgery or in the setting of intracranial hemorrhage due to scant and conflicting data.

## Cardiac surgery

Strong definitive evidence to support an approach to platelet transfusion in the cardiac surgical patient remains sparse, and further investigations are warranted. In a recent meta-analysis of available literature, it was concluded that platelet transfusion did not appear to be independently associated with added perioperative risk—including operative mortality, stroke, myocardial infarction, reoperation for bleeding, infection, or dialysis requirements.<sup>364</sup> The AABB dissuades the routine administration of preoperative prophylactic platelet transfusion in thrombocytopenic patients scheduled to undergo cardiac surgery with bypass. They do, however, advocate for platelet transfusion in the presence of clinical signs of bleeding and/or platelet dysfunction.<sup>294</sup>

## CHAPTER 40

# Transfusion therapy in the care of trauma and burn patients

### The evolution of the approach to blood product resuscitation for severely injured patients

The oldest reports of successful blood transfusions for trauma come from the American Civil War. However, it was more than 50 years later, at the end of World War I, that recognizably modern blood banking was developed.<sup>1</sup> During the Korean War (1950–1953), the US Army's Surgical Research Team studied blood loss, the evolution of shock, and the effects of fluid resuscitation with the tracer deuterium heavy water.<sup>2</sup> Further, they reported on the safety of massive transfusion with stored universal donor blood and on the use of plastic bags for fluid and blood administration. A decade later in the Vietnam War, these concepts and products were integrated into systems for early resuscitation, rapid transportation, massive transfusion, and early surgical intervention which reduced the death rate from wounds in field hospitals to 3%.<sup>3,4</sup> Altogether, the US armed forces transfused 600,000 units of whole blood or red cells in Vietnam.<sup>5</sup> They further demonstrated the relative safety of group O universal donor red cells, with over 100,000 units transfused, given that all seven fatal hemolytic transfusion reactions in Vietnam occurred in patients receiving crossmatched but mistransfused blood. The use of large volumes of crystalloid for resuscitation was also common in the Vietnam War and likely contributed to the first described cases of acute respiratory distress syndrome (ARDS).<sup>6</sup>

The Coconut Grove nightclub fire in Boston on 28 November 1942 was a critical event in the history of burn care. It led to the first burn resuscitation formula, the first systematic evaluation of the use of blood plasma in burn resuscitation, and the first burn unit in the United States.<sup>7,8</sup> While the first two concepts remain controversial, a strong case can be made that the ready availability of blood and blood components has improved survival among elderly burned patients and patients with associated medical problems who otherwise would not have tolerated a low hemoglobin level.<sup>9</sup> Interoperative transfusion also allowed wider more complete debridement procedures, rapidly reducing the inflammatory burden of irrevocably damaged tissue, thereby decreasing the number of surgical procedures and the length of hospital care needed by a burned patient.<sup>10</sup>

The development of trauma centers and burn units in the late 1970s coincided with the development of blood bags and blood component therapy and with a general increasing demand for blood components in hospitals to support more advanced surgery and The War on Cancer.<sup>11</sup> Despite an expanding blood supply system, blood products were frequently in short supply, especially universal donor group O Rh-negative red cells (6% of donors) and group AB plasma (4% of donors). Managing a limited inventory of AB plasma meant keeping it frozen in the blood bank until the patient had a blood type and an indication in the form of a prothrombin time (PT) or activated partial thromboplastin time (aPTT) greater than 1.5 times normal.<sup>12</sup> In addition, studies of hemorrhagic shock conducted in animals during this time period supported the increased use of crystalloid during resuscitation.<sup>13</sup> These studies demonstrated that poor tissue perfusion secondary to hypovolemic hypotension became life threatening after approximately 30% blood loss, but perfusion could be restored by volume replacement with crystalloid fluids.<sup>14</sup> With continued blood loss and volume replacement, red cell mass became critically low after 60% of total blood volume loss. Red cell transfusion corrected this problem. Decreasing colloid osmotic activity led to blood flow-limiting edema after 120% blood volume removal that could be corrected with albumin. With concomitant volume and red cell and albumin replacement, hemorrhagic complications occurred spontaneously after 180% volume was lost that were related primarily to plasma coagulation factor deficiency. Platelets became limiting only after 220% volume removal and replacement of the other blood components. These isovolemic models of controlled hemorrhage and blood component replacement suggested that volume and oxygen transport were the critical early issues in the treatment of hemorrhagic shock and that coagulopathy was largely dilutional and a late complication. This logic was codified in the ATLS resuscitation algorithm in which injured patients were given crystalloid fluids to maintain volume and red cells to maintain oxygen transport only if more than 2 L of crystalloid fluid was required to maintain blood pressure.<sup>15</sup> Plasma was to be given based on laboratory measures of a prolonged PT or aPTT greater than 1.5 times normal, platelets when the platelet count was less than 50,000/ $\mu$ L, and cryoprecipitate

when the fibrinogen was less than 100 mg/dL. This approach worked well for moderately injured patients and led to reduced overall mortality, especially from renal failure.

However, in severely injured patients with uncontrolled hemorrhage, the use of large volumes of crystalloid fluid led to massive tissue edema and severe coagulopathy. Cold crystalloid resuscitation caused hemodilution and hypothermia which further exacerbated coagulopathy, a phenomenon that came to be known as the “bloody vicious cycle.” This led to the approach of damage-control surgery and complications related to abdominal compartment syndrome.<sup>16</sup> Nevertheless, for patients who needed 10 units of RBCs, mortality was typically 40%, and for those who needed 20 units, it was 50%.<sup>17</sup>

In the past two decades, three areas of clinical investigation led to the use of more plasma and less crystalloid in the resuscitation of severely injured patients. The first involved reducing the amount of crystalloid fluid given for volume expansion because there were situations in which it was not necessary and certain patients appeared to do better without the extra volume. The second line involved experiences, almost entirely military, in which dramatically better hemostasis was achieved with the use of fresh whole blood. The third involved the purposeful administration of plasma early in resuscitation to prevent coagulopathy because once coagulopathy had developed it proved difficult to treat with conventional blood components.

Bickell and colleagues used an aortic tear in swine to demonstrate that crystalloid resuscitation could be harmful.<sup>18</sup> In this model, a loop of stainless steel suture was placed in the aorta and brought out through the skin. A week later, with the animal awake, the suture was torn out to create a 0.45 cm aortic tear. Pigs sustaining this injury typically lay down, dropped their blood pressure to 30 Torr systolic for an hour while the injury bleeding clotted firmly, and then the blood pressure slowly returned to normal with 85% of the animals surviving. Attempting to resuscitate the swine with crystalloid raised their blood pressure causing further bleeding and coagulopathy resulting in 100% fatality. This observation led to a randomized controlled trial for patients sustaining penetrating truncal trauma in Houston, TX.<sup>19</sup> Hypotensive patients were randomized to standard crystalloid resuscitation vs. no crystalloid resuscitation beginning in the field and extending to the operating room. Mortality was higher in the resuscitated group. A second smaller randomized study conducted by Dutton and colleagues also showed no benefit to early resuscitation in the short time between admission and exploratory surgery in hypotensive injured patients in a level 1 trauma center.<sup>20</sup>

US military experience with the use of fresh whole blood to treat battlefield casualties in situations where platelets were not available also led to a widening appreciation of the ability of whole blood to rapidly achieve hemostasis in badly injured soldiers. In the first Iraq war, in Somalia, Bosnia, Kosovo, and then in Afghanistan and the second Iraq war, situations repeatedly occurred where casualties with uncontrolled coagulopathic bleeding after resuscitation with red cells and crystalloid were able to achieve hemostasis after the administration of fresh whole blood.<sup>21</sup>

The recognition that crystalloid fluids and red cells did not prevent coagulopathy led to many attempts at more balanced resuscitation. Hiipala wrote about the importance of early administration of plasma in massively bleeding trauma patients in the 1990s, but groups like the British Committee for Standards in Haematology continued to advocate for limiting plasma use and strict transfusion triggers.<sup>22,23</sup> However, with the descriptions of the acute coagulopathy of trauma in 2003, and reports of devastating injuries from improvised explosive devices in the second Iraq war, the need to prevent and reverse coagulopathy early in resuscitation came to the fore.<sup>24</sup> The US military published its first theater guideline recommending early initiation of

balanced hemostatic resuscitation in 2004 and published a national recommendation in 2007 stating red cells, plasma, and platelets be given in 1:1:1 ratios to the most seriously injured.<sup>25</sup> Since that time, a series of consecutively more rigorous studies of the resuscitation of massive hemorrhage were conducted in the civilian community including the Trauma Outcomes Group study (2009), the Prospective Observational Multicenter Massive Transfusion Trial (PROMMTT, 2012), and the Pragmatic Randomized Optimal Plasma and Platelet Ratios trial (PROPPR, 2015). These data constitute the best evidence for resuscitation of massive hemorrhage using balanced ratios of conventional blood products. The American College of Surgeons has followed with educational projects such as the Educational Initiative on Critical Bleeding in Trauma and the Trauma Quality Improvement Project Best Practice Guidelines for Massive Transfusion published in 2012.<sup>26,27</sup> In Northern Europe, a similar process has been led by Johansson through his work at the University of Copenhagen and in the Scandinavian Conferences on Critical Bleeding.<sup>28</sup> The use of whole blood is also returning in the civilian community as described below.

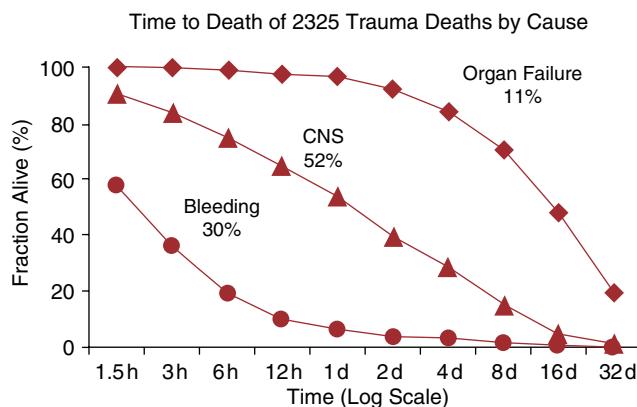

## The epidemiology of physical injury

Injury is common and over the last decade mortality has increased.<sup>29,30</sup> In the United States, approximately 1 individual in 10 receives a significant physical injury requiring medical attention every year and 1 in 100 is hospitalized because of such an injury annually. Approximately 1 in 1000 individuals receives a blood transfusion for injury each year, and just over 180,000 people die of physical injury annually. Costs are greater than \$400 billion each year. About 95,000 of these deaths are the result of unintentional injury, with the remainder divided between suicides using physical methods and deaths from injuries intentionally inflicted by others. Injury is the third leading cause of death overall, and because it occurs so frequently in children and young adults, it is the leading cause of loss of years of productive life through the age of 75 years. As noted, to deal with these injuries, the United States and Canada have established more than a thousand trauma centers and more than 100 burn centers.

Motor-vehicle-related injuries, interpersonal violence, and falls are the most common causes of fatal injuries. Work and recreational accidents also contribute to the toll. All of the common causes of injury are subjects of ongoing efforts at primary prevention through engineering and social controls, but faster cars, higher caliber handguns, and a rising elderly population limit the decline in the overall incidence of both injuries and deaths.

Half of all injury-related deaths in civilians occur outside the hospital, either because of rapid death from massive injury or because they occur in remote or unobserved locations so that movement to advanced care is too late. In the Vietnam War, 85% of battlefield deaths occurred in the field with 40% occurring essentially instantaneously, 65% being dead within 5 minutes, 80% within 30 minutes, and 90% within 2 hours of injury.<sup>31</sup> For civilian casualties that arrive at the hospital alive and subsequently die a hemorrhagic death, a similar compression of early deaths occurs with 50% of such patients dead in two hours and 80% dead in six hours (Figure 40.1). Later deaths are caused largely by central nervous system injury or multiple organ failure.<sup>32</sup> Autopsy series of those who die in the field suggest that 15–20% have a potentially correctable hemorrhagic cause of death.

Blood use in the injured is strongly related to injury severity. In an examination of blood usage rates in a trauma center, only 8% of all admissions received RBCs, and only 3% of all admissions received 10 or more units.<sup>33</sup> Increased anatomic injury severity was strongly associated with increased RBC use and mortality. Nevertheless, there does not appear to be an upper limit to the number of RBC units

**Figure 40.1** Time to death of 2325 trauma patients directly admitted to Maryland Shock-Trauma who survived at least 15 minutes and died in care. Median time to death for patients with uncontrolled hemorrhage as their major cause of death was two hours. Only 4% of all admissions died during their primary hospital admission. Source: Data from Dutton et al. (2010).

that can be successfully transfused to a surviving patient; survivorship after massive transfusion was 60%, after transfusion of 20 U of RBC it was about 45%, and after 50 units of RBC it was in the 15–20% range.<sup>34</sup> Thus, while massive transfusion is associated with a high mortality, it is not a marker of therapeutic futility.

Due to the large distances and limited resources in rural areas in the United States and Canada, access to blood products can be limited. Rural hospitals have a limited supply and can only support the storage of frozen plasma creating inherent delays in administration. This delay creates a need for alternative blood products for austere environments such as freeze-dried plasma and frozen platelets.<sup>35</sup> Further investigations are needed for widespread adoption of these strategies.

### Clinical approach to the trauma patient

Traditionally, there are four phases of trauma care: prehospital, emergency department, operative care, and postoperative intensive care. From the perspective of resuscitation, these phases have become less distinct as hemostatic resuscitation has been pushed further forward into the prehospital phase of care. The military has been pushing blood products into the forward surgical environment, and in the civilian community many aeromedical services and some ground services have begun to carry either red cells and liquid plasma or whole blood. Early studies have demonstrated improved patient outcomes and minimal blood product wastage from these programs.<sup>36</sup>

Half of all civilian trauma deaths occur in the prehospital environment. Rapid movement of patients from the local site where injury occurred to a trauma center provides the greatest benefit because most rapidly fatal injuries are truncal and require surgical or radiographically guided hemorrhage control. Nevertheless, opportunities exist to limit extremity bleeding in the prehospital environment through the use of tourniquets, a measure which has objectively improved prehospital mortality in potentially survivable trauma. This mortality reduction was first described in the military, where Eastridge *et al.* reported a nearly eightfold reduction in extremity hemorrhage deaths after implementation of routine tourniquet use.<sup>37</sup> Teixeira *et al.* noted a similar reduction with tourniquet use in civilians, where prehospital tourniquet application was independently associated with a sixfold mortality reduction in patients with peripheral vascular injuries.<sup>38</sup> Neck, scalp, and truncal soft tissue bleeding can also be reduced by the application of direct pressure

and hemostatic bandages such as QuikClot Combat Gauze, a kaolin impregnated dressing used to stop bleeding with pressure recommended in the Tactical Combat Casualty Care Guidelines.

Keeping patients warm and limiting blood dilution with crystalloids are also important goals. The administration of crystalloid fluids in the field to prevent acute renal failure does not appear to be necessary with modern casualty evacuation times in urban and suburban areas, and raising blood pressure is associated with the loss of more of the patient's blood through vascular defects particularly in penetrating trauma. In situations where red cells and plasma are available in the field or in transport, they can be given, but only about 15% of patients undergoing helicopter transport to trauma centers appear to be candidates for transfusion even when blood products are available.<sup>39</sup> The recent PAMPer study confirmed the benefit of such a practice. This phase 3 cluster-randomized controlled trial enrolled hypotensive tachycardic trauma patients to receive either two units of FFP or standard resuscitation. Primary outcome was 30-day mortality. The plasma group had a significantly lower 30-day mortality (23% vs. 33%,  $p = 0.03$ ) with lower median prothrombin time as well.<sup>40</sup> While the COMBAT study also examined prehospital plasma use in the same trauma patient population, there were some notable differences in comparison with PAMPer. While both groups had similar median BP, COMBAT patients had a higher incidence of penetrating injury (50% vs. 20%) as well as higher ISS (27 vs. 22). In contrast, patients enrolled in COMBAT experienced shorter transport times (median transport time 19 minutes compared to 42 minutes in PAMPer) which could have contributed to the lower mortality in the COMBAT study when compared to PAMPer (12.5% vs. 30%). Taking the information from both studies into account, the benefit of pre-hospital blood product transfusions may only exist with long transport times and in the sickest trauma patients.

In the emergency room, there is an emphasis on rapid and systematic evaluation. The primary survey of airway (A), breathing (B), circulation (C), neurologic disability (D), and full exposure (E) (ABCDEs) is followed by a more systematic evaluation and the mobilization of teams to deal with specifically identified problems. Hypotension and penetrating injury suggest major internal bleeding and urgent need to move to the operating room (OR) as do significant tachycardia and the presence of fluid in body cavities assessed in a focused ultrasonographic survey for trauma (FAST). A combination of these two signs as the ABC score has close to 80% power to predict massive transfusion and served as a major inclusion criterion in the PROPPR study.<sup>41</sup> For patients who do not require immediate operative intervention, further studies leading to a complete secondary survey of the patient are the next goal. Hemorrhage must always remain a concern. There are multiple body cavities where it is possible to lose enough blood to cause shock from hypovolemia: pleural spaces and the mediastinum in the chest, peritoneal and retroperitoneal spaces in the abdomen, pelvis and thighs, as well as subcutaneous spaces. Whole body imaging is important for patients stable enough to tolerate it, and computerized tomographic (CT) scanning identifies additional sites of injury such as intracranial bleeding, pericardial hemorrhage, major vascular disruption, major organ fracture or laceration, and bowel, biliary, and urinary tract disruption that need prompt attention. Moreover, musculoskeletal injuries are frequent and need at least initial stabilization to make patients movable for nursing care. Simply placing a pelvic binder to reduce the volume of the pelvic ring can often limit venous bleeding and prevent further arterial injury in the early phases of patient assessment.

In the OR, time remains of the essence. Historically, it was observed that 40 minutes of open abdominal exposure in a hemorrhaging

trauma patient resulted in the loss of a degree centigrade in core temperature. Thus, attention on the rapid administration of blood products with active warming is important. A damage-control approach to surgery seeks to minimize OR time by focusing on the goals of hemorrhage control and control of contamination from intestinal, biliary, and urinary tract injury with delayed reconstruction. The need for damage-control surgery rates has declined as iatrogenic resuscitation injury is avoided.<sup>42</sup> This can allow for the identification of correctable sources of bleeding that can be dealt with by vascular repair or ligation, repair or removal of injured organs, and closure.

Increasingly, close collaboration between surgeons and interventional radiologists (IR) has led to procedures that are partially performed by one specialty and partially by the other. In order to manage multiple sites of bleeding, some patients require an initial procedure in the OR followed by embolization in the IR suite. Modern hybrid ORs now allow these procedures to be done simultaneously.<sup>43</sup> Transfusion support for such highly complex and high blood loss situations is similar to other massive transfusion situations and involves ongoing balanced resuscitation shaped to the clinical situation and the available laboratory data. At the end of such procedures, patients are moved to intensive care units (ICUs) for continued resuscitation. Bleeding is often slowed but not stopped, and provision for continuing blood product support and planning for potential return of frank hemorrhage if packing fails or is reinitiated with unpacking is prudent. In the recovery room or ICU, bleeding is usually slow enough that its replacement can be guided by laboratory measures. It is still important to remember that the limitations of resuscitation imposed by multiple different blood components diluting each other make it prudent to avoid components such as platelets in additive solution that do not maximize plasma dose.

### Trauma-associated coagulopathy

The physiology of massive injury leads to both rapid degradation of the body's already limited coagulation capacity as well as the release of inflammatory mediators further enhancing the coagulopathy. Dilution, acidosis, hypothermia, consumption, and fibrinolysis all contribute to an inability to take full advantage of the limited blood clotting resources that the body has available.<sup>44</sup> In combination, these factors result in many severely and most profoundly injured patients presenting with coagulopathy when they arrive at medical care.

Loss of coagulation factors and platelets start with the acute blood loss of injury which can be in excess of 40% in patients arriving in deep shock. Attempts to raise blood pressure with a sanguinous fluid to sustain tissue perfusion will lead to further blood loss through uncontrolled defects in vascular integrity. Dilution of platelet numbers and coagulation factor concentrations occurs naturally as remaining intravascular blood is watered down by physiologic vascular refill. Normally, blood pressure pushes water into the tissues which returns through the lymphatic circulation. As blood pressure falls in hemodynamic shock, water moves back into the vascular space down a concentration gradient to dilute the colloid osmotic activity of plasma proteins.

Acidosis, which develops rapidly with tissue hypoperfusion, has profound effects on plasma coagulation. Normally, activated plasma coagulation factors assemble into complexes on negatively charged phospholipid rafts on the surfaces of exposed subendothelial cells, platelets, and endothelium in ways that increase the clotting activity of the enzymes in these complexes by 10,000- to a million-fold. However, the increased concentration of protons present when pH drops destabilizes these coagulation factor complexes and reduces their activities. The reduction is 50% at pH 7.2, 70% at pH 7.0, and 80% at pH 6.8.<sup>45</sup> All these levels are commonly seen in patients suffering severe hemorrhagic shock.

Hypothermia also affects the plasma coagulation enzymes, reducing their activities by about 10% per °C, but actually has a much greater effect on platelet activation. Normally, platelets activate when they adhere to exposed subendothelium through bridging von Willebrand factor. The von Willebrand factor binds to the platelet glycoprotein receptor Ib with one end and to collagen on the other end, creating traction and torsion of the receptor leading to platelet activation. However, this receptor torsion–platelet activation coupling is lost with mild cooling and is essentially gone at 30 °C.<sup>46</sup> In the past, the combination of a low core temperature and severe injury with uncontrolled bleeding was viewed as fatal, but now the combination of extracorporeal blood warming, avoidance of blood dilution, and an array of hemorrhage control strategies allow many trauma patients who present with severe hypothermia to survive.

Consumption of platelets and coagulation factors can occur both within wounds, and diffusely with the embolization of tissue factor-bearing tissue fragments, phospholipids, and diffusion of thrombin. In high energy blunt or penetrating trauma, the extent of endothelial disruption may extend to billions of endothelial microtears, each associated with the exposure of tissue factor-bearing cells and subendothelial basement membrane collagen. Under these circumstances, factors VII, VIII, and V as well as platelets can be depleted. Factor VII is present normally in only nanomolar amounts, so the exposure of a few hundred grams of mesothelial cells presents enough tissue factor to bind all of the factor VII available. Factors VIII and V are classically consumable factors, activated by thrombin and inactivated by protein C. The blood can be exposed to multiple cycles of activation and inactivation in its course through injured tissue with resultant consumptive loss of much procoagulant activity. Finally, platelet activity can be consumed with either reduction in platelet numbers or depletion of platelet granule contents, membrane, and energy. The net result is that severely injured patients typically present with normal numbers of platelets which then decline over the first hour in the hospital, and their remaining platelets appear to have reduced activity, a phenomenon called platelet fatigue.<sup>47</sup>

Fibrinolysis, in the context of trauma-associated coagulopathy, is the early and inappropriate breakdown of fibrin clot resulting in the loss of hemostasis and the substrate for further coagulation and vascular healing. Pathologic fibrinolysis following trauma is typically caused by plasmin or neutrophil elastase. Plasmin is activated by tissue plasminogen activator released in response to low blood flow, and its breakdown is delayed by early destruction of plasminogen activator inhibitor by protein C. Neutrophil elastase is released in large amounts in injured tissue, and levels of its signature fibrin fragments increase significantly following severe injury.

An endotheliopathy of trauma is also being increasingly recognized as another manifestation of trauma-associated coagulopathy. Shock and hypoperfusion lead to shedding of the endothelial glycocalyx along with increased circulating syndecan-1 and danger-associated pattern molecules (DAMPs). The injured endothelium leads to vascular hyperpermeability, while the increased levels of syndecan-1 and DAMPs are associated with shock, inflammation, and are independent predictors of mortality. In animals, vascular hyperpermeability and increased levels of syndecan-1 and DAMPs are attenuated when resuscitation is performed using plasma but not crystalloids.<sup>48</sup>

In severely injured patients, all of these activities limiting stable clot formation can be going on at once. In fact, a review of the risks for uncontrolled coagulopathy following injury by Cosgrove and colleagues found that the risks were additive.<sup>49</sup> Patients with severe injury but without shock, acidosis, or hypothermia were rarely coagulopathic. With profound injury about 10% were coagulopathic at presentation, and with shock requiring diluting resuscitation it increased to 40%. With profound injury and hypothermia,

coagulopathy was present in 50% and with acidosis in 60% of all patients. However, when three or more of these factors were present simultaneously, the incidence of coagulopathy increased to 85–98%. Thus, the most severely injured patients will develop the most profound coagulopathies.

What was not widely recognized until a decade ago is that about one in four severely and profoundly injured patients arrive at the hospital with coagulopathy already established. In 2003, Brohi and his colleagues described a thousand patients arriving at the Royal London Hospital by helicopter from motor vehicle collisions on the London ring road. These patients had received only 400 mL of crystalloid fluids on average before arrival, and yet a quarter showed prothrombin time (PT) prolongation beyond 1.5 times normal.<sup>50</sup> Moreover, the quarter with the prolonged PT had a fourfold excess in-hospital mortality. Brohi called the finding the acute coagulopathy of trauma. A month later, MacLeod and her colleagues from the Ryder Trauma Center in Miami reported a similar finding in 20,000 patients seen over a five-year period.<sup>51</sup> In their series, 28% of all seriously injured patients had a prolonged PT that was associated with a 35% excess in-hospital mortality, and 8% had a prolonged partial thromboplastin time (PTT) that was associated with a 426% excess in-hospital mortality. In 2007, Hess and his colleagues described the prevalence of abnormal coagulation measures in 35,000 direct admissions to the Cowley Shock-Trauma Center in Baltimore over a seven-year period. They showed greater prevalence of PT, PTT, fibrinogen, and platelet count abnormalities with increasing injury severity. Furthermore, the magnitude of these laboratory abnormalities was paralleled by increased in-hospital mortality.<sup>52</sup> At the highest levels of injury severity observed, the prevalence of abnormal admission coagulation tests was 45%, and in-hospital mortality was 80%. In a search for clinical and mechanistic drivers of the acute trauma coagulopathy, Cohen and his colleagues from the Prospective Observational Multicenter Massive Transfusion Trial (PROMMTT) found that 42% of 1198 severely injured patients had an INR  $\geq 1.3$  and that they generally had depressed concentrations of factors I, II, V, and VIII, and evidence of increased concentrations of activated protein C.<sup>53</sup> Decreased concentrations of platelets on admission were much less frequent. As noted, most patients with severe injury present with normal platelet counts. However, when platelet levels on admission are low, a dose-dependent increase for in-hospital mortality is observed.

It should be noted that there has been an argument in the literature about whether the acute coagulopathy of trauma is a separate pathophysiologic entity or is just the early and hypocoagulable form of disseminated intravascular coagulation (DIC).<sup>54</sup> On the one hand, the International Society of Thrombosis and Hemostasis supported the latter view and used trauma as their prototypical example. On the other hand, it is confusing and imprecise to call a condition DIC that is not disseminated, intravascular, or associated with increased coagulation. Rather, others believe that acute coagulopathy of trauma is a concise and descriptive term for a process initiated by multiple local injuries, with hemorrhagic manifestations, and extravascular or at least extra-endothelial mechanisms. This argument is purely semantic.

### **Damage-control resuscitation**

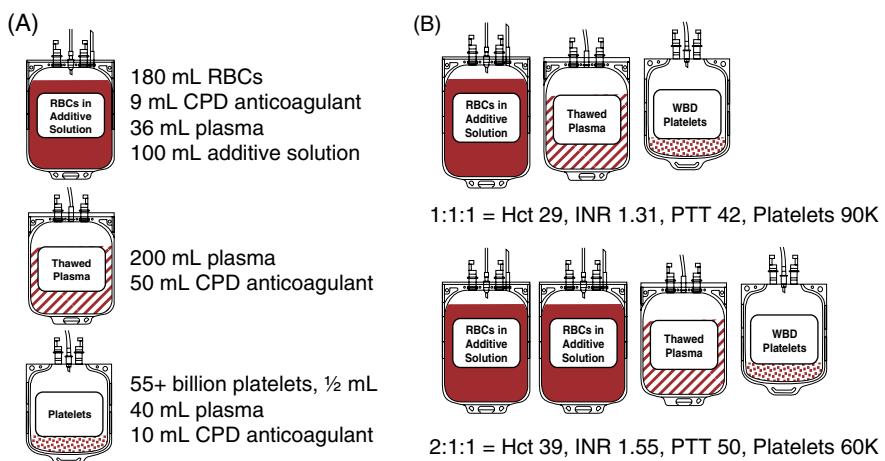

Several large autopsy series suggest that the majority of potentially savable lives that are currently lost to injury are in the group of seriously injured patients with uncontrolled hemorrhage who die in the early hours after presentation.<sup>55,56</sup> The autopsy series suggest that such patients may represent 8–19% of all injury deaths, and the deaths represent a combination of missed diagnostic and therapeutic opportunities that in turn result in delayed hemorrhage control.

As these deaths clearly overlap with the excess mortality associated with the acute coagulopathy of trauma, designing resuscitation systems to limit coagulopathy is a priority.

In an instructive case, a young soldier seen in the combat support hospital in Baghdad with massive injuries from an improvised explosive device received 18 units of RBCs during approximately 50 minutes of hospital care, but died before type-specific plasma was thawed. In reviewing the case among the hospital staff in Baghdad, the surgeons pointed to the need to get plasma into the patient sooner while the supporting transfusion service pointed to the limited supplies of universal donor group AB fresh-frozen plasma (FFP) and the potentially massive waste of plasma products associated with the administrative requirement to use FFP within six hours of thawing. The transfusion service had adopted the protocol of first obtaining the patient's ABO type and only then thawing type-specific plasma to provide the best matched product, limit frozen plasma wastage, and balance usage by ABO type. However, the end result was dead patients. An outside consultant suggested that the problem could be partially ameliorated by the simple expedient of relabeling thawed FFP as "thawed plasma" that could be kept for five days under refrigerated conditions. Furthermore, keeping four units of AB plasma thawed at all times would provide a buffer of plasma for immediate use, and the patients might benefit as well from prompt initial treatment of the acute coagulopathy of trauma. After confirming the definitions of thawed plasma and assuring a continuing supply of AB FFP, this plan was adopted. It was further agreed that units of red cells and plasma would be given alternately to the profoundly injured to keep the combined hematocrit of the administered products close to 30% and provide an easy protocol for administration in the chaotic situation of a massive injury resuscitation (Figure 40.2).

The clinical results were dramatic. All involved in the immediate care of the wounded casualties viewed the new resuscitation strategy as an improvement. More patients appeared to survive initial resuscitation, their injured tissues were easier to treat in the operating room with less spontaneous bleeding and edema, and the required duration of ventilator support was shorter because patients received less blood and fluids altogether. Other surgical groups in theater, both United States and allied in Iraq and Afghanistan, adopted the procedures and by the end of 2004 the use of 1:1 unit ratios of red cells and plasma for resuscitation had become the standard theater guideline. A retrospective review of cases performed at the Baghdad hospital showed a strong correlation between the plasma:red cell transfusion ratio and survival.<sup>57</sup>

Because this 1:1:1 (red cells:plasma:platelets) blood component therapy (BCT) resuscitation strategy was at variance with both conventional surgical dogma and with evolving transfusion medicine doctrine, as exemplified by the drive to reduce plasma usage generally, the authors gathered panels of experts to review the findings. These panels were asked to develop data and position papers on critical issues surrounding early massive transfusion for trauma. The meeting took place at the US Army Institute of Surgical Research in San Antonio, 25–27 May 2005, and the results were published as a supplement to the *Journal of Trauma* in September of 2006.<sup>58</sup> Several major findings were presented in these publications. First, when comparing data from the German Trauma Registry and the US Miami and Baltimore Trauma Registries, significant correlations were observed between common clinical and laboratory data (injury severity, number of units of RBCs transfused, and admission coagulation measures) and outcomes (time to death and in-hospital mortality).<sup>59</sup> Second, in contacting 80 academic trauma centers, formal massive transfusion protocols were rare.<sup>60</sup> Third, a number of high volume trauma centers including those in Sydney,

**Figure 40.2** (A) Whole blood-derived blood components processed by the platelet-rich plasma method have the average contents shown above. (B) Giving RBC, plasma, and platelets in a 1:1:1 unit ratio results in a hematocrit (Hct) of 29%, a plasma concentration of 65%, and a platelet concentration of about 90 K/mcL. An additional unit of RBC dilutes the plasma to 52% and the platelet count to 60 K/mcL while raising the Hct unnecessarily. Source: Data from Arman and Hess, 2003 (*Transfus Med Rev* 2003 Jul;17[3]:223–31) and Kornblith et al., 2014 (*J Trauma Acute Care Surg* 2014 Dec; 77[6]:818–27).

Baltimore, and Helsinki had switched their resuscitation blood orders from emergency un-crossmatched transfusions to type compatible blood in a 1:1:1 BCT ratio as soon as a blood type was available. Fourth, concerns about the safety of red cell and plasma transfusion were widespread, especially among groups writing standards, but the size of the associated risks and the effects of risk reduction strategies such as leukoreduction were not known. Fifth, for the group of severely injured patients with ongoing massive uncontrolled hemorrhage, resuscitation with a 1:1:1 ratio was recommended as long as resuscitation was running ahead of available laboratory data. Finally, it was widely acknowledged that there was a general lack of useful data to allow the identification of injured patients at risk for massive transfusion; determine what the best clinical and laboratory tests were to guide subsequent transfusion; and evaluate the safety and efficacy trade-offs involved in blood-product-based resuscitation. Furthermore, while early balanced resuscitation appeared to reduce morbidity and mortality, no groups performed such resuscitation in an ideal way, and the trauma community was poorly positioned to gather the data that would be needed to justify the costs and risks of such a commitment of resources. The meeting was a watershed event.

In the five years following the conference, a number of retrospective studies of massive bleeding were published that described differences in outcome associated with differences in resuscitation on large, essentially consecutive series of patients. Borgman and his colleagues published the results of the Baghdad series showing a 50% reduction in mortality with high-plasma as compared to low-plasma resuscitation of combat injuries. Johansson and colleagues reported a 33% drop in massive transfusion mortality at the University of Copenhagen Hospital after instituting hemorrhage control resuscitation.<sup>61</sup> Cotton and colleagues reported a 40% improvement in 30-day survival after damage-control laparotomy when damage-control resuscitation was used.<sup>62</sup> Holcomb and the Trauma Outcomes Group gathered 466 cases of massive transfusion from the records of 16 trauma centers and showed a strong relationship between the plasma to red cell transfusion ratio and outcome.<sup>63</sup> Also noted was a strong relationship of platelet count on admission, and platelet transfusions, to outcome. However, all of these important studies were subject to the criticism that it was impossible to

separate out the effects of receiving blood products from the effects of surviving long enough to receive the products, known as “survival bias.”<sup>64</sup> In a review of 10 published series, Stansbury and her epidemiologic colleagues pointed out a number of reasons for believing that the reported effect of a high plasma to RBC ratio was real, most importantly the declining overall mortality. However, the investigators ultimately concluded that randomized and prospective data would be necessary to overcome the biases introduced by patient selection and time to treatment differences.<sup>65</sup>

Obstacles to conducting randomized trials in trauma patients are multiple. They include problems with study design, informed consent, study team building, and support. The trials of recombinant human blood clotting factor VIIa (rFVIIa) conducted by its manufacturer, and of hypertonic saline by the Resuscitations Outcomes Consortium (ROC), provided experience and object lessons. In the rFVIIa hemorrhage trials, informed consent turned out to be a difficult problem as half of all hemorrhagic deaths occurred in the first two hours after arrival in the trauma center, and the mean time to obtaining consent from next of kin or other legally authorized representative was three hours. This meant that a \$40 million trial with a planned mortality of 40% could have only 11% mortality and a statistically negative outcome in the patients who could be consented.<sup>66</sup> Fortunately, the hypertonic saline trials provided experience with conducting large publicly funded resuscitation research under the exception from informed consent (EFIC) regulations of the US government. While these studies showed no benefit for this low-volume resuscitation technique, the investigations were successfully completed and provided a model for the conduct of transfusion resuscitation trials.<sup>67</sup>

The first large prospective trial of hemostatic trauma resuscitation, PROMMTT, was observational only.<sup>68</sup> Designed to gather data in preparation for a randomized trial, in 15 months it screened 12,560 patients with highest level trauma team activations at 10 level 1 trauma centers. PROMMTT enrolled 1245 patients with apparent uncontrolled hemorrhage who survived at least 30 minutes and received at least one unit of red cells within six hours of admission. A subset of 905 of these patients who went on to receive at least three blood products in the next six hours became the analysis cohort. In the first six hours of observation, 95 patients died

including 77 of uncontrolled hemorrhage, whereas in the period between six hours after admission and 30 days only 18 of 125 further deaths were associated with uncontrolled bleeding. A Cox proportional hazards analysis showed that deaths in the first six hours were strongly associated with the ratio of plasma to red cell units transfused; the hazard ratio for death was four times greater in the patients who received less plasma (plasma:red cell ratios of less than 0.5). However, even these high-volume level 1 trauma centers had trouble delivering plasma in a timely manner, 65% of patients received no plasma in the first hour, 40% received no plasma in the first two hours, and 20% received none in the first three hours. Infusion times for platelets were even slower. Median time to hemorrhagic death was 2.6 hours. Ultimately, while 25% of patients in the evaluation cohort died, only one-third died of hemorrhage, and most of them during the first six hours when active resuscitation was occurring. The study showed that it was possible to gather accurate time of transfusion data on large numbers of trauma patients in a short time period. However, the study unfortunately also showed that the process was labor-intensive and required screening large numbers of patients to enroll the few patients likely to benefit. Furthermore, and even in the best centers, the resulting data would still be subject to risks of survival bias because of long delays in delivering plasma and platelets to the bedside. Nonetheless, considering these caveats, timely administration of balanced resuscitation appeared to provide a large therapeutic benefit, reducing hemorrhage-related mortality by as much as 75%.

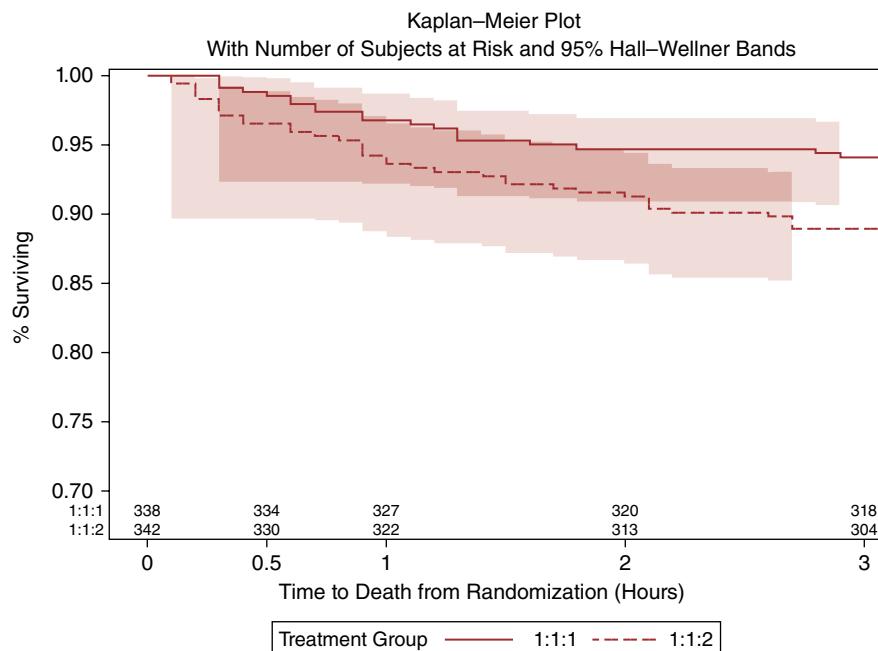

The PROMMTT study suggested that a prospective randomized trial of 1:1:1 BCT transfusion in severely injured and massively bleeding trauma patients was possible. However, such a trial would require access to more than 10,000 trauma patients and the ability to screen patients and enroll those at high risk for active ongoing hemorrhage while simultaneously excluding those with severe head injury unlikely to benefit from resuscitation. It would need to submit them to randomization quickly with EFIC, and to treat them

promptly with blood products available within minutes after arrival so that there were no delays between the time of randomization and treatment that might create survival bias.

The PROPPR study was conducted between August 2012 and January 2014.<sup>69</sup> It screened 14,000 patients and enrolled 680 who had an Assessment of Blood Consumption (ABC) score of 2 or more and no evidence of unsurvivable head injury. The 12 participating trauma centers had to prove that their transfusion service could make six units of universal donor RBCs and plasma available within 10 minutes of notification and have six more units available within 20 minutes of patient arrival. The patients were randomized to receive plasma:platelets:red cells in either 1:1:1 or 1:1:2 unit ratios and followed to 24-hour and 30-day mortality end points. The trial was completed with better than 97% protocol compliance and 100% follow-up for the primary end point.

The results are complicated only in the sense that the US Food and Drug Administration (FDA) required that the primary end points be 24-hour and 30-day survival as a condition of granting the permission to conduct the study under EFIC regulations. The results showed no significant differences between these two ratios at these primary end points. However, over the course of resuscitation from 10 minutes to 3 hours, a significantly greater proportion of patients treated with the 1:1:1 ratio survived, and the absolute difference in mortality was significant at the end of resuscitation and persisted from 3 hours to the end of the study (Figure 40.3). In the PROPPR study, the number of hemorrhagic deaths occurring during resuscitation was reduced by almost 50%, and the relative reduction in total deaths over 30 days was 18%. Overall mortality in the treated arm was 18%, much lower than the 40–70% mortality in similar patients in series reported a decade ago.

What the PROPPR study did not answer was whether the benefit of balanced hemostatic resuscitation was the result of the extra plasma, the platelets, or both. It addressed only the difference between resuscitation with a 1:1:1 versus a 1:1:2 BCT ratio. Planned

**Figure 40.3** Mortality in the resuscitation phase of the PROPPR trial comparing resuscitation with a 1:1:1 unit ratio of RBC-plasma-platelets with a 2:1:1 ratio as a Kaplan-Meier plot with 95% Hall-Wellner confidence intervals. Data from Holcomb et al. (2015).

blood sampling at admission and two hours after admission missed most of the intermediate differences that led to excess early deaths in the 1:1:2 arm. Regardless of these caveats, rapid delivery of balanced hemostatic resuscitation has become the new standard of care. It has been adopted by the American College of Surgeons in their Trauma Quality Improvement Guidelines for Massive Transfusion Protocols required for trauma center accreditation,<sup>70</sup> and it is required for Patient Blood Management program accreditation through the AABB.<sup>71</sup>

## Clinical approach to the mass casualty trauma situation

Mass casualty trauma situations are uncommon, and those requiring large amounts of blood are rare. In the United States, between the years 1975 and 2000 there were only such four events that required more than 100 units of RBCs to treat all of the resulting casualties in their first 24 hours of care.<sup>72</sup> Furthermore, these events are used by media to encourage the population to donate blood, resulting in a temporary increase in blood collections and a subsequent outdating of large quantities of that blood. For example, 600,000 extra units of blood were collected after 11 September 2001, most of which had to be destroyed. The exception to this is mass shootings, with the deadliest being the Las Vegas shooting on 1 October 2017. This mass casualty event resulted in 58 deaths and injured more than 600 people. The shooting utilized more than 500 units of blood in the first 24 hours, while 800 units of blood were donated by the public immediately after the shooting, resulting in only 17% waste.<sup>73</sup>

The rarity of massive blood use in multicasualty events is to be contrasted with the frequency of massive blood use in single individuals with poly-trauma or transplant; these cases more commonly create situations where one patient uses more than 100 units of RBCs in 24 hours. A critical difference between these scenarios is the need to have well-practiced protocols to maintain the unique identity of each patient in a multicasualty setting. The use of universal donor products in disaster situations where casualties may be unidentified or more importantly misidentified is an important precaution. It should be remembered that more than 100,000 universal donor whole blood and red cell units were given in the Vietnam War and that all seven fatal acute hemolytic reactions there were associated with the misidentification of recipients of crossmatched red cells.

## Initial resuscitation of the burn patient

The resuscitation of patients with severe burns is different than that of patients with penetrating and/or blunt force trauma. For trauma patients in hemorrhagic shock with ongoing acute blood loss, the priorities are hemorrhage control and resuscitation with blood products. Burn patients without mechanical trauma, however, develop hypovolemia due to systemic capillary leak. Often these patients will have a higher initial hemoglobin concentration due to the redistribution of plasma water into the interstitium and intracellular space. The priority in burn patients is to replace this volume loss and prevent the patient from progressing to severe hypovolemic shock.<sup>74</sup> Therefore, the initial resuscitation utilizes crystalloid and colloid solutions, and blood product transfusion is less common. However, later during the treatment course, cumulative blood loss increases due to burn excision and grafting, anemia of critical illness, and laboratory testing. It is during this latter period

in the hospital course that attention should be given to increased blood product utilization and the type and quantity of blood transfusions given to patients with severe burns.

In the initial period (24–48 hours after injury), resuscitation is conducted according to standard burn resuscitation formulas; however, no single formula provides an exact volume required. Resuscitation formulas are a starting point, from which physicians will need to titrate fluid volumes to the patient's response. Burns of less than 20% total body surface area (TBSA) typically do not require fluid resuscitation, except in children and older adults, for whom a 15% TBSA cutoff is generally used. Utilizing the American Burn Association Consensus Formula, fluids for the initial 24 hours resuscitation are calculated at 2–4 mL/kg of fluid per percentage of TBSA. The first half of the calculated volume is given over the first eight hours from injury, not from the beginning of resuscitation; the rest is given over the next 16 hours.<sup>75,76</sup> Lactated Ringers' solution is preferred given the large volumes administered and increased electrolyte derangements with other isotonic fluids. Children should also receive maintenance fluids containing dextrose in addition to the resuscitative fluid. The presence of inhalation injury can increase the volume of fluid required to achieve adequate resuscitation. Colloids may minimize the total volume of fluid administered during resuscitation, though it is debated whether or not this improves mortality or outcomes like respiratory complications. Albumin 5% is the colloid of choice started at a rate of 0.3–0.5 cc/kg/%TBSA and titrated alongside the crystalloid rate based on resuscitation end points. Colloids should be considered for patients with extensive burns or for those requiring fluid volumes in excess of Consensus Formula prediction.<sup>77–79</sup> Fluids are titrated to the patient's specific hemodynamics with a goal urine output of 0.5–1 mL/kg/hour.<sup>76</sup> It bears repeating that the consensus formula is a starting point, fluid must be titrated to urine output and patient physiology.

Release of vasoactive mediators from injured tissue results in a diffuse capillary leak starting soon after injury. In larger burns, this occurs in both the burned and unburned tissues. Immediately after injury, the loss of microvascular integrity results in extravasation of crystalloid and colloid solutions. However, after 6–12 hours, this will begin to subside in nonburned tissue, and this is the time frame in which many centers will initiate albumin resuscitation.<sup>76</sup>

It is important to note that there is renewed interest in the use of plasma in the resuscitation of burn patients. While plasma was used historically as a volume expander in burns, it is not widely used in modern burn centers. However, animal models have demonstrated that plasma may have benefits beyond its oncotic effects. In particular, plasma may play a role in preserving the endothelial glycocalyx (EGC). In a rat burn model, resuscitation with plasma was associated with preservation of the pulmonary ECG.<sup>80</sup> Currently, there is a multicenter randomized trial to investigate the use of plasma in acute burn resuscitation.

## Transfusion therapy in the care of the severely burned

Patients with less than 10% total body surface area (BSA) burns rarely receive transfusions.<sup>81</sup> Increasing burn size, age, and presence of anticoagulants significantly increases the use of blood transfusions, but deciding when to transfuse can be difficult.<sup>82</sup> The hypermetabolic response to severe burns significantly alters normal physiologic parameters that are commonly relied upon to determine transfusion indications. When considering transfusions in

burn patients, several factors are evaluated including the acuity of the anemia, blood loss mitigation techniques, and the potential physiologic benefits as compared to transfusion risks.

During the initial resuscitative period, burned patients will have an acute blood loss anemia that is not associated with large volume blood loss, but rather from destruction of erythrocytes within the cutaneous circulation and by hemorrhage into the burn wound. This initial anemia is typically not significant enough to require transfusion as evident by data showing an average of  $5.3 \pm 0.3$  days from admission to the first transfusion.<sup>81</sup> The greatest blood loss, and subsequently the use of large volume transfusions, occurs during burn wound excision and grafting. Further blood loss can occur from postoperative dressing changes on areas of open wounds. The average transfusion requirement for a 40% burn, for example, is at least 11 units of packed red blood cells.<sup>83</sup>

Efforts made to mitigate the use of transfusions during burn excision include the use of hemostatic techniques such as topical thrombin, epinephrine-soaked gauze, tourniquets, and fibrin sealants.<sup>84,85</sup> Intraoperative blood loss is an important factor limiting the extent of excision and grafting performed. Initial steps to control hemorrhage use electrocautery devices or pressure. Thrombin spray and laparotomy pads saturated with thrombin and epinephrine can be applied directly to the wound bed to limit intraoperative blood loss. The use of tourniquets for excision and grafting of extremities can further decrease blood loss during extremity excision.<sup>86</sup> As in the care of trauma patients, the importance of normothermia in preventing coagulopathy is recognized, and patients are actively warmed, or more importantly not allowed to get cold at the time of surgery.

Data from a multicenter study evaluating the effects of blood transfusion in severe burns revealed that 70% of blood transfusions for burn victims occur outside of the operating room.<sup>87</sup> This anemia is multifactorial in origin and due in part to mild ongoing blood loss from dressing changes and phlebotomy, impaired red blood cell production from erythropoietin insensitivity, malnutrition and metabolic demands. As with operative excisions, some efforts can be undertaken to mitigate this anemia as well. Minimizing blood draws and using pediatric blood collection tubes can decrease iatrogenic anemia. Maintaining adequate nutrition is important for all patients, and some studies have identified up to 13% of critically ill patients are deficient in nutrients necessary for erythropoiesis.<sup>88</sup> Administration of exogenous erythropoietin has been extensively studied in multiple critically ill populations but has yet to show any efficacy in patients with burns.

Transfusing patients with thermal injuries must be tempered with the known risks and benefits of blood and blood products. Increasing hemoglobin concentrations is the only method to increase oxygen carrying capacity, but the known transfusion associated morbidity documented in multiple specialties is also seen in burn patients. The safety of a restrictive transfusion strategy, to maintain a hemoglobin level of 7–8 mg/dL, was demonstrated in the Transfusion Requirements in Critical Care (TRICC) trial.<sup>89</sup> However, patients with a 3 g/dL drop in hemoglobin or ongoing bleeding were excluded, thus the applicability of this trial to the burn population is limited. Nonetheless, burn patients remain at risk for complications of transfusion. In a large, multicenter retrospective analysis of 666 burn patients, the number of infections per patient increased with each unit of blood transfused. This translated to a 13% increase in developing an infection per unit of blood transfused.<sup>81</sup> The Transfusion Requirement in Burn Care Evaluation (TRIBE) study was a multicenter, controlled trial that randomized

345 burn patients across 18 centers to a restrictive or more liberal transfusion strategy.<sup>90</sup> The restrictive group received a median 8 (IQR 3–24) units of red cells compared with a median of 16 (IQR 7–40) in the liberal group ( $p < 0.0001$ ). There were no differences in any outcome, including mortality or infection. No intraoperative adverse outcomes were related to protocol adherence. This study provides level 1 evidence for pursuing a more restrictive transfusion strategy for red cells in burn patients.

The appropriate use of plasma during intraoperative blood loss from burn wound excision is not well defined. As described above, increasing the volume of plasma in relation to packed red blood cells has shown definitive benefit in trauma patients with hemorrhagic shock. In one study comparing higher FFP usage in burn patients (1:1 vs a 4:1 [RBC:FFP]), there was a decrease in overall blood product usage and a trend toward shorter duration of hospital stay, infectious complications, and organ dysfunction in the 1:1 group.<sup>87</sup> However, in military patients with severe thermal injuries, the use of plasma was associated with the development of acute respiratory distress.<sup>91</sup> There is a recent trend to use viscoelastic analysis in guiding transfusion resuscitation, and early use of this test during burn wound excision shows promise in reducing the amount of blood products transfused, but further investigation is warranted.<sup>92</sup>

## Adjuncts in transfusion therapy for trauma and burn patients

### Tranexamic acid

Tranexamic acid (TXA) and epsilon-aminocaproic acid are lysine analogs used as antifibrinolytics.<sup>93</sup> Newly formed fibrin polymer has exposed lysine residues that serve as binding sites for plasmin and facilitate the plasmin-dependent breakdown of fibrin polymer. During normal coagulation, a strong thrombin burst activates the thrombin-activated fibrinolysis inhibitor (TAFI) that removes these lysine residues to prevent fibrin breakdown.<sup>94</sup> However, after trauma and especially with the acute coagulopathy of trauma, the intensity of thrombin activation is reduced and as a result TAFI is not activated. Furthermore, activation of plasmin by tissue plasminogen activator secreted in response to hypotension and inactivation of plasminogen activator inhibitor by activated protein C led to high plasmin activity. The combination of high plasmin activity and widely available plasmin binding sites on fibrin leads to rapid degradation of fibrin polymer. Using TXA to inhibit fibrinolysis stabilizes newly formed clot and reduces blood loss.

TXA has been demonstrated to reduce blood loss in several non-trauma settings such as knee and hip joint replacement, craniosynostosis surgery, and after tooth removal in patients with hemophilia. Knee and hip joint replacement trials have shown reduced blood drainage after surgical site irrigation with a suspension of the drug.<sup>95</sup> In infants undergoing craniosynostosis surgery, a randomized trial demonstrated an almost 50% reduction in blood loss and red cell replacement requirements with IV TXA.<sup>96</sup> In hemophilia patients undergoing dental extraction, oral wash and swallow with a suspension of the drug reduced the duration of bleeding.<sup>97</sup>

For trauma patients, the international CRASH-2 trial and the MATTERs study are the basis for recommendations for wide use of the drug. The CRASH-2 trial was a large simple randomized trial of TXA use or nothing in 20,211 trauma patients in 274 hospital in 40 countries.<sup>98</sup> Use of the drug led to a 1.5% reduction in overall mortality with a reduction in the odds of hemorrhagic mortality by 15%. However, in patients treated more than three hours after

injury, mortality was increased. Criticisms of the CRASH-2 trial include the participant centers were mostly in third world countries, only half of the patients enrolled received a blood transfusion, and only 30% of the patients were hypotensive. These caveats have led some to question the mechanistic impact of TXA. The Military Application of Tranexamic acid in Trauma Emergency Resuscitation study (MATTERs) was a retrospective review of 896 consecutive admissions to a British Army medical facility in Afghanistan that demonstrated better survival in patients treated with TXA.<sup>99</sup> The mortality benefit observed in patients receiving TXA was almost 50% in those receiving more than 10 units of RBCs. Lastly, there exists a potential benefit for TXA in isolated Traumatic Brain Injury patients as demonstrated in the CRASH-3 trial (mortality 18.5% with TXA and 19.8% without); however, the mortality benefit did not carry over to a recently published US multicenter RCT (14% vs. 17%,  $p = 0.26$ ).<sup>100</sup>

Despite occasional reports of thrombotic complications after TXA administration, a large meta-analysis of randomized trials of the drug did not reveal excess thrombosis or mortality after its use. This suggestion of broad safety has led to recommendations that TXA be given in prehospital situations and this drug is rapidly becoming a standard of care for hemorrhagic shock trauma patients.

Interestingly, studies suggest that fibrinolysis is not a major contributor to coagulopathy in burns, and the use of TXA or other fibrinolytics should be limited to burn patients with demonstrated fibrinolysis.

### **Plasma-derived coagulation factors**

Plasma-derived coagulation factors potentially allow rapid restoration of coagulation system activity in severely injured patients. Recent studies have focused on the use of four-factor prothrombin complex (PCCs) and recombinant activated factor VIIa (rVIIa). Potential benefits of PCC include its ease of storage and reconstitution, high concentrations of extrinsic pathway factors, blood-type independence, low volumes, and virologic safety profile. Disadvantages include the 20-minute reconstitution time, the lack of other plasma proteins including factors I, V, VIII, XI, XIII (which, when deficient, confer a very high mortality), as well as the low volume of the product that does not address volume loss in a hemorrhaging trauma patient.

Data regarding four-factor PCC in trauma is limited. A small single center randomized controlled trial from Innerhofer and colleagues in Austria randomized coagulopathic trauma patients to FFP or coagulation factor concentrates. The study was halted early due to medical safety concerns as the FFP group required more massive transfusion and (30% vs. 12%) and had a higher need for rescue therapy (52% vs. 4%).<sup>101</sup> A retrospective propensity matched ACS-TQIP study by Zeeshan and colleagues demonstrated reduced blood product transfusion (6 units vs. 10 units,  $p = 0.02$ ), reduced respiratory distress syndrome (1.3% vs. 4.7%,  $p = 0.04$ ), and a lower mortality (17.5% vs. 27.7%,  $p = 0.01$ ) in patients receiving PCC.<sup>102</sup> While both studies had numerous limitations, the results are intriguing and pave the way for future multicenter randomized controlled trials to determine the role for PCCs in the management of hemorrhaging trauma patients who need volume as well as clotting factors.

rVIIa has been identified as an additional adjunct to the treatment of the bleeding trauma patient. Boffard *et al.* renewed trauma interest in the drug after publishing a randomized controlled trial demonstrating reduction in blood product usage (by 2.6 units) and need for massive transfusion, as well as trends toward reduced mortality.<sup>103</sup> A subsequent retrospective cohort study by Rizoli *et al.* out of

Toronto again found decreased blood product usage and a significant mortality benefit (OR 3.5); however, the study had few patients receiving the rVIIa (n=38) with expected wide range of potential benefit.<sup>104</sup> rVIIa received additional attention in 2009 with the FAST trial in acute cerebral hemorrhage patients with the medication being associated with decreased growth of the hematoma; however, there was no impact on survival or functional outcome.<sup>105</sup> With earlier access to blood products and restricted crystalloid use, the initial enthusiasm for using rVIIa in mature trauma systems has faded.

### **Cryoprecipitate**

The glycoprotein fibrinogen has been shown to mediate platelet and endothelial function and is thought to play a role in the stabilization of syndecan-1 and correction of endotheliopathy (in addition to the effects stated above). There is also evidence that fibrinogen is the first clotting factor to become critically low in trauma patients and is independently associated with mortality.<sup>106</sup> Cryoprecipitate is the most common method of fibrinogen supplementation. Prepared from plasma, cryoprecipitate contains fibrinogen, von Willebrand factor, factor VIII, factor XIII, and fibronectin. CRYOSTAT-1 was an unblinded RCT in 2015 that demonstrated the feasibility of early cryoprecipitate transfusion in bleeding trauma patients<sup>107</sup> CRYOSTAT-2 is an international multicenter randomized controlled trial designed to determine whether the addition of early cryoprecipitate to massive transfusion protocols improves survival in major trauma hemorrhage.

### **Freeze-dried plasma**

While high ratios of plasma:pRBCs and early plasma transfusion have been shown to reduce mortality and correct trauma associated coagulopathy, there remain significant limitations to plasma-first resuscitation including the transport, storage, availability, and administration of FFP. Due to these factors, there is a renewed interest in freeze-dried plasma as it is easier to store (room temperature), readily transportable, and reconstitutes easily (three minutes). This has led to approval in Germany, France, and South Africa, as well as FDA emergency use authorization for military use in the United States in 2018. Numerous studies have shown that clotting factors are well preserved in freeze-dried plasma, and that this product can attenuate trauma-induced coagulopathy in animals and *in vitro*. Several studies have also confirmed its safety profile and efficacy in trauma patients. A retrospective 2018 study at a level 1 trauma center by Nguyen *et al.* examined the effects of French lyophilized plasma versus FFP in patients receiving 2U RBCs.<sup>108</sup> They found several advantages of lyophilized plasma, including a shorter time to transfusion, a higher plasma:RBC ratio, faster time to 1:1 ratio, and significantly fewer cases of massive transfusion. This retrospective study's findings were corroborated in a French randomized controlled trial by Garrigue *et al.* in 2018.<sup>109</sup> This trial enrolled adult trauma patients deemed by the attending physician to need massive transfusion who were subsequently randomized to French lyophilized plasma or FFP. The lyophilized plasma group had a shorter time from randomization to transfusion of plasma (14 minutes vs. 77 minutes) leading to higher fibrinogen and factor concentrations and reduced prothrombin times. Both of these studies were carried out at centers without access to thawed plasma, so the improvements were likely related to shorter times to plasma transfusions. Lyophilized or freeze-dried plasma present reasonable alternatives for hospitals without access to thawed plasma (due to reduced need or increased waste); however, the FDA has not yet approved this product for civilian use.

## Whole blood

With the trend of reduced mortality with BCT in 1:1:1 physiologic ratios, there has been a renewed interest in whole blood (WB) transfusion. The concept is logical, to replace bleeding trauma patients blood loss with equivalent ratios of three separate blood products or whole blood. Whole blood has a 21-day shelf life at 4 °C. Several retrospective military studies have demonstrated a mortality benefit when WB was used.<sup>110,111</sup> Cotton *et al.* performed a pilot RCT in 2013 comparing WB without platelets and BCT in a civilian patient population of 107 patients and failed to find a difference in transfusion volumes or a mortality benefit.<sup>112</sup> However, when excluding TBIs in the sensitivity analysis, there was significantly reduced transfusion volumes in the WB group. This study is supplemented by a propensity matching study at two level 1 trauma centers by Hazelton *et al.* comparing 91 WB and 182 BCT hypotensive bleeding trauma patients.<sup>113</sup> This study demonstrated that WB transfusions increased hemoglobin and hematocrit at 24 hours and decreased trauma bay mortality (2.2% in WB, 8.8% in BCT,  $p = 0.039$ ); however, there was no difference in 30-day mortality. Finally, Hanna and colleagues performed a retrospective TQIP study of transfused trauma patients, comparing those that received WB and BCT to therapy with BCT alone.<sup>114</sup> While this is a database retrospective study, they did find that WB transfusions were associated with significantly lower 24-hour mortality (17% vs. 25%,  $p = 0.002$ ), reduced in-hospital mortality (29% vs. 40%,  $p < 0.001$ ), fewer major complications (29% vs. 41%,  $p < 0.001$ ), and shorter length of stay (9 vs. 15 days,  $p = 0.011$ ). Overall, the results are promising, and many major trauma centers have implemented WB resuscitation into their transfusion algorithms (as well as the prehospital algorithms). However, more conclusive randomized controlled trials are needed prior to exclusively focusing on WB resuscitation early in hypotensive trauma patients.

## Summary

As described in this chapter, transfusion support of the trauma and burn patients has undergone significant improvements over the last two decades. For example, recent modifications to trauma resuscitation and trauma care protocols have led to an almost

50% reduction in the incidence of hemorrhagic deaths in trauma centers carrying out damage-control resuscitation. These improvements in BCT, which were validated in the PROPPR study, centered on the early administration of balanced hemostatic resuscitation with plasma and platelets aimed at early correction of the acute coagulopathy of trauma. The reduction in blood transfusion in the care of burned patients has also been dramatic (three- to fivefold) as burn surgeons have learned to manage blood loss and accept lower transfusion triggers. These are examples of patient blood management evolving in surgical fields, sometimes occurring independently of transfusion-medicine-driven changes.

The challenges of extending these improvements in care to injured patients arriving in smaller centers and to soldiers and civilians in the field will center on developing ways to deliver current blood products earlier in care and the wider use of hemostatic adjuncts such as tranexamic acid, hemostatic bandages, and fibrinogen concentrates. It will also require a national commitment to collecting the amounts of universal donor blood products needed to make the system work. Achievement of this goal will additionally be facilitated by developing a new generation of blood products such as more accessible freeze-dried plasma, more effective plasma derivatives, and frozen platelets.

## CHAPTER 41

# Transfusion support for the oncology patient

Kristin M. Stendahl, Wade L. Schulz, & Edward L. Snyder

Department of Laboratory Medicine, Yale School of Medicine, Yale University; and Blood Bank, Yale-New Haven Hospital, New Haven, CT, USA

Transfusion support for patients with cancer is a complex, multifaceted medical therapy meant to assist in the management of complications related to chemotherapy, radiation, transplantation, or widespread metastatic disease. Oncology patients frequently require chronic transfusion support and present several unique challenges in providing appropriate blood products. For these patients, greater attention must be paid to the selection, preparation, modification, and response to blood components to help ensure better outcomes. This chapter highlights the most challenging aspects of transfusion therapy for oncology patients encountered by clinicians and transfusion services on a routine basis.

## Red cell transfusion

### Indications

The goal of red blood cell (RBC) transfusion in oncology patients is the same as in other populations—to increase the oxygen-carrying capacity of whole blood for patients with anemia. Unfortunately, there is currently no evidence-based laboratory criteria upon which to determine when transfusion is appropriate for oncology patients. Studies in other critically ill patient populations have shown that hemoglobin levels of 7–10 g/dL can be tolerated without the need for allogeneic transfusion.<sup>1</sup> There is no evidence to suggest that higher hemoglobin levels provide any therapeutic benefit, and there is some evidence to suggest that “hypertransfusion” may be detrimental to patient outcomes.<sup>2</sup> Therefore, oncology patients should be transfused for symptomatic anemia or at predetermined hemoglobin or hematocrit levels defined by a hospital’s oncology service.

### Selection of ABO group for RBC transfusion

For most oncology patients, no special consideration is required for the appropriate selection of ABO group for RBC units as well as other blood products. However, for patients who have received an allogeneic hematopoietic stem cell transplant (HSCT), selecting the appropriate ABO group can be more difficult. This is particularly true in the case of ABO mismatch between the hematopoietic progenitor cell (HPC) donor and recipient. Up to half of HSCTs are

ABO mismatched as a consequence of priority given to matching for human leukocyte antigens (HLA).<sup>3,4</sup> While ABO mismatch between the donor and recipient does not seem to have any short-term drawbacks, providing appropriate transfusion support in the period after transplantation can be complex.<sup>5,6</sup> These patients generally require more transfusion support due to delayed cellular engraftment and red cell aplasia. They are also at risk for acute and delayed hemolytic reactions from ABO incompatibility while engraftment occurs.<sup>6,7</sup> Although outcome results following ABO mismatched HSCTs have been mixed, ABO-mismatched HSCT does not appear to adversely impact outcome or long-term survival in either pediatric or adult populations.<sup>5,6,8</sup>

An ABO mismatch, however, can lead to concerns during HSC infusion as well as post-transplantation. In the setting of allogeneic transplantation, there are several possibilities for ABO antibody mismatch including minor mismatch, major mismatch, as well as a combination of both a minor and a major mismatch. When the donor possesses antibodies against recipient red cells, patients are deemed to have a minor mismatch. An example of a minor mismatch is when a patient (recipient) with group A red cells receives HPCs from a group O donor. On the other hand, a major mismatch occurs when the recipient has antibodies targeted to donor red cells. This most frequently occurs when a group O patient (recipient) receives HPCs from a group A, B, or AB donor. Finally, “two-way” incompatibility can occur in the presence of both a major and a minor mismatch, for example when a group A patient (recipient) receives HPCs from a group B donor. Table 41.1 summarizes both major and minor incompatibility scenarios by blood group. The key to successful transfusion for any of these mismatches is to prevent or reduce hemolysis during HPC infusion. For patients with a minor mismatch, this can be achieved by plasma reduction of the HPCs to significantly lower the amount of offending antibody. For patients with a major mismatch, red cell depletion of the HSC product can be used to prevent acute hemolysis during infusion.<sup>9</sup> However, it is important to keep in mind that the latter process will likely decrease the content of progenitor cells in the product as well. Therapies used post-transplant to manage red cell aplasia include glucocorticosteroids, immunosuppressive agents, and rituximab, among others. In addition, recent reports have shown success with

**Table 41.1** Compatibility by ABO Group in Hematopoietic Stem Cell Transplantation

Recipient ABO Blood Group	Donor ABO Group			
	O	A	B	AB
O	Compatible	Major	Major	Major
A	Minor	Compatible	Major and minor	Major
B	Minor	Major and minor	Compatible	Major
AB	Minor	Minor	Minor	Compatible

Compatible, major incompatibility, minor incompatibility, and major and minor incompatibility ("two-way" incompatibility).

**Table 41.2** Transfusion Protocol for HSCT Patients

Recipient	Donor O			Donor A			Donor B			Donor AB		
	RBC Type	FFP/PLT Type	Second Choice PLT	RBC Type	FFP/PLT Type	Second Choice PLT	RBC Type	FFP/PLT Type	Second Choice PLT	RBC Type	FFP/PLT Type	Second Choice PLT
O	O	O	A or B	O	A	O	O	B	O	O	AB	A
A	O	A	O	A	A	O	O	AB	A	A	AB	A

AB	O	AB	A	A	AB	A	B	AB	B	AB	AB	A or B

NOTE: If a recipient is Rh negative, they will continue to receive Rh negative products.

the use of daratumumab, the human monoclonal antibody against CD38, for the treatment of refractory red cell aplasia following ABO-mismatched HSCT.<sup>10</sup>

Transfusion support in the post-transplant period requires careful consideration given that antibodies can persist for weeks to months after transplantation, which can lead to ongoing issues in the selection of proper blood components. Patients can also present as chimeras after HSCT, with two distinct blood groups seen by routine blood typing.<sup>11</sup> Fortunately, standardized strategies have been developed to provide the most compatible ABO components for these patients. For patients with major incompatibility from recipient anti-A or anti-B directed to donor red cells, recipient-type RBC units are necessary until ABO antibodies are no longer detected.<sup>12–14</sup> For patients with minor incompatibility, recipient-type plasma and platelets should be used until the recipient's red cells are no longer detected. Donor-type RBC units can be used immediately after HSCT for patients with minor incompatibility.<sup>12–14</sup> Patients with two-way incompatibility require group O RBC units and group AB plasma and platelets until the offending antibodies and cells are no longer detectable. Table 41.2 provides a transfusion protocol that can be followed for ABO-mismatched HSCT.<sup>12–14</sup>

If a recipient is transplanted with a Rh negative HPC, they will receive Rh negative products.<sup>25</sup>

### Alloimmunization to red cell antigens

Despite significant immunosuppression, patients with malignancy can still mount immune responses to foreign red cell antigens, which can complicate transfusion and increase the risk for hemolysis.<sup>15,16</sup> Rates for red cell alloimmunization in oncology patients have been most studied in patients with hematologic malignancies undergoing HSCT. These studies have shown that alloimmunization occurs in 2–8% of patients in these populations.<sup>17,18</sup> Additionally, a multicenter case-control study evaluated the association of various malignancies and treatment modalities with alloimmunization rates and found reduced rates of alloimmunization in patients with

acute leukemia and mature lymphoma as well as stem cell transplant patients compared to patients without these malignancies. On the other hand, for patients with solid tumors or other oncologic conditions, the study found similar rates of alloimmunization compared to the general transfused population.<sup>19</sup>

### Component modification: leukocyte reduction and irradiation

Prestorage leukocyte reduction techniques decrease the number of white blood cells within transfusion components, which has been shown to reduce the risk of HLA alloimmunization.<sup>20,21</sup> In addition, leukocyte reduction can lower the rate of blood-borne transmission for pathogens that are carried within white cells, such as cytomegalovirus (CMV).<sup>22</sup> According to the 2017 National Blood Collection Utilization Survey, approximately 95.8% of all red cell units in the United States were leukocyte reduced, most before storage.<sup>23</sup>

Despite the use of leukocyte-reduced units, however, many oncology patients are still at risk for transfusion-associated graft-versus-host disease (TA-GVHD) because of their immunocompromised state. In cases of TA-GVHD, donor lymphocytes generate a profound immune response against the recipient's cells.<sup>24</sup> The underlying causes and manifestations of TA-GVHD are discussed in Chapter 50. Prevention of TA-GVHD can be accomplished by either gamma or X-ray irradiation of cellular blood components.<sup>25</sup> Some in the field of transfusion medicine have argued for a policy of universal blood component irradiation as the process has few side effects and may prevent cases of TA-GVHD in patients whose high-risk status is not known.<sup>26</sup> However, the practicality and cost-effectiveness of such a policy are still under review. The main disadvantage of irradiation is the induction of a potassium leak within the red cell membrane, thereby shortening the shelf of an RBC unit to no more than 28 days from the date of irradiation or the original expiration date, whichever comes first. There are no such concerns regarding the irradiation of platelets or plasma products. The latter component does not require irradiation as it does not contain viable cells.

### Alternatives to allogeneic red cell transfusion

For oncology patients undergoing a surgical intervention, intraoperative blood recovery—a process where shed whole blood is centrifuged, washed of contaminants, and then reinfused—may be of benefit to reduce allogeneic blood usage.<sup>27</sup> Although concern has been raised about the promotion of tumor cell metastasis with the use of such blood recovery procedures in some cancer patients, several trials conducted in patients with hepatobiliary and genitourinary cancers have shown no evidence of decreased patient survival.<sup>28–31</sup> Additional techniques including acute normovolemic hemodilution (ANH) and the use of preoperatively donated autologous whole blood can also be considered. However, these techniques are often not feasible in oncology patients who are often too anemic and who can require surgery at unpredictable times. The lack of cost-effectiveness for preoperative autologous donation also limits its utility to oncology patients undergoing major surgery.<sup>32</sup>

Another alternative to allogeneic red cell transfusion utilized in the past was the administration of erythropoietin-stimulating agents (ESAs). However, given the growing awareness of the severe associated risks, ESAs are no longer recommended. Several studies have found that the use of ESAs in patients with cancer and other critical illnesses can lead to an increased risk for venous thromboembolism and stroke.<sup>33</sup> In addition, erythropoietin may accelerate tumor growth and lead to decreased survival. Finally, studies have also shown that the use of ESAs does not significantly decrease the need for allogeneic transfusion in critically ill patients.<sup>34,35</sup> These findings led to a black box warning regarding the use of ESAs in the setting of cancer-related anemia.<sup>36</sup> As such, it is recommended that before initiation of an ESA, a detailed history, physical, and diagnostic work-up be performed to identify causes of anemia aside from hematopoietic malignancy or chemotherapy.

## Platelet transfusion

### Indications

More than one-third of platelets in the United States are administered to support oncology patients.<sup>37</sup> The goal of platelet transfusion is to stop or prevent bleeding in thrombocytopenic patients. The use of platelet transfusion is a first-line therapy for acute hemorrhage in patients with thrombocytopenia or those receiving anti-platelet medication. The use of platelet transfusion for bleeding prophylaxis, however, is somewhat controversial. Initial studies that supported the use of platelets for bleeding prophylaxis arose from trials in leukemic patients who were noted to have decreased bleeding episodes after platelet transfusion.<sup>38</sup> Later studies also demonstrated that prophylactic transfusion resulted in better outcomes and lower mortality compared to the use of therapeutic transfusion in patients with hematologic malignancy.<sup>39</sup> In the early 1990s, the goal for routine bleeding prophylaxis was to keep platelet counts greater than 20,000/ $\mu\text{L}$ .<sup>40</sup> More recent trials, however, have shown that spontaneous hemorrhage is unlikely, even with platelet counts as low as 5000–10,000/ $\mu\text{L}$ . In addition, patients transfused utilizing more restrictive criteria appear to have no change in morbidity and use significantly fewer blood products, thereby reducing costs as well as adverse effects associated with transfusions including reactions and alloimmunization.<sup>41–46</sup> A 2015 Cochrane review examined prophylactic versus therapeutic platelet transfusion in patients with hematologic disorders who had received myelosuppressive chemotherapy or HSCT. The review found that the therapeutic transfusion group was associated with an increased risk of bleeding

compared to the prophylactic group.<sup>47</sup> Analysis of the multicenter platelet dose (PLADO) trial, which evaluated bleeding with different doses of platelet transfusions, found that patients younger than 18 years of age had a higher risk of bleeding compared to adults, particularly for patients receiving autologous HSCT.<sup>48</sup> This finding highlights the special considerations needed when planning transfusion support for pediatric patients.

### Selection of ABO group and Rh type for platelet transfusion

Platelets express ABO antigens, although interactions between these antigens and host antibodies do not usually mediate clinically significant transfusion reactions.<sup>49</sup> Although type-specific platelets are preferred, most blood banks, especially during periods of inventory shortages, transfuse ABO-mismatched platelets to adults without significant concern for incompatibility. The use of ABO-mismatched platelets in oncology patients, however, can result in decreased therapeutic benefit or adverse reactions. For instance, a form of platelet refractoriness is mediated by ABO antibodies, with mismatched platelets cleared from circulation minutes to hours after infusion.<sup>49</sup> Another concern is the possibility that high-titer ABO antibodies in the plasma of donor platelets units may lead to hemolytic transfusion reactions in ABO-incompatible recipients.<sup>50–52</sup> Children in particular may demonstrate clinically significant hemolysis to ABO-incompatible platelet transfusions owing to their small blood volume. Therefore, it is recommended that oncology patients with low platelet counts receive ABO-compatible platelet products when feasible. For populations undergoing HSCT, other considerations regarding major and minor mismatches are also relevant. Table 41.2 summarizes guidelines for platelet transfusion therapy in the peri-transplant period.

Even though platelets lack Rh antigens, there remains a small concern for Rh alloimmunization in RhD-negative recipients during platelet transfusion due to the potential exposure to small numbers of residual red cells in the platelet product collected from RhD-positive donors. Because of the immunogenicity of the D-antigen, even a milliliter or less of red cells can lead to alloimmunization in Rh-negative recipients. However, recently published studies have shown that the overall rate of alloimmunization is quite low.<sup>53,54</sup> There is evidence to suggest that, in part due to immunosuppression, both adult and pediatric patients with hematologic malignancies are unlikely to form anti-D responses to Rh-incompatible platelet transfusions.<sup>55,56</sup> Thus, the provision of Rh-incompatible platelet products is unlikely to cause D alloimmunization in oncology populations. In addition, this risk may be further reduced through the use of apheresis platelets as these units have fewer residual red cells.<sup>57</sup> Nonetheless, it is still advisable to prevent Rh alloimmunization in children and females of childbearing potential because of the consequences of anti-D development in these populations. Prevention of alloimmunization can be achieved with a dose of 50–300  $\mu\text{g}$  of Rh immunoglobulin (RhIg) provided within 72 hours of D antigen exposure.<sup>58</sup>

### Selection of platelet products

Historically, the majority of platelet products were derived from whole blood by centrifugation, followed by pooling into groups of four to yield a product intended to increase the platelet count by approximately 50,000/ $\mu\text{L}$ .<sup>59</sup> These platelet products are referred to as pooled random donor platelets. With advances in apheresis technology in the 1970s, an increasing number of platelet units were obtained from single donors by apheresis collection, referred to as

apheresis platelets, that provided a platelet dose equivalent to the pooled product.<sup>59,60</sup> The decision to use apheresis platelets versus pooled platelets relates to concerns about exposure to multiple donors, risk of alloimmunization, risk of adverse reactions, and platelet quality rather than increases in baseline platelet count as both products have similar viability and recovery.<sup>61</sup> The risk for many of these issues are not specific to oncology and are discussed in greater detail in Chapter 35.

One particular concern for oncology patients is a possible increase in risk for platelet alloimmunization due to the large number of transfusions administered to these patients. This was a significant concern prior to the era of leukocyte reduction, especially for pooled platelet products. However, several studies, including the Trial to Reduce Alloimmunization to Platelets (TRAP), have demonstrated that the risk of alloimmunization is identical between leukoreduced pooled platelets and apheresis units.<sup>20</sup> Once a patient has become alloimmunized, however, the use of pooled platelets may be advantageous until crossmatch-compatible or HLA-matched platelet units are available. In this scenario, an alloimmunized patient may be more likely to respond by chance to one of the four or five donors whose units are part of a platelet pool. Therefore, in alloimmunized patients, apheresis platelets generally should be used only if the unit is crossmatch-compatible or HLA-matched.<sup>59</sup>

### **Platelet refractoriness and alloimmunization**

Chronically transfused oncology patients often experience lower than expected platelet increments. This is known as platelet refractoriness. Obtaining two consecutive corrected count increments (CCIs) following platelet transfusion is recommended as the initial screen to determine if a patient is platelet refractory. An acceptable CCI value is defined as  $>7.5 \times 10^6/\mu\text{L}$ , although some use a lower threshold of  $>5 \times 10^6/\mu\text{L}$ .<sup>62</sup> Additional alloimmunization studies can be performed if the CCI is below this value. Refractoriness to platelets can be due to either immune or nonimmune causes. Platelet alloimmunization and refractoriness are further discussed in detail in Chapter 54. In oncology patients, over 70% of cases of platelet refractoriness are due to nonimmunologic factors.<sup>59</sup> There are a few clinical management options for patients with nonimmunologic platelet refractoriness. When possible, correcting the underlying cause (e.g., splenectomy for hypersplenism, removal of offending medications, and treatment of sepsis and DIC) can alleviate refractoriness. For the acutely bleeding patient or for hemorrhage prophylaxis, strategies of continuous platelet infusion (platelet drip) have shown moderate success.<sup>63,64</sup> The platelet drip, wherein half a unit of an apheresis platelet bag is infused slowly over a four-hour period, is intended to provide an ongoing source of platelets to maintain vascular integrity, while addressing the practical concern of managing an often limited blood bank platelet inventory.

Although they constitute a minority of cases, the underlying cause of refractoriness in the remaining 20–30% of oncology patients is likely due to an antibody to a platelet antigen. Platelets express class I HLA and numerous other platelet-specific antigens. Human leukocyte antigens are the most common mediator of immunologic platelet refractoriness, although studies have shown that alloantibodies can develop to any platelet antigen.<sup>59,65</sup> The treatment strategy for immune-mediated refractoriness is to provide antigen-negative components. Although often not a cause of true refractoriness, the first approach is to provide ABO-compatible units, which may lead to a more sustained increase in platelet count. The next option is to provide crossmatch-compatible platelets from

the hospital blood bank or donor center. This is typically done by a solid-phase capture method in which the patient's plasma is crossmatched with a variety of random donor platelets and selecting units that do not cause agglutination.<sup>66</sup> Crossmatch compatible platelets have been proven to be as effective as HLA-matched platelets in raising platelet counts in alloimmunized patients.<sup>59,65,66</sup> Therefore, the decision to provide HLA-matched platelets should depend upon factors such as quality of the HLA match, severity of alloimmunization, and availability of crossmatched products. If a majority of tested donors are incompatible and HLA-matched products are needed, the recipient can be HLA typed to provide antigen-matched products.<sup>59,65</sup> Polymorphisms of HLA class I antigens can complicate compatibility testing and make the process of finding fully matched donors difficult.

Unfortunately, once alloimmunization has occurred, immune modulation with corticosteroids, plasmapheresis, and intravenous immunoglobulin (IVIG) are of little benefit.<sup>67</sup> Therefore, the best strategy to reduce immune-mediated platelet refractoriness is prevention of HLA and platelet antigen exposure. Leukocyte reduction has helped reduce the incidence of alloimmune platelet refractoriness by limiting exposure to HLA.<sup>20</sup> Conservative transfusion strategies have also helped prevent exposure to HLA and platelet-specific antigens and may play a role in reducing the frequency of alloimmunization.

### **Component modification: irradiation, leukocyte reduction, and volume reduction**

As is the case with RBC units, platelets can be modified to maximize safety for oncology patients. The process of leukoreduction can achieve a four-log reduction in leukocytes. Despite this reduction in leukocytes, platelet units still contain small amounts of white cells, generally below  $5 \times 10^6$ . Therefore, patients at risk for TA-GVHD should receive irradiated platelets.<sup>24</sup> As mentioned previously, leukocyte reduction of platelet products helps reduce the rate of alloimmunization.<sup>20</sup> According to the 2017 National Blood Collection and Utilization Survey, approximately 99.2% of all whole-blood-derived platelet units were reported as leukocyte reduced.<sup>37</sup> In addition, all apheresis platelets are leukocyte reduced as part of the collection process.

Volume reduction of platelet products via centrifugation and resuspension in saline should be considered for oncology patients who have experienced severe allergic or anaphylactic reactions to platelet products.<sup>68</sup> However, centrifugation damages platelets and can result in blunted in vivo response; therefore, centrifugation should be used sparingly. Volume reduction is also efficient in removing the plasma fraction of platelet products to reduce the risk of hemolysis associated with ABO-incompatible transfusion as well as the risk of volume overload.<sup>68</sup>

Recent advances to reduce adverse effects of platelet transfusions, particularly bacterial contamination of platelets, led to the development of pathogen-reduced platelets. Pathogen reduction technology uses ultraviolet light in conjunction with photoactive agents to damage the nucleic acid of infectious agents such as bacteria and viruses. Three pathogen reduction technologies are under study, including Mirasol, which uses riboflavin (vitamin B2) as the photoactive agent, and Intercept, which uses a psoralen compound as the photoactive agent. Lastly, Theraflex uses UVC without a photoactive agent. Psoralen-UVA-treated pathogen-reduced platelets are the only one of the three protocols that are approved by the FDA for both pathogen reduction of platelet concentrates and for the prevention of TA-GVHD. The ultraviolet light manufacturing

procedure causes damage to the DNA in the donor lymphocytes, thus eliminating the risk of TA-GVHD and the need to X-ray or gamma-irradiate pathogen-reduced platelets (see Chapter 42).

### Alternatives to platelet transfusion

For severe platelet refractoriness, or for patients unwilling to undergo platelet transfusion, several medical therapies may be beneficial during bleeding episodes. A commonly prescribed drug, 1-deamino-8-D-arginine vasopressin (DDAVP or desmopressin), acts to stimulate the release of von Willebrand factor from endothelial cells, which can enhance platelet activity even at very low platelet counts.<sup>69</sup> DDAVP is also of proven benefit for platelet dysfunction and bleeding associated with uremia.<sup>70</sup> Antifibrinolytic therapies have also been employed as an adjunct to platelet transfusions for the bleeding patient. Medications such as aminocaproic acid and tranexamic acid have been successfully used to reduce hemorrhage and allogeneic transfusion requirements in the bleeding patient.<sup>71,72</sup>

Chemical and cytokine-based stimulation of the marrow to endogenously increase platelet production has also been attempted. Agents such as thrombopoietin (TPO) and megakaryocyte growth factors have been synthesized, but clinical trials with some of these drugs led to the development of neutralizing antibodies and thrombocytopenia in some recipients.<sup>73,74</sup> TPO and TPO-like growth factors are now used for some conditions such as immune thrombocytopenic purpura (ITP), and studies in oncology populations have been promising.<sup>75</sup> Several agents, such as romiplostim and eltrombopag, have been licensed by the US Food and Drug Administration (see Chapter 52). Interleukin-11 (IL11), a cytokine that drives megakaryocyte production and division, has also been approved for use in thrombocytopenic patients.<sup>73,74</sup>

Clinical studies looking at a lyophilized platelet-derived hemostatic agent, Thrombosomes, as an alternative to traditional platelets are currently ongoing. Unlike the short five-day storage life of traditional platelets, Thrombosomes can be stored for up to 24–36 months at room temperature. Studies have shown Thrombosomes are able to adhere to a collagen surface and contribute to clot formation and generate thrombin.<sup>76</sup> Further clinical trials are ongoing.

## Plasma and plasma-derived product transfusion

### Indications for plasma transfusion and product selection

The indications for transfusion of plasma and plasma-derived derivatives, such as cryoprecipitated antihemophilic factor (AHF), intravenous immune globulin (IVIG), and fibrinogen concentrate (RiaSTAP), are similar between oncology and other patient populations. For the majority of oncology patients, no additional concerns are involved with the selection of an ABO group for plasma so long as the unit is ABO compatible with the recipient. Cryoprecipitate contains significantly less plasma volume as compared to platelets and plasma. The risk of hemolysis from ABO-incompatible cryoprecipitate is very low; thus, blood banks routinely issue ABO-incompatible cryoprecipitate.<sup>77</sup> Rh compatibility between donor and recipient is not a consideration for infusion of plasma or cryoprecipitate. As mentioned in this chapter, however, for patients who have undergone allogeneic HSCT, the choice of ABO group can be complex and should be based upon consideration of major and minor mismatches. Table 41.2 summarizes guidelines for plasma

transfusion therapy in the peritransplant period. The guidelines for cryoprecipitated AHF are identical to those for plasma. Irradiation of these products is not required given that they are acellular.

### Alternatives to plasma transfusion

For some oncology patients, plasma transfusion may be contraindicated, may be ineffective, or may not provide rapid enough reversal of coagulopathic states. In these situations, there are several alternatives to plasma products, consisting of concentrated or recombinant coagulation factors. Recombinant factor VIIa (NovoSeven), a potent activator of the coagulation cascade, is one of the most commonly used agents for acute moderate to severe bleeding.<sup>78</sup> Successful use of factor VIIa has been reported to help control massive bleeding in a variety of oncology patients.<sup>79–81</sup> In addition, there is a role for use of factor VIIa as a bypass agent for those oncology patients who acquire inhibitors to circulating coagulation factors, mainly factor VIII.<sup>82</sup> However, factor VIIa failures in bleeding oncology patients have been reported for gastrointestinal bleeding and alveolar hemorrhage.<sup>83,84</sup>

Few adequate clinical trials have been conducted to determine the safety and efficacy of factor VIIa in oncology populations; therefore, it is difficult to recommend the broad application of this therapy for bleeding oncology patients. Furthermore, appropriate dosing regimens are imprecise and mostly based on data gathered in trials performed in other critically ill patient populations. Factor VIIa also carries a number of serious risks, including severe or even fatal arterial and venous thromboembolism.<sup>85</sup> Therefore, factor VIIa may be considered as an alternative to plasma infusion but should be used only after other interventions have failed.

### Intravenous immunoglobulin

IVIG is used to provide passive immunity in highly immunosuppressed individuals and has also been used as an immunomodulatory therapy for patients with conditions such as immune thrombocytopenic purpura (ITP).<sup>86,87</sup> For recipients of HPC products, IVIG has been associated with improved immune defense against pathogens such as CMV and has helped to decrease the complications of acute GVHD.<sup>88,89</sup>

IVIG infusion is usually tolerated without significant adverse events in oncology patients. The common side effects include myalgia, flushing, headache, fever, and fatigue, which are typically mild and transient.<sup>90</sup> Current IVIG products have not transmitted hepatitis B, hepatitis C, or human immunodeficiency virus, but there are rare case reports of transmission of parvovirus B19, a serious pathogen for oncology patients;<sup>91</sup> however, plasma is screened for this virus prior to being pooled.

## Granulocyte transfusion

### Indications

Although rarely used today, granulocyte infusions have been used in oncology patients with severe neutropenia to treat life-threatening, antibiotic-refractory infections such as mucormycosis. The decision to initiate granulocyte transfusion usually represents failure of other forms of therapy. Only patients with a chance at sustainable marrow recovery after resolution of the underlying infection are candidates for granulocyte products.<sup>92</sup> It has been shown that humans should produce approximately  $2-3 \times 10^{11}$  polymorphonuclear cells daily to clear significant bacterial or fungal infections. For oncology patients whose marrow cannot support

this level of production, doses of  $1 \times 10^{11}$  granulocytes per square meter of body area have been attempted to support the immunologic response.<sup>93</sup>

### **Granulocyte donation and donor preparation**

The safety and efficacy of granulocyte transfusion using G-CSF stimulation in healthy donors has been evaluated in a number of trials. Some studies suggest that granulocyte infusions may be effective for the treatment of bacterial and fungal infections.<sup>94</sup> However, it has been hypothesized that improved outcomes may be seen with higher granulocyte doses. To obtain a larger number of granulocytes, the Safety and Effectiveness of Granulocyte Transfusion in Resolving Infection in People with Neutropenia (RING) study used G-CSF and dexamethasone to stimulate donors. Although this multicenter trial found that there was no difference in success rates between antibiotic and granulocyte therapies, the study was severely limited by a low accrual rate resulting in ~47% power to detect a difference.<sup>95</sup>

Healthy donors who qualify to donate granulocytes should be ABO-compatible with the intended recipient, and products must be crossmatched before infusion as granulocyte products may contain 6–12% red cells. Typically, donors receive 5–10 µg/kg G-CSF subcutaneously approximately 12 hours before leukapheresis. Granulocyte collections can be performed daily, over 4–5 days to collect multiple doses for neutropenic patients. Granulocyte donation is generally well tolerated with mild, short-lived side effects such as bone pain, headache, and fatigue as a result of the G-CSF administration and apheresis.<sup>92,96,97</sup>

### **Alloimmunization**

Alloimmunization from granulocyte transfusion can occur.<sup>98</sup> In addition, patients previously alloimmunized to HLA may demonstrate a reduced response to granulocyte infusion.<sup>99</sup> If granulocyte transfusion is necessary for these patients, antigen matching for HLA may be required. However, this is rarely performed given the low use of granulocyte transfusions overall.

### **Granulocyte storage, component modification, and infusion**

Granulocytes are stored for up to 24 hours from the time of collection at 20–24 °C without agitation.<sup>100</sup> The granulocyte product should be transfused as soon as possible, ideally within 6–8 hours of collection, given the limited lifespan of neutrophils. Prior to release from the blood bank, the granulocyte product is crossmatched as well as irradiated to prevent recipient TA-GVHD. Granulocytes should be infused through a 150–260-µm filter, but leukocyte reduction filters must never be used.<sup>101</sup> There are reports of patients developing pulmonary toxicity while simultaneously receiving amphotericin B and granulocyte infusions. Additional studies, however, did not confirm a relationship between the development of pulmonary toxicity due to interaction between amphotericin B and granulocyte transfusions.<sup>102</sup> In vitro studies have shown reduced neutrophil aggregation when liposomal formulations of amphotericin B are used; therefore, these formulations are preferred when simultaneously using granulocyte infusions.<sup>103</sup>

### **Adverse reactions to blood transfusion**

Oncology patients undergoing transfusion therapy are subject to the same set of adverse reactions as are seen in any patients receiving blood components. However, oncology patients are at increased

risk for many more types of adverse reactions. In addition, discerning between an adverse transfusion event and exacerbation of an underlying condition can be difficult.

Oncology patients are often immunosuppressed; therefore, they are at increased risk for TA-GVHD (discussed in Chapter 50) and many transfusion-transmitted infections. CMV is one of the most problematic transfusion-transmitted infections for oncology patients. The virus has a seroprevalence of 50–70% and has been found in the mononuclear cells of both seropositive and seronegative blood donors.<sup>104,105</sup> Although CMV infections are rarely significant in immunocompetent hosts, in immunosuppressed patients infection can lead to severe pathology such as CMV-related pneumonia, gastrointestinal inflammation, and delayed HSCT engraftment. Obtaining CMV-seronegative blood can be challenging given the high seroprevalence in the general population. In addition, even seronegative individuals can harbor infectious viral particles. Leukocyte reduction is also employed to prevent CMV transmission by reducing the number of transfused mononuclear cells potentially harboring the virus. Several studies have found that leukocyte reduction is as effective as the use of seronegative units; and most physicians consider leukoreduced units to be "CMV-safe."<sup>106,107</sup> However, the risk of CMV is not completely eliminated with these maneuvers; thus, while the use of donor screening and leukocyte reduction is beneficial and most often used clinically, oncology patients are still at some degree of risk for CMV exposure from blood transfusion. Use of pathogen reduced apheresis platelets, however, essentially eliminates the risk of CMV transmission by platelet transfusion.

### **Adverse effects of hematopoietic progenitor cell infusion**

The majority of adverse events associated with HPC infusion are associated with the dimethyl sulfoxide (DMSO) content of the progenitor product. DMSO is a chemical modifier used in a majority of cryopreservatives that allows for the controlled freezing and thawing of mononuclear cells without development of membrane lysis.<sup>108</sup> However, *in vivo*, DMSO is a toxic substance and has been linked to fever, nausea, vomiting, and chills during and immediately after HPC infusion. DMSO has also been linked to pulmonary and cardiovascular problems during HPC infusion, including dyspnea, hypotension, bradycardia, and arrhythmia.<sup>108</sup> Due to the amount of DMSO infused, small children and those patients receiving multiple HPC units are more susceptible to DMSO-related problems.<sup>108</sup>

Researchers have also evaluated whether HPC components other than DMSO can lead to infusion toxicity. Several studies have correlated adverse events to the numbers of granulocytes present in HPC products.<sup>109,110</sup> These studies found that even after DMSO depletion, over half of patients undergoing HPC infusion experienced an adverse event such as fever, rigors, or dyspnea. It is therefore possible that the dyspnea associated with HPC infusion is not entirely caused by DMSO, but that granulocytes may contribute through transfusion-related acute lung injury (TRALI)-like mechanisms. These studies argue that a reduction in granulocyte content of the final HPC product would lead to fewer reactions. However, this is technologically challenging to achieve as removal of granulocytes would also remove a percent of the HPCs.

Bacterial contamination of HPC products can occur during collection or processing of the cells.<sup>111</sup> Adequate field sterilization practices during stem collection and the processing of HPC products in sterile areas with air-controlled biosafety cabinets can reduce the risk of bacterial contamination.<sup>112</sup> However, due to the

significant handling of HPC products, bacterial contamination can be a frequent issue, especially during bone marrow collections.<sup>113</sup> Because of this risk, units are routinely cultured and, if bacterially contaminated, provided to patients in conjunction with prophylactic, broad-spectrum antibiotics. Interestingly, one study has demonstrated that, of 33 patients who received bacterially contaminated HPCs, only 6 developed evidence of bacteremia and none had any long-term complications.<sup>114</sup> Thus, bacterial contamination of an HPC product need not be an absolute barrier to infusion.

### **Chimeric antigen receptor (CAR) T-cell therapy**

CAR T-cells contain CAR fusion protein genetically engineered into autologous T cells. After modification to produce cytotoxic immune T cells targeted to tumor-specific antigens, the CAR T-cells are reinfused to the patient. The first use of CAR T-cell therapy was in 2017 for the treatment of acute lymphoblastic lymphoma. Since then, the use has expanded to include other lymphoid malignancies, typically for refractory or relapsed disease. Patients can experience severe adverse reactions to CAR T-cell infusion, most notably a cytokine release syndrome (CRS).<sup>115</sup> Symptoms of CRS include fever, hypoxia, and hemodynamic instability. Studies have shown that the infusion dose, tumor burden, and proliferation of CAR-T cell *in vivo* may correlate with the severity of CRS.<sup>116</sup> The exact mechanism of CRS is still under investigation; however, it is believed to result from cytokine release during the interaction between the immune effector cells and tumor cells. Several cytokines are released during CRS including IL-6, IL-10, TNF, among others. Tocilizumab, an IL-6 receptor blocker, and siltuximab, a chimeric anti-IL-6 monoclonal antibody, are used for the treatment of CRS after CAR T-cell therapy.

### **Summary**

Transfusion support is a major component to the therapy for patients with oncologic disorders. However, given their typically increased transfusion needs and immunosuppressed state, they are often at increased risk for adverse events due to transfusion. Compared to other patient populations, oncology patients are at

increased risk for TA-GVHD, certain transfusion-transmitted diseases, alloimmunization to cellular antigens, as well as disease states altered by immunomodulations. In addition, HPC transplant patients present unique challenges to transfusion services as they require specific assessment for potential ABO incompatibility. Careful selection of blood components and component modification is therefore necessary to provide appropriate therapy to these patients. Significant advances that have been made in transfusion therapy, including more sensitive donor testing, blood component alternatives, and pathogen reduction technologies, continue to improve the safety of transfusion for oncology patients.

## Introduction

The field of transfusion medicine has made significant improvements regarding blood safety during the last 40 years with the development of methods to screen and identify donors with risk factors for transfusion-transmitted infections (TTIs). These advances include excluding donors with histories of travel to regions endemic for some blood-borne pathogens, requiring blood testing using serologic and nucleic acid assays for specific infectious agents (e.g., HIV, HTLV-I, and Hepatitis), and implementing routine bacterial culture testing of platelet concentrates.<sup>1–3</sup> Despite the success of these efforts, these measures are still just “reactive” in that they are implemented after a new blood-transmissible pathogen is identified. Unfortunately, the pathogen may have already threatened the safety of both the donor and the transfusion recipient populations by the time the infectious agent has been isolated and identified.<sup>2,3</sup> During the HIV crisis, blood transfusions resulted in the transmission of HIV to more than 12,000 recipients and over half of the 16,000 hemophiliacs in the United States in the 1980s.<sup>1</sup> This illustrates how a reactive approach to reducing TTIs may not work quickly enough to prevent the transmission of a novel blood-borne pathogen and thus allow patients to be harmed before effective preventive steps can be implemented.

In contrast, a proactive approach can have a substantive and beneficial impact on donor availability and recipient safety by adding a pathogen-reducing manufacturing step to donated blood components prior to transfusion. The pathogen reduction agent should substantially mitigate the infectious risk caused by a known or unknown pathogen by blocking the pathogen’s blood-borne transmission—even before the new offending agent is identified. Examples of situations in which a reactive approach is not an effective deterrent to blood-borne transmission include scenarios dealing with the following cases:

- Endemic diseases such as CMV, EBV, Chikungunya, Malaria, and Dengue, in which infected donors may escape detection because donor blood screening tests for these pathogens are not required or not routinely performed.
- Pathogens with limited geographic distribution—such as Babesia, Dengue, or Chikungunya—for which preventative measures are not universally in place. This is a critical point since donors today

are much more mobile. Asymptomatic but infected individuals who live in an endemic area may travel and donate in a nonendemic area, and thus their infection may escape detection despite the health history questionnaire performed by donor centers.

- Seasonal pathogens such as West Nile virus or Babesia.

The myriad of possible infectious agents that can be missed by a reactive donor screening and testing approach has motivated the development of a fundamentally different “proactive plan” involving pathogen reduction (PR) technology. This approach has great potential value for improving the safety of the blood supply.<sup>2,3</sup> Across all cellular and plasma-based blood components, PR technology is becoming the central approach for developing a proactive policy for controlling and hopefully eradicating transfusion-transmitted diseases. PR technology utilizes a variety of reagents and techniques to either inactivate or reduce potential pathogens present in blood products with minimal adverse effects on the quality and efficacy of the therapeutic blood component.

## Overview of pathogen reduction technologies

Pathogen reduction technologies encompass techniques and reagents used to inactivate or reduce the infectious potential of pathogens that might be found not only in cellular or plasma-based blood components but in blood derivatives as well. The terms “pathogen inactivation” and “pathogen reduction” are often used interchangeably. Colloquially, both terms refer to decreasing or inactivating the amount of an infectious pathogen in a blood component.<sup>4</sup> We favor the term pathogen reduction and use it exclusively in this chapter because “inactivation” may inadvertently and inaccurately imply complete eradication of the pathogen.

PR technologies fall into two broad categories: (1) methods that target and damage DNA or RNA to prevent microorganisms (e.g., bacteria or viruses) or cells (e.g., lymphocytes) from replicating, and (2) methods that damage primarily microbial lipids. Methods that target and modify single-stranded/double-stranded DNA or RNA reduce the risk of infectious disease transmission in blood components by preventing nucleic acid replication and thus the reproduction of the microorganisms.<sup>5</sup> It

A summary of the major categories of pathogen reduction technology and the applicable blood components, the mechanism of action for inactivating pathogens, and the current regulatory status for each technology.<sup>3</sup>  
ROS: reactive oxygen species.

should be noted that the doses of gamma radiation used to prevent transfusion-associated graft-versus-host disease (TA-GVHD) do not inactivate microbes. Because none of the standard blood components (i.e., red cells, platelets, or plasma) require nucleic acid replication to provide a therapeutic in vivo effect, this mechanism of PR does not significantly interfere with the clinical effectiveness of the blood component. Since all pathogens except prions require nucleic acid replication for reproduction and for infection, these methods are particularly effective for broadly reducing the risk of infectious disease transmission in blood components. Importantly, PR technologies that utilize reactions with nucleic acids also effectively prevent lymphocytes from replicating and thus should markedly restrict the risk of TA-GVHD without need for gamma or X ray irradiation. The PR technologies that fall in this category are amotosalen/UV-A, riboflavin/UV, amustaline/glutathione, methylene blue/visible light, and UV-C alone (Table 42.1).

Chemical treatment methods primarily disrupt lipid-enveloped viruses and also the lipid bilayers of bacteria. The only US Food and Drug Administration (FDA) approved technology that utilizes this technique is a solvent/detergent (S/D) method using tri-*n*-butyl phosphate and octoxynol (Triton X-100, a nonionic surfactant). Because this technique renders most types of cells nonviable by disrupting their plasma membranes, this approach is limited to noncellular blood components such as fresh frozen plasma and blood derivatives such as IVIG and clotting factor concentrates. Pathogen reduction techniques like S/D treatment are most effective for inactivating lipid-enveloped viruses and to a lesser degree disrupting bacteria and fungi. However, S/D treatment is not effective against nonlipid-enveloped viruses or spores.<sup>6,7</sup>

As of writing this chapter, there are four pathogen-reduced blood components approved by the US FDA for human use: (1) single donor platelets, (2) fresh-frozen plasma, (3) cryoprecipitate, and (4) pooled S/D plasma. The first three components are manufactured using amotosalen/UV-A PR technology. Platelets and plasma prepared with riboflavin technology and platelets treated with UV-C technology are only approved for use outside the United States. In this chapter, we review the PR technologies currently under development or in use for the various blood components and derivatives. We discuss their mechanisms of action, efficacy profile against various pathogens, published

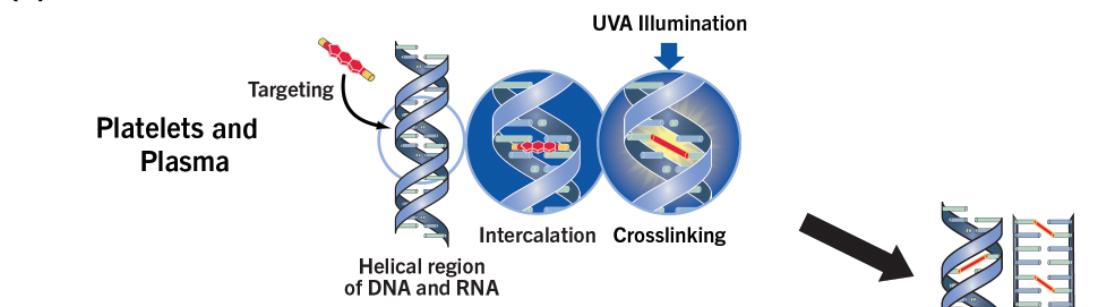

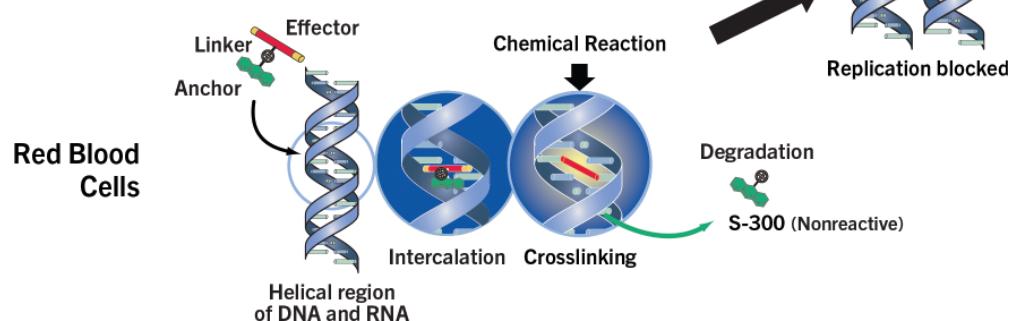

in vitro and in vivo studies, reported immunological effects, product safety, and toxicology.

## Pathogen reduction technologies—mechanisms of action

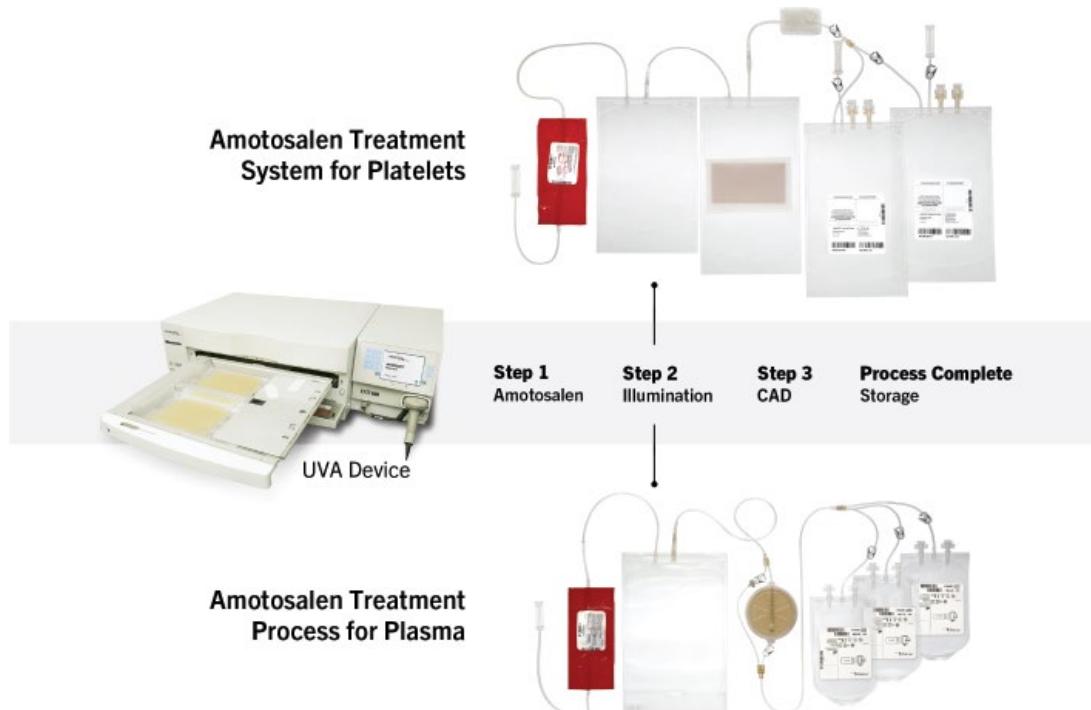

### Amotosalen/UV-A

For the amotosalen/UV-A methodology, a synthetic psoralen compound called amotosalen (S-59, Cerus Corp., Concord, CA) is added to platelets or plasma in the component bag and mixed together by agitation. The amotosalen-treated platelet or plasma component is then exposed to a UV-A light source through a process called photoillumination. This maneuver causes double-stranded or single-stranded nucleic acid damage by the formation of monoadducts and crosslinking of base pairs with the psoralen. Amotosalen belongs to a class of molecules called psoralens, which are a group of naturally occurring chemicals found in foods and plants such as figs, grapefruit, and celery.<sup>8</sup> As mentioned before, amotosalen intercalates into helical regions of nucleic acids, including both single- and double-stranded DNA and RNA. Activation by UV-A light (320–400 nm) causes covalent monoadduct crosslinking (Figure 42.1A). These crosslinks prevent the separation of chromosomal nucleic acids and tertiary RNA structures and thus effectively block nucleic acid replication (Table 42.1). After amotosalen is added to a blood component and photoactivated by UV-A light, a compound adsorption device (CAD) is used to reduce the concentration of residual photoproducts (Figure 42.2). This manufacturing technique is currently approved in Europe (CE Marked) and in the United States by the FDA for single donor platelets, fresh-frozen plasma, and cryoprecipitate.

Amotosalen/UV-A cannot be used to effectively pathogen reduce units of whole blood or RBCs because red blood cells absorb UV-A light, blocking the photoactivation of psoralens and lowering the efficiency of the pathogen reduction process.<sup>9</sup> Amotosalen/UV-A technology is effective against lipid-enveloped viruses, Gram-positive and Gram-negative bacteria, fungi, spirochetes, parasites, and many nonenveloped viruses (e.g., hepatitis A, hepatitis E, parvovirus B19, and poliovirus), bacterial spores (e.g., *Bacillus cereus*), and prions show resistance to amotosalen/UV-A inactivation.<sup>10,11</sup> Nucleic acid crosslinking by amotosalen/UV-A also affects leukocytes and thus effectively reduces the risk of TA-GVHD.<sup>5</sup>

**(A) Amotosalen (S-59)****(B) Amustaline (S-303)**

**Figure 42.1** (A) The intercalation of amotosalen (S-59) into the nucleic acid helical region is seen with the crosslinking occurring following UV-A illumination. (B) UV-A does not effectively pathogen reduce red blood cells. Amustaline (S-303) intercalates and crosslinks without need for UV light. Importantly, the amustaline intercalation occurs more quickly than its degradation. Thus, amustaline can efficiently inactivate pathogens in red cells. (Figure is courtesy of the Cerus Corporation and is used with permission.)

**Figure 42.2** The illumination system used for amotosalen. For platelets, in Step 3, a small bag containing a compound absorptive device (CAD) is used to remove residual photoproducts. For the platelet process, the CAD is incubated with the platelets for 16 hours to ensure adequate photoproduct removal. For plasma, the compound absorption material is contained in a device placed in-line with the fluid path. Since there are no cells in plasma, the adsorption process occurs much more quickly in plasma than in platelets. Amotosalen is light sensitive and is stored in a dark colored bag to protect potency prior to addition to the blood component. Courtesy of the Cerus Corporation, used with permission.

### Riboflavin/UV

Another pathogen reduction approach utilizes the addition of riboflavin (vitamin B2) to the blood component following collection, with subsequent exposure to UV light (290–320 nm). Riboflavin is a photosensitive compound that intercalates with DNA or RNA, and the exposure to UV light causes riboflavin photolysis and induces guanine oxidation, resulting in single-strand breaks (Figure 42.3A).<sup>3,12–14</sup> The mechanism of action is thought to involve the generation of reactive oxygen species (ROS) as well.<sup>12</sup> This process likely causes extensive damage to guanine bases that overwhelms DNA repair and prevents nucleic acid replication (Table 42.1). Riboflavin acts by selectively binding to nucleic acids and lipids but not to proteins. The breakdown products formed after UV light exposure are naturally occurring and are present at low concentrations (Figure 42.3B and 42.3C). Riboflavin breakdown products do not need to be removed from the blood component after photoactivation.<sup>15</sup> Riboflavin/UV shows efficacy against Gram-positive and Gram-negative bacteria, many lipid-enveloped viruses, spirochetes, and parasites, and a number of nonenveloped viruses. Like amotosalen/UV-A, riboflavin/UV has shown to have less efficacy against nonenveloped viruses (e.g., hepatitis A) and spore-forming bacteria, and no efficacy against prions. This technology has been approved for RBCs, plasma, platelets, and whole blood outside the United States (e.g., CE marked in Europe) but has not been approved for use with any blood component in the United States. Riboflavin causes enough damage to DNA in leukocytes to effectively reduce the risk of TA-GVHD.

### Amustaline/glutathione

Amustaline/glutathione technology is currently in development with several Phase-III randomized clinical trials being conducted for red blood cells. Since UV-A light is not effective for ensuring adequate pathogen reduction of RBCs, a different technology suitable for red cell products was developed. Amustaline (S-303, Cerus Corp., Concord, CA) is a small molecule that contains an alkylating component that crosslinks nucleic acids without the need for photoactivation. This pH-sensitive system utilizes amustaline and glutathione (Figure 42.1B).

Amustaline is composed of three distinct moieties that form the basis for its mechanism of action as a pathogen-reduction agent: (1) a nucleic acid acridine anchor that noncovalently binds to the nucleic acids of contaminating pathogens and white blood cells, (2) a bifunctional alkylator group that crosslinks nucleic acids, and (3) a cleavable linker that spontaneously hydrolyzes in blood (Figures 42.1B and 42.4). Amustaline has a half-life of about 25 minutes and decomposes through spontaneous hydrolysis. The hydrolytic reaction is much slower than is the alkylation crosslinking reaction, allowing amustaline to inactivate nucleic acids before being degraded.<sup>16</sup> The main product resulting from decomposition of amustaline is called S-300, and this product has a much lower affinity for nucleic acids than amustaline. Amustaline can also react with molecules such as plasma proteins or RBC membrane proteins. To avoid these unwanted chemical reactions, glutathione is added as a quenching agent to prevent further reactivity.<sup>9</sup> Furthermore, although amustaline crosses cell and viral membranes, glutathione remains in the extracellular compartment and thus does not reduce

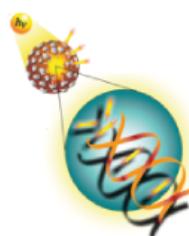

**(A) The Riboflavin/UV system inactivates pathogens by altering their nucleic acids in two primary ways**

**UV light only: reversible inactivation**

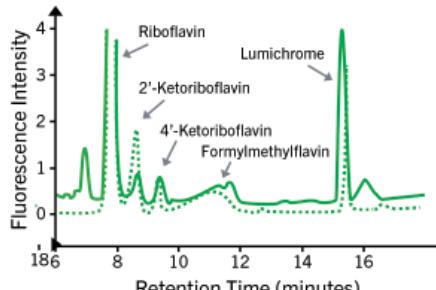

- UV light alone breaks chemical bonds in nucleic acids

**UV light + riboflavin: irreversible inactivation**

- Riboflavin molecules form complexes with nucleic acids
- UV light from the illuminator activates the riboflavin molecule in the complex
- Photoactivated riboflavin induces alterations to nucleic acids, making pathogens unable to replicate

**(B)**

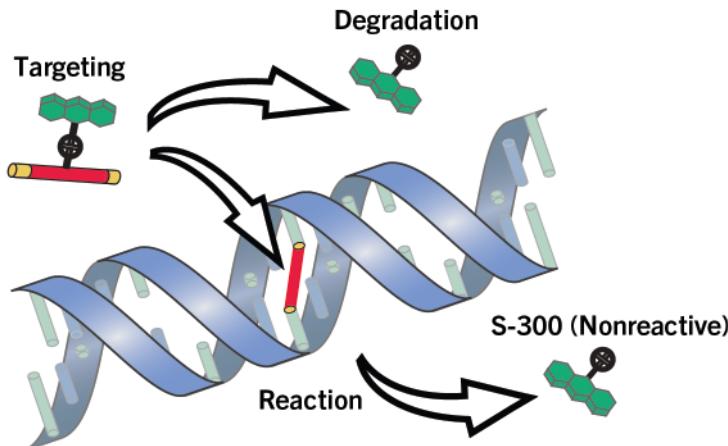

**(C)**

**Figure 42.3** (A) Two mechanisms by which riboflavin/UV inactivates nucleic acids. (B) Riboflavin-related compounds before (solid line) and after (dotted line) exposure to UV light. There is no significant change in these naturally occurring compounds. (C) An example of a riboflavin illuminator. (Figures are courtesy of the Terumo Corporation and are used with permission or are already in the public domain.)

## Amustaline (S-303) Reaction Mechanism

**Figure 42.4** A close view of the mechanism of action of amustaline, showing degradation of the anchor and effector components. The photoproduct S-300 is nonreactive. (Figure is courtesy of the Cerus Corporation and is used with permission.)

the ability of amustaline to crosslink nucleic acids. Amustaline/glutathione has been shown to be effective against a large range of pathogens including Gram-positive and Gram-negative bacteria, many nonenveloped and enveloped viruses, and certain parasites.<sup>17–22</sup> It is also efficient in inhibiting lymphocyte DNA replication and thus effectively prevents TA-GVHD.<sup>23</sup>

### Ultraviolet C Light

Ultraviolet C light technology uses UV-C light (100–280 nm) alone as the pathogen reducing agent to damage DNA without any need for additional compounds. Currently, this technique is only approved in Europe (CE marked) for platelets and not approved for any product in the United States. UV-C light causes the formation of cyclobutene pyrimidine and pyrimidine-pyrimidone dimers, preventing DNA duplication and thus cell replication of contaminating pathogens (Table 42.1).<sup>24,25</sup> The mechanism of action also involves generation of ROS. An ultraviolet C (UV-C) dose of 0.2–0.4 J/cm<sup>2</sup> has been reported to inactivate bacteria and viruses while maintaining cell quality.<sup>24</sup>

UV-C treatment has been shown to be effective against nonspore forming bacteria and nonlipid-enveloped viruses (e.g., hepatitis A and porcine parvovirus, a model for parvovirus B19) with less efficacy against spores and lipid-enveloped viruses, including retroviruses such as HIV.<sup>24,26–28</sup> Evidence suggests that UV-C inactivates T cell replication as efficiently as gamma irradiation and thus can be used to prevent TA-GVHD.<sup>29</sup>

### Methylene blue/visible light

Methylene blue (MB) is a phenothiazinium dye that is used to treat many different conditions—including nitrate poisoning, malaria, and methemoglobinemia—and it also has been utilized as a PR agent.<sup>30</sup> MB causes damage to DNA and RNA in the presence of visible light (390–700 nm)<sup>31,32</sup> by intercalating into DNA or binding to the DNA helix depending on the concentration and ionic strength of Mg<sup>2+</sup> in the blood component (Table 42.1).<sup>33</sup> Exposure to light (with peak absorption at 620–670 nm) causes photo-oxidative reactions to occur and generate ROS, which causes damage to guanine residues on nucleic acids.<sup>34,35</sup> After photoactivation, any remaining MB is removed by a filtration process.<sup>36</sup> MB treatment inactivates enveloped

viruses but has limited activity against bacteria and nonenveloped viruses<sup>30,33</sup> MB does not readily pass through cell membranes and hence is not effective against intracellular viruses.<sup>37</sup> In addition, MB is not used for pathogen reduction of cellular products because it does not cross cell membranes, and it thus cannot affect nucleic acids of bacteria, fungi, and parasites. MB does not inactivate leukocytes and does not lower the risk of TA-GVHD.<sup>30</sup> MB plasma is only approved in Europe and not in the United States (Table 42.1).

### Solvent/detergent

S/D treatment is currently used in the production of pathogen-reduced plasma. The production of S/D plasma involves pooling a large number of plasma units together (up to 1500 ABO-identical donors) and then treating the pooled plasma. The treatment entails filtration with 1-μm filters and then processing with 1% tri(n-butyl) phosphate and 1% octoxynol (Triton X-100) for 60–90 minutes. These reagents are then removed with various extraction steps. The solvent/detergent treatment dissolves the membrane of lipid-enveloped viruses (Table 42.1). Due to this mechanism, nonenveloped viruses are not inactivated.<sup>7,30</sup> The pooling step in the manufacturing process is thought to reduce the risk of infection transmission simply due to the fact that any present pathogens are diluted. This technology cannot be used for cellular products because the treatment would destroy red cells and platelets. As expected from its mechanism of action, S/D treatment effectively disrupts bacteria, fungi, and lipid-enveloped viruses but is not effective against spores or nonlipid-enveloped viruses.<sup>6,7</sup> The only currently approved formulation of S/D-treated plasma is fresh-frozen plasma.

### Efficacy of pathogen reduction

The primary objective of PR technology is to inactivate infectious agents that could be contaminating blood components. Large amounts of data have accumulated showing the inactivation capacity of the major PR technologies as measured by log<sub>10</sub> reduction in pathogens (Table 42.2). The technologies have different effects on different pathogens and not all pathogens are completely eliminated—hence the term pathogen *reduction* and not pathogen *elimination*. Maintaining a balance between pathogen

¶ Evaluated in plasma, not platelets in PAS

§ Evaluated in whole blood

^ Evaluated in plasma

\* Unclear if these values are from cell-free or cell-associated models; “—” indicates no data available.

(Note: Refs. [173–183] refer to values only listed in this table.)

Inactivation of pathogens by four pathogen reduction technologies as measured by log<sub>10</sub> reduction. Values shown as greater than (>) or greater than or equal to (≥) indicate reduction levels below the limit of detection of the assay, and the actual levels of reduction could be higher for these organisms than indicated. Some of the data presented here were performed on analogous pathogens used as models for the listed pathogens. These details are available in the cited references in the table. Amotosalen/UV-A reduction numbers are assessments in platelets suspended in 65% platelet additive solution-3 (PAS-3)/35% plasma unless otherwise noted. Riboflavin reduction numbers shown are assessments in platelets unless otherwise noted. Riboflavin log<sub>10</sub> reduction results from standard in vitro assays for infectivity (TCID50) were calculated as per Appendix II of European Agency for the Evaluation of Medicinal Products, Committee for Proprietary Medicinal Products—Note for Guidance on Virus Validation Studies. UV-C and methylene blue reduction numbers were assessed in plasma. Amustaline/glutathione reduction numbers were assessed in RBCs. Values indicated with an asterisk (\*) for riboflavin technology were provided by Terumo Corporation.

reduction and preserving blood cell viability limits the ability of PR technologies to fully eliminate pathogens from blood components, and thus PR treatment is unlikely to always sterilize the transfusion product.

Several approaches have been used to determine the inactivation capacity of pathogen reduction technologies. Studies to establish pathogen reduction capabilities have generally utilized *in vitro* or *in vivo* animal models in addition to human trials. One clinical trial demonstrated a reduction in the transmission of malaria from use of riboflavin-treated whole blood in a patient population living in an endemic malarial region.<sup>38</sup> Another study, as part of a national hemovigilance program in several European countries, has reported the monitoring of the decrease in septic transfusion reactions associated with use of amotosalen/UV-A-treated platelets.<sup>39</sup> The results of pathogen inactivation studies are usually given as the number of organisms killed *in vitro* and reported as log<sub>10</sub> reduction values. These numbers are often used to predict *in vivo* effectiveness and to compare technologies. However, this approach tends to be an oversimplification<sup>40</sup> because there are several factors in addition to the virus level which affect the likelihood of infection transmission (Table 42.3).<sup>41</sup> Many results are reported as genome equivalents,<sup>40</sup> but the infectivity of a genome is not known with certainty because the pathogen reduction technology might alter or damage the nucleic acid sequences or even cut out parts of the genome. Thus, segments of a genome could be detected by nucleic amplification testing but not be infectious, and the level of virus detected would not necessarily relate to infectivity.<sup>40</sup> Also, the frequency of replication of competent viruses differs based on the type of virus and stage of infection in the donor.<sup>42</sup> For instance, blood components with the same viral levels may or may not transmit infection. Furthermore, components from the same contaminated unit of whole blood may or may not transmit infection, which is in part related to the lower volume of the derived components and the resulting lower doses of the virus.

**Table 42.3** Factors that can influence the infectivity of contaminated blood components.

<b>Viral factors</b>
Viral load
Viral genotype/clade
Genome mutations
Ratio of detectable nucleic acid equivalents to infectious particles
Stage of viral infection (acute vs. chronic)
Binding of virus to endogenous neutralizing antibodies
Diminishing viral replicative capacity with component storage
<b>Donor factors</b>
Stage of infection
Presence of antibody to the agent
<b>Transfusion factors</b>
Transfusion of other components with neutralizing antibody
Blood component being transfused (see below)
<b>Product factors</b>
Specific component (e.g., RBCs or FFP)
Storage duration of RBCs
<b>Patient-related factors</b>
Existing immunity through natural infection or vaccination (HBV)
Lack of viral receptors (i.e., resistance to infection)
Degree of immunosuppression
Body weight and/or blood volume

All of these factors must be considered when evaluating the efficacy of pathogen reduction since *in vitro* log reduction numbers may not necessarily correlate directly with clinical benefit. Adapted from Kleinman *et al.* (2009).<sup>41</sup>

The pathogen inactivation data in Table 42.2 are useful for providing general information, but for reasons discussed above and in Table 42.3, they do not serve to provide for direct comparisons among the various pathogen reduction technologies. This point is illustrated by the prevention of malaria transmission from donors with higher levels of circulating parasites than was to be expected based on riboflavin *in vitro* data.<sup>38,43</sup>

Bacteria provide a unique threat via transfusion as small numbers of organisms are able to proliferate in the product bag after collection. Furthermore, if any viable bacteria are left after PR, they can quickly grow back to life-threatening concentrations. For this reason, McDonald *et al.* have emphasized the need to assess PR effectiveness for bacteria in terms of sterility at outdate (e.g., for platelets, this is either after five or seven days of storage).<sup>44</sup> Assessment of nine different bacterial strains demonstrated dramatic differences among PR technologies, with amotosalen/UV-A and UV-C showing the highest degrees of efficacy.

## Pathogen reduction for noncellular blood components

Pathogen-reduced plasma products have been available in Europe since the 1990s. Earlier pathogen-reduced plasma components included both methylene blue and solvent/detergent-treated products.<sup>45</sup> Newer techniques using UV photoactivation include amotosalen/UV-A plasma approved for use in the United States by the FDA and riboflavin/UV-treated plasma, which is CE marked in Europe. There are reported changes in levels of various coagulation factors after PR treatment. These changes vary among the different technologies used and among the published reports. Overall, however, the PR-treated plasma components have been shown to be hemostatically effective for use in clinical practice.<sup>46</sup>

### Fresh-frozen plasma

#### Amotosalen/UV-A

Amotosalen/UV-A-treated plasma has been shown to have lower levels of certain coagulation factors compared to nonpathogen-reduced FFP. The treated plasma showed lower levels of factor V, factor VIII, protein S, and protein C with mild increases in coagulation times.<sup>47,48</sup> However, there has been no evidence to suggest diminished clinical efficacy.<sup>47</sup> Amotosalen/UV-A-treated plasma has fibrinogen levels within the reference range for conventional FFP. One study has shown that fibrin clots formed in PR plasma are denser and made up of thinner fibers, but these findings have unclear clinical implications.<sup>49,50</sup> Although amotosalen/UV-A-treated plasma is FDA-approved for use in the United States, it is not being regularly manufactured and is not in regular use in US transfusion services as of writing this chapter. It is being evaluated by researchers such as for a postmarket study of plasma transfusion for severe burns by the Coalition for National Trauma Research (NCT04681638). Amotosalen/UV-A plasma is also CE marked and is in routine use in European countries.

#### Riboflavin/UV

Plasma treated with riboflavin for pathogen reduction has reduced levels of some plasma coagulation factors compared with those levels of untreated plasma.<sup>48,50,51,52</sup> Riboflavin-treated plasma is as effective as conventional plasma and provides improvement in INRs, but slightly more riboflavin-treated plasma was required for a clinical effect.<sup>53</sup> Riboflavin-treated plasma had similar efficacy compared to conventional plasma in patients with an acquired coagulopathy.<sup>53</sup> Riboflavin plasma is CE marked and is used only outside of the United States.

### UV-C

Currently, no plasma products treated with UV-C light are approved for use in any country. UV-C light is known to damage proteins,<sup>26</sup> and although a proof of principle has been demonstrated for plasma, UV-C-treated plasma has been reported to have lower activities of some coagulation factors.<sup>54</sup> In addition, proteins in plasma can “quench” the ability of UV-C to reduce pathogens and thus pose challenges to applying this technology to plasma components.

### Methylene blue

MB-treated plasma is currently available in Europe but is not approved in the United States. Plasma treated with MB has lower levels of fibrinogen, protein S, and factors V, VIII, and XI. Further, the thrombin-generating capacity of MB plasma has been shown to be reduced.<sup>45,56</sup> There is a lack of large, randomized controlled trials evaluating the clinical efficacy of MB-treated plasma, and there are conflicting results from prospective and observational studies of MB-treated plasma.<sup>57</sup> Studies have shown no significant differences in time of in vivo bleeding, and blood loss between MB-treated and S/D-treated plasma in patients undergoing cardiac surgery,<sup>57,58</sup> but others have noted increased volumes of MB-treated plasma used in liver transplant patients.<sup>59</sup> In addition, one retrospective study has indicated that MB-treated plasma may be less effective in treating thrombotic thrombocytopenic purpura compared to fresh-frozen plasma.<sup>60</sup>

Although MB-treated plasma is approved in Europe, concerns due to a reportedly higher risk of severe allergic reactions to MB-treated plasma<sup>61</sup> have resulted in discontinued use in France.<sup>37</sup> Other European countries, however, have not observed increases in allergic reactions,<sup>57</sup> and one prospective, multicenter, nonrandomized study has shown low rate of serious adverse reactions of 0.5 per 10,000 MB-treated plasma units.<sup>37</sup>

### Solvent/detergent

Various S/D-treated plasma products have been available in the market, but currently the only S/D plasma product approved by the FDA for use in the United States is Octaplas (Octapharma, Hoboken, NJ), which is available in all ABO types. In Europe, a “universal” S/D plasma product is available.<sup>62,63</sup> Earlier formulations of S/D-treated plasma were associated with adverse events such as thromboembolic complications and were withdrawn from the market.<sup>7</sup> Current S/D plasma products have not been reported to have these complications.<sup>64</sup> Available S/D plasma products today have coagulation factor levels similar to those of FFP with the exception of lower protein S levels, but the clinical significance of these findings have not been fully assessed.<sup>64–66</sup>

### Cryoprecipitate

Cryoprecipitate is capable of transmitting viruses as well as being a source of bacterial contamination.<sup>67</sup> Cryoprecipitate is often transfused as a pooled component—usually a pool of five whole blood units. Pooling components increases the risk of TTIs proportional to the number of units in the pool. Because cryoprecipitate is stored at room temperature after thawing, conventional cryoprecipitate has a shelf-life of six hours for single units and for products pooled with an FDA-cleared sterile connecting device. The shelf life is four hours for cryoprecipitate pooled without a sterile connecting device. In contrast, for cryoprecipitate derived from plasma treated with amotosalen/UV-A (known as pathogen-reduced cryoprecipitated fibrinogen complex), the FDA has permitted an extension of

the post-thaw shelf life to five days at room temperature.<sup>68</sup> Cryoprecipitate derived from amotosalen-treated plasma is reported to have lower levels of fibrinogen and factor VIII but comparable levels of vWF compared to conventional cryoprecipitate.<sup>69</sup> Amotosalen/UV-A cryoprecipitate is available for use in the United States. For cryoprecipitate derived from riboflavin-treated plasma, decreased levels of factor VIII, von Willebrand factor, and fibrinogen have been reported compared with conventional cryoprecipitate, but these levels exceed the minimal requirements of the Council of Europe.<sup>70</sup> S/D cryoprecipitate made from S/D-treated plasma has been reported to have acceptable levels of factor VIII, vWF, and fibrinogen.<sup>71</sup> Cryoprecipitate derived from MB-treated plasma has also been studied and has been shown to have higher levels of factor VIII, lower levels of factor XIII, and similar levels of fibrinogen activity compared to cryoprecipitate derived from amotosalen-treated plasma.<sup>72</sup>

### Plasma derivatives and factor concentrates

Derivatives manufactured from pools of plasma from large numbers of human donors must be processed to maximize product safety. Pathogen reduction technologies have been used to reduce the risk of infectious disease transmission. Intravenous immunoglobulins (IVIG) are produced from fractionated donor plasma.<sup>73</sup> Methods for reducing pathogenic risk in IVIG products include the fractionation process itself, pasteurization, nanofiltration, and solvent/detergent treatment.<sup>73,74</sup> Factor concentrates are mostly recombinant and do not present a risk of blood-borne pathogen contamination. However, coagulation factor concentrates that are manufactured from pooled human plasma are pathogen-reduced with S/D treatment. Albumin is derived from large pools of human plasma, but the manufacturing steps use processes such as fractionation and pasteurization and do not utilize pathogen reduction technology.<sup>75</sup>

### In vitro and in vivo quality of pathogen-reduced cellular components

#### In vitro platelet function tests—background

In vitro tests of platelet function fall into two categories: (1) indirect tests such as platelet count, metabolism, structure, presence of receptors, or activation markers and (2) direct in vitro measurements of adhesive, aggregating, and procoagulant activities. These in vitro tests have been used to assess platelets that have been pathogen reduced. We provide a brief discussion about these assays and some considerations that need to be made when assessing the function of PR platelets.

Parameters such as platelet counts, metabolic functions such as glucose, pH, and lactic acid are the easiest to measure, and all these parameters are routinely studied to evaluate the quality of platelet concentrates. Glucose consumption by cells and importantly by any contaminating bacteria generate a high level of lactic acid, which reduces the pH of the unit of platelets and contributes to platelet damage. These cellular activities reduce the recovery and survival of radiolabeled platelets in healthy subjects. However, good platelet function can be maintained even with glucose levels of zero, so the absence of glucose does not necessarily imply poor platelet function.

Platelets have a discoid shape which affects light scattering and causes a well-known “swirling effect.” During storage, platelets progressively become activated and undergo a disc-to-sphere

transformation, lose their discoid shape, become spherical, and lose the ability to display "swirl." While the presence of swirling is predictive of a satisfactory pH value, the absence of swirling is less helpful because many platelet concentrates with poor swirl still have an adequate pH.<sup>76</sup> Platelet swirl is thus a poor quality measure.

The hypotonic shock response has been used to evaluate platelet quality as an indication of platelet membrane integrity and the ability of platelets to contract as part of the release reaction. However, these various platelet assays do not provide direct information about platelet hemostatic function, such as adhesive, aggregating, and procoagulant functions. Flow cytometry has limitations since different antibodies will recognize different specific binding sites within antigens. Also, these markers cannot predict the functional effect of the binding of a specific antigen to a specific receptor. Decreased glucose levels and increased lactate production lead to lower pH, alterations in platelet morphology, decrease in surface glycoproteins, enhanced expression of platelet activation markers, and reduced functional or aggregation response. However, none of these changes or combination of changes have been shown to directly relate to *in vivo* hemostasis.

In summary, *in vitro* tests of platelets evaluate limited aspects of the complex hemostatic action of platelets. Tests provide information on different aspects of platelet function, but results from these tests are not necessarily predictive of the clinical hemostatic capacity of platelet concentrates once they are transfused.<sup>77</sup> Thus, results of *in vitro* tests of PR platelets should be evaluated with these issues in mind.

### **In vitro testing of pathogen-reduced platelets**

Extensive testing has been performed on both amotosalen and riboflavin treated platelets. It is important again to note that *in vitro* platelet function tests do not predict impaired hemostatic effects.<sup>78</sup> In general, testing results are similar between amotosalen and riboflavin treated platelets.<sup>77</sup>

### **Amotosalen/UV-A *in vitro* platelet quality**

The changes associated with amotosalen/UV-A treatment of platelets are decreased glucose, increased lactate accumulation, and a falling pH.<sup>79–82</sup> In addition, alterations in platelet morphology, decrease swelling, and a decreased resistance to hypotonic shock also occur.<sup>79–82</sup> There are moderate reductions in membrane glycoproteins with increased expression of P selectin, which suggests platelet activation.<sup>83,84</sup>

### **Riboflavin/UV *in vitro* platelet quality**

Alterations induced by riboflavin are similar to those induced by amotosalen with increased anaerobic metabolism followed by a decline in pH, morphologic alterations, reduction in swirling, and decreased resistance to hypotonic shock.<sup>85–90</sup> There are moderate reductions in membrane glycoproteins with enhanced expression of platelet activation markers indicating apoptosis.<sup>86–88,90–98</sup> Thus, riboflavin-treated platelets have some altered *in vitro* functional properties, but these are similar to amotosalen-treated platelets.<sup>77</sup> One *in vitro* thromboelastography study of riboflavin-treated platelets has been reported to show weaker clot strengths.<sup>99</sup>

### **UV-C *in vitro* platelet quality**

The metabolic and morphologic changes in UV-C-treated platelets are similar to those described for amotosalen and riboflavin. This involves a moderate decrease in glucose, increase in lactate, decrease

pH, alterations in swirling, and reduction in hypotonic shock response. Changes in membrane proteins and expression of P selectin are slightly less pronounced than for amotosalen and riboflavin.<sup>100–103</sup>

### **Summary of *in vitro* quality of PR platelets**

More direct platelet function is measured by adherence, aggregation, and procoagulant generation. Both amotosalen-treated<sup>81,104,105</sup> and riboflavin-treated<sup>76–78,85</sup> platelets have decreased aggregation responses, but these responses are somewhat better preserved with UV-C treatment.<sup>91–93</sup> In studies under flow conditions which more closely evaluate the adhesive function of platelets, amotosalen-treated platelets showed results similar to control untreated platelets.<sup>106</sup> Stivala *et al.* showed reduced adhesion and aggregation of amotosalen-treated platelets to von Willebrand factor collagen substrates.<sup>105</sup> Riboflavin-treated platelets had reasonably well-preserved adhesive and cohesive functions comparable to control untreated platelets<sup>93</sup> and were similar to the results with amotosalen-treated platelets. Overall, these studies suggest that the functional changes noted in *in vitro* tests are less pronounced in the blood flow testing settings, and the changes are similar among all three PR methods. Use of thromboelastogram metric assays that measure the contribution of thrombin, fibrinogen platelet glycoproteins, and cytoskeleton in clot formation has shown reductions in the maximum clot strength of riboflavin platelets and similar results from UV-C platelets.<sup>97,107–109</sup> While many changes have been documented as a result of both amotosalen, riboflavin, and UV-C treatment, these have a weak impact on the overall proteome of platelets and thus do not reveal any remarkable changes of clinical concern.<sup>110</sup> In published studies comparing the effect of gamma radiation versus riboflavin/UV and amotosalen/UV-A, gamma irradiation resulted in changes seen as if there was an acceleration of the platelet storage lesion.<sup>77,111,112</sup> A large number of studies show that different pathogen reduction technologies cause similar modifications in *in vitro* tests, and these studies do not, in general, indicate any specific adverse effect on hemostatic efficacy.<sup>77</sup>

### **In vivo studies in healthy human subjects**

#### **Radiolabeling studies**

Studies of radiolabeled platelets in healthy research subjects showed a lower recovery and shorter survival of both amotosalen<sup>113–115</sup> and riboflavin-treated platelets<sup>92</sup> compared to nontreated platelets (Table 42.4). Thus, it could be expected that post-transfusion platelet count increments would be lower, and the time to the next platelet transfusion from a prior one would be shorter after the transfusion of riboflavin- or amotosalen-treated platelets. This has been confirmed in randomized controlled clinical trials.<sup>116</sup> *In vivo* recovery and survival of UV-C light-treated platelets also were reduced. This finding is similar to that of other PR systems.<sup>100</sup>

#### **In vivo randomized controlled clinical trials of pathogen-reduced platelets**

There have been 10 randomized controlled clinical trials of PR platelets,<sup>116</sup> 7 of amotosalen,<sup>117–123</sup> and 3 of riboflavin platelets.<sup>123–125</sup> In trials of amotosalen platelets, a total of 1922 patients have been studied (954 PR and 968 control). In trials of riboflavin platelets, a total of 862 patients have been studied (434 PR and 428 control).

For the seven amotosalen trials, bleeding was the end point in three and corrected count increment (CCI) in four.<sup>116</sup> For

**Table 42.4** In vivo Recovery and Survival of Radio-Labelled Pathogen-Reduced Platelets

Recovery		
	Amotosalen	Riboflavin
Control Platelets	50.3% ± 7.7%	66.5% ± 13.4%
PR Platelets	42.5% ± 8.7%	50.0% ± 18.9%
Survival		
	Amotosalen	Riboflavin
Control Platelets	144 ± 29 hours (6 ± 1.2 days)	142 ± 26 hours (5.9 ± 1.1 days)
PR Platelets	115 ± 31 hours (4.8 ± 1.3 days)	104 ± 26 hours (4.3 ± 1.1 days)

In vivo recovery and survival of radiolabeled pathogen-reduced platelets. Since both amotosalen and riboflavin platelets have less recovery and shorter survival after being transfused, CCls for pathogen-reduced platelets are expected to be lower.<sup>92,113</sup> Data are expressed as mean ± standard deviation.

riboflavin-treated platelets, bleeding was the end point in two and CCI in one trial.<sup>116</sup> In all of these trials, there was no difference in the portion of patients who experience WHO grade 2 or greater bleeding between patients who received conventional platelets or those who received PR platelets. This indicates that PR platelets are as clinically effective as standard platelets. In most trials, transfusions with PR platelets were associated with lower CCI and shorter time to the next transfusion. These findings are not unexpected based on the studies of radiolabeled platelets in healthy research subjects (Table 42.4). In most trials, there was less than one additional unit of PR platelets transfused compared to conventional platelets, but the duration of platelet support was similar, and the use of red blood cell transfusion was no different.<sup>126</sup> Similar results were found in a quality assurance review of PR platelet usage in pediatric and adult patients.<sup>127,128</sup> These results indicate that patient receiving PR platelets did not experience exceptional bleeding. In contrast, one randomized controlled trial measuring one-hour CCI in patients receiving UV-C-treated platelets compared to conventional platelets failed to show noninferiority.<sup>129</sup>

The frequency and nature of adverse events were not different following the transfusion of either PR or conventional platelets, indicating that there are no unusual safety concerns from these transfusions. Studies from Europe with amotosalen/UV-A platelets showed marked decrease in bacterial contamination in PR platelets compared to conventional platelets.<sup>39</sup> An analysis of data from the hemovigilance programs from Belgium, Switzerland, and France showed, in aggregate, zero probable or definite/certain septic reactions following transfusion of 609,290 amotosalen/UV-A platelet units. These results were significantly lower than those reported with concurrently transfused and/or historic septic reaction rates from the transfusion of non-PR treated platelets for these countries.<sup>39</sup>

### Whole blood and red blood cells

#### Amotosalen/UV-A

Amotosalen/UV-A is not used for RBCs or whole blood pathogen reduction as mentioned above since UV-A light does not efficiently reduce units of red cells. However, riboflavin technology can be used to treat RBCs and whole blood. Amustalen/glutathione technology is actively being studied in several clinical trials for the treatment of RBCs.<sup>130,131</sup>

#### Riboflavin whole blood and red blood cells

Riboflavin technology can be used to treat either whole blood or red blood cells.<sup>132–136</sup> The process is similar to that used for platelets and plasma. Riboflavin is added to the whole blood or red blood cells and exposed to UV light. Cell quality data show satisfactory in vitro results to support storage of the blood for up to 21 days.<sup>132–134</sup> Two in vivo studies of radiolabeled riboflavin-treated red cells in healthy research subjects showed slightly reduced recovery and shortened survival leading to a 21-day storage duration.<sup>135,136</sup> Normal red cell shelf life is 35–42 days depending on the preservative/anticoagulant used for storage. The IMPROVE I trial determined the recovery and survival of RBCs, and in vitro testing of platelets and plasma from nonleukoreduced whole blood in 12 subjects has been performed.<sup>135</sup> Treated whole blood was separated into components, each of which was tested at the beginning and at the end of storage. Autologous RBCs radiolabeled with <sup>51</sup>Cr were transfused into the healthy subjects, and 24-hour recovery and survival half-lives after 42 days storage were determined. Red cell recovery at 24 hours post-transfusion was 82.5% for riboflavin-treated cells and 91.7% for control-untreated cells, which are values that meet US FDA criteria for satisfactory recovery.

One trial performed was a prospective, randomized, double-blind, controlled, single-center study at the Komfo Anokye Teaching Hospital in Ghana.<sup>38</sup> The objective of this study was to determine whether riboflavin-treated whole blood was less likely to transmit malaria. Patients were randomized 1:1 to receive ≤2 transfusions of either riboflavin-treated or untreated (i.e., standard preparation) whole blood. If additional transfusions were required, standard untreated whole blood was used. Subjects were followed for 28 days post-transfusion, and parasite detection was carried out on Days 1, 3, 7, and 28. Transmission of malaria was reduced by 87% in patients who received the riboflavin whole blood compared to standard whole blood.<sup>38</sup> Importantly, this study was able to show reduction of infection from the transfusion of pathogen-reduced red cells.

#### Amustaline/glutathione red blood cells

Red blood cells treated with amustaline/glutathione are currently under active investigation with several randomized controlled clinical trials.<sup>130,131,137</sup> A radiolabeling study of amustaline-treated RBCs reported that these RBCs show sufficient post-transfusion recovery to satisfy FDA criteria.<sup>136</sup> One randomized controlled trial showed no difference between hemoglobin content, RBC usage, or clinical outcomes between amustaline-treated and conventional RBCs.<sup>130</sup> As of writing this chapter, two US clinical trials are currently being performed: the ReCePi trial is studying the efficacy and safety of amustaline-treated RBCs in patients undergoing complex cardiac surgery, and the ReDeS trial is studying the increases in hemoglobin levels in patients receiving amustaline-treated RBCs and the reduction of risk of transmission of the Zika virus and other TTDs.

### Immunological effects of pathogen-reduced blood components

#### Alloimmunization to platelet transfusions

About 20% of cases of refractoriness to platelet transfusions are due to immunological causes. Alloimmunization to different HLA Class I molecules is a frequent underlying etiology. As discussed by Maier *et al.* in Chapter 16, pathogen reduction technol-

ogy has been investigated as a method for reducing the risk of alloimmunization to platelet transfusions. The use of ultraviolet irradiation and/or the treatment with photoactivating agents to damage DNA are thought to reduce the immunogenicity of leukocytes found in the blood component and thus reduce antibody responses to HLA molecules. However, conflicting results among preclinical animal studies and several clinical trials have led to mixed conclusions on the effect of pathogen reduction on platelet alloimmunization.

Observations from several animal studies suggest evidence of reduction in alloimmunization with PR platelets due to various effects in reducing the immunogenicity of contaminating donor leukocytes. These observed effects include inhibition of antigen presentation, reduced survival and expression of HLA Class II in antigen-presenting cells, and induction of tolerance, leading to decreased anti-MHC alloantibody formation.<sup>138–141</sup> These results contrast with often conflicting and unexpected conclusions from data collected from clinical trials showing a range of increases, decreases, and no differences in alloimmunization rates from platelets treated with various different PR technologies. For example, a subanalysis of the PREPARES trial showed increased rates of HLA I class alloimmunization to riboflavin-treated platelets<sup>142</sup> while the SPRINT trial found no significant difference in HLA antibody formation rates from amotosalen-treated platelets.<sup>143</sup> One hospital system reported increased rates of incompatible platelet crossmatch tests concurrent with increased transfusions of amotosalen-treated platelets.<sup>144</sup> However, an analysis of the Italian IPTAS study demonstrated no association of amotosalen-treated platelets with platelet alloimmunization. It was suggested that the observations of increased clinical refractoriness may have been due to intrinsically lower CCIs from PR platelets rather than alloimmunization.<sup>145</sup> As discussed in Chapter 16, these disparate results could be due to differences in clinical trial designs and product preparation unrelated to pathogen reduction. It is likely that resolving these discordant observations will require the completion of ongoing clinical trials and careful data analysis.

### **Prevention of transfusion-associated graft-versus-host disease**

Pathogen reduction techniques that cause nucleic acid damage in pathogens also damage nucleic acids in lymphocytes and prevent their proliferation in blood components.<sup>146–152</sup> Thus, PR blood components should not cause TA-GVHD. This has been established in animal studies,<sup>150</sup> but it is unlikely that a classic randomized controlled clinical trial will ever be conducted in humans. Many centers have discontinued irradiating amotosalen/UV-A or riboflavin/UV PR platelets and have not observed TA-GVHD as a consequence.<sup>153,154</sup> Thus, it seems reasonable that other PR techniques could eliminate the need for gamma or X-ray irradiation for the prevention of TA-GVHD.<sup>155</sup> The package insert for amotosalen/UV-A-treated platelets states that amotosalen/UV-A can be used “as an alternative to gamma irradiation for the prevention of transfusion-associated graft-versus-host disease” and provides FDA-approved language that PR platelets do not need to be irradiated. In fact, irradiating PR platelets could cause a “double hit injury” to the platelets that could potentially decrease post-transfusion platelet recovery and survival. However, early PR trials involving amotosalen/UV-A platelets, including the SPRINT study, did include irradiated amotosalen/UV-A platelets that were shown to be clinically effective.<sup>5,156</sup>

## **Safety and toxicity of pathogen-reduced technologies**

### **Amotosalen**

Amotosalen preclinical toxicity has been evaluated in several studies, including assessments for acute toxicity, reproductive effects, neonatal toxicity, phototoxicity, carcinogenicity, safety pharmacology, genotoxicity, and neoantigenicity.<sup>8,49,157–159</sup> These studies have found no evidence of organ or reproductive toxicity, neonatal toxicity, carcinogenicity, or neoantigenicity.<sup>160</sup> It was determined that dermal phototoxicity occurs at psoralen concentrations that are 1000 times higher than those levels used clinically or found naturally in diets.<sup>161</sup> Animal studies have also shown no toxicological effects in adult, juvenile, and neonatal animals. There have been concerns expressed regarding use of amotosalen/UVA platelets in neonates and infants. Specifically, these concerns relate to photodermatitis—skin rashes—in children who received a psoralen pathogen-reduced platelet and were treated for hyperbilirubinemia with blue light phototherapy.<sup>162</sup> As such, amotosalen-treated platelets are contraindicated in neonates receiving treatment with “phototherapy that emit a peak energy wavelength less than 425 nm or have a lower bound of the emission bandwidth less than 375 nm.”<sup>163</sup> Phototherapy devices used clinically in the United States do not emit energy in these wavelengths. Recent studies have shown no adverse events in adult or pediatric patients attributed to amotosalen/UV-A pathogen-reduced products.<sup>127,128</sup> As such, amotosalen/UV-A pathogen-reduced platelet and plasma products are FDA approved for all populations.<sup>10,11</sup> There had been some early reports of increased risk of acute respiratory distress syndrome (ARDS), but this has not proven to be a clinical problem and these platelets have come into wide use.<sup>11,156,164</sup> Results of a large hemovigilance study of adult and pediatric hematology patients have shown no increased risk of pulmonary complications of PR platelets compared to conventional non-PR platelets.<sup>126</sup> One promising study has shown no increase in adverse effects of amotosalen-treated platelets with seven-day storage compared to conventional platelets with five-day storage, but as of writing this chapter, an extended storage time has not yet been FDA approved.<sup>165</sup>

### **Riboflavin**

Since riboflavin is a vitamin—namely vitamin B2—its toxicity has been well studied, and it is generally regarded as safe. When riboflavin is subjected to UV light, four breakdown products are produced in the circulation that occur physiologically at low concentrations.<sup>166,167</sup> Thus, as no new, nonphysiologic compounds are generated, there is no need for a post-treatment removal process. The toxicity of these compounds and the amounts infused as part of the pathogen reduction process have been well studied and have been shown to be well within accepted safety limits.<sup>167</sup>

### **Amustaline/glutathione**

The systemic toxicity, genotoxicity, and carcinogenicity of amustaline- and glutathione-treated RBCs have been studied in rats, dogs, and mice.<sup>16,168</sup> As described before, amustaline has side reactions with plasma proteins and proteins found on the extracellular surface of the RBC membrane, and glutathione is used to quench these reactions. One report studied the systemic toxicity and pharmacokinetics of amustaline-treated red cells in dogs and rats by administering RBCs with levels of amustaline up to five times higher than those used in RBCs for clinical use and with levels of glutathione

that would not completely quench the amustaline.<sup>16</sup> This study showed no effect on mortality and no evidence of organ toxicity, and pharmacokinetics assessment demonstrated no accumulation of amustaline breakdown products in the plasma. A second study from the same group investigated the genotoxicity and carcinogenicity of amustaline-treated red cells.<sup>168</sup> There were no carcinogenic effects found in a heterozygous p53<sup>+/−</sup> mouse model, and no cytogenetic aberrations were found in an *in vitro* clastogenicity assay in human peripheral blood lymphocytes or in an *in vivo* mouse bone marrow micronucleus assay. These findings support the safety of amustaline/glutathione PR-RBCs.

### UV-C

Evaluations of the toxicity of UV-C treated platelets are limited. The lack of the addition of a photoactive chemical excludes the need for a traditional toxicological assessment.<sup>169</sup> One preclinical study performed repeated transfusions of UV-C-treated autologous platelet concentrates in beagle dogs and found no signs of intolerance to the transfusions.<sup>170</sup> This study assessed immunogenicity with high-resolution proteomics, which detected few modifications in platelet proteins due to UV-C treatment, and did not detect any antibody responses.

### Methylene blue

Methylene blue has been demonstrated to have an overall good safety profile with low toxicity.<sup>32,37</sup> Adsorbent filtration of MB plasma has been shown to reduce residual MB down to undetectable levels.<sup>171</sup> However, there are reports of allergic and anaphylactic reactions from plasma treated with MB, leading to the discontinuation of its use in certain countries as discussed previously.<sup>30,172</sup>

### Solvent/detergent

Residual amounts of solvent and detergents in S/D-treated plasma are at very low levels and are of little concern for toxicity. The European Pharmacopoeia allows for less than 2 µg/mL of trinitrobutylphosphate solvent and less than 5 µg/mL of Triton X-100 in S/D-treated plasma, which are significantly lower than concentrations considered to be toxic.<sup>7</sup> In fact, the majority of S/D plasma products have been found to have levels of these compounds below the threshold of detection.<sup>30</sup> There have also been no

known reports of toxicity or adverse reactions after the transfusion of millions of S/D plasma units.<sup>7</sup>

### Summary

The importance of pathogen reduction for the public health aspects of the blood supply cannot be overstated. Bacterial and viral contamination of blood components is an ongoing concern as transfusion transmitted diseases have serious and even fatal consequences. The additional potential for contamination with unknown yet to be encountered pathogens exacerbates the concerns for a safe blood supply. Despite the upfront costs of pathogen reduction, proactively reducing the overall risk of transfusion-transmitted diseases will prove to be economically and socially invaluable, particularly when a new blood-borne disease arises in the future. Advances in utilization and efficacy of pathogen reduction technologies will play a major role in maintaining and ensuring a safe blood supply.

# **Adverse sequelae of transfusion**

## CHAPTER 43

# Hemovigilance: weighing the risks versus benefits of transfusion

Scott Koepsell

University of Nebraska Medical Center, Omaha, NE, USA

## Introduction

Transfusion of blood products can be a life-saving procedure. Like all medical procedures, the act of blood transfusion includes risk for the recipient. Even the act of not transfusing a blood product may pose the risk of life-threatening anemia or bleeding to a patient. Although generally considered safe, the donation of blood products also involves risk for donors who can experience injury related to the donation process. Around the globe, a wide variety of legislation, regulations, rules, and voluntary programs exist which are designed to monitor and minimize risk for both the donor and the recipient. While stringent requirements, oversight, and data reporting may increase the safety of blood transfusion or donation, resource limitations often constrain blood safety controls in order to meet demand. In addition, the prevalence of transfusion-associated risk such as transfusion-transmitted diseases can vary among blood donors in different areas due to disease prevalence. As such, the evaluation of the risk versus benefit of blood product transfusion is setting dependent and requires the integration of a significant amount of data to determine whether a transfusion is indicated. Hemovigilance systems can help determine the risk–benefit ratio.

## Risk

Although there is no agreed upon definition of the concept of risk, in general risk is thought of as the likelihood that harms or something untoward occurs because of an intervention.<sup>1</sup> The intervention can be an action, such as giving a blood product, or an inaction, such as deciding to withhold a transfusion. In medicine, risk is often understood and conveyed through both subjective and objective terms.<sup>2</sup> Examples of subjective risk include how impactful or significant an adverse reaction is to a patient, whereas objective examples include how often or frequently an adverse event occurs. Two approaches for reducing risk in transfusion have been widely employed and include quality monitoring systems and standardized reporting and learning systems (RLS).<sup>3,4</sup> Systematic and consistent categorization of adverse events related to transfusion or donation is needed to truly understand and improve the accuracy of our risk assessments.

## Reporting and learning systems in transfusion

The term *hemovigilance* has become widely used over the past decade to describe the systematic surveillance of adverse transfusion reactions and events, encompassing the whole transfusion chain from donor to recipient, or “vein to vein.”<sup>5,6</sup> The concept for RLS in transfusion medicine has been to establish hemovigilance systems to identify, track, and understand risks in blood donation and blood product transfusion in order to improve safety. A wide variety of RLS exist around the world (Table 43.1).

Hemovigilance systems range from voluntary to compulsory. The Canadian Patient Safety Institute (CPSI) found that voluntary systems were best, and some established hemovigilance systems, such as SHOT and the Danish Registration of Transfusion Accidents (DART), are voluntary. Voluntary systems are often started by professional or scientific bodies, and participants may therefore feel more ownership and, hence, more willingness to participate. Compulsory systems are usually initiated by governments and supported by laws, regulations, or directives.

## Hemovigilance methods

### Reporting systems

Hemovigilance systems rely on the reporting of data from members. Both WHO and CPSI recommend nonpunitive and confidential hemovigilance systems to encourage accurate reporting, especially given that many adverse events and near misses involve human error.<sup>7</sup> When reporting systems are used for learning purposes, it is important that details that could be used to identify people or places are removed or changed.

Data can be collected in either a passive or an active manner. Passive systems report only recognized adverse events or near misses, whereas active systems also tend to report when a transfusion or blood donation was uncomplicated. Even with active reporting systems, adverse events related to a transfusion or donation may be missed. One reason for not recognizing transfusion or donation-related adverse events is lack of awareness of the signs and symptoms of a reaction or attributing the adverse event to some other cause. The number of adverse events that are missed could be significant.

**Table 43.1** Examples of Hemovigilance Systems

Country	Date of Initiation, Scope of Reporting (Voluntary at Inception Unless Otherwise Mentioned)	Governance
Japan	1993: Transfusion-associated adverse reactions and infectious diseases	Japanese Red Cross Society
France	1994: Mandatory system created by national legislation; all severity levels	Inspectorate for Healthcare Products (currently: Agence Nationale de Sécurité du Médicament et des Produits de Santé)
United Kingdom	1996: Serious Hazards of Transfusion (SHOT); serious reports	Professional societies
Denmark	1999: Danish Registration of Transfusion Accidents (DART); modeled on SHOT	Society for Clinical Immunology Early emphasis on donor adverse reactions (Danish Donor Society)
South Africa	2000: All severity levels; donor reactions included from 2010	South African National Blood Service
Netherlands	2002: Transfusion and transplantation reactions in patients (TRIP); "all"	Professional societies
Norway	2004: TROLL. Reports on transfusion reactions and complications of blood donation from 2004. Reports on other adverse events from 2007	From 2004 to 2007: The Norwegian Society for Immunology and Transfusion Medicine (Professional Society). From 2007: The Norwegian Directorate of Health is responsible for hemovigilance, but the system is operated by the Norwegian Knowledge Centre for the Health Services
New Zealand	2005: All severity levels	New Zealand Blood Service
United States	2006: National Healthcare Safety Network, Biovigilance reporting system. Gradual increase of participation; incorporated donor vigilance from inception	US Biovigilance Network (public-private collaboration between the US Department of Health and Human Services, including the Centers for Disease Control and Prevention, and organizations involved in blood collection, transfusion, tissue and organ transplantation, and cellular therapies)

For example, careful review of vital signs during transfusion found that up to 75% of transfusion reactions may not be reported.<sup>8</sup> Catching adverse events may be more likely in the future with the implementation of computer health information systems that use algorithms to detect and alert staff to potential adverse events.<sup>9</sup>

Another reason for underreporting adverse events in transfusion is that the adverse event is not temporally adjacent to the transfusion or donation. For example, in donors, adverse reactions that occur while the blood donor still is present in the blood bank or donor center are fairly easy to capture, whereas some serious complications, like faints that occur after leaving the blood bank or donor center, may not be reported until the time of the next donation, if ever. Another example of temporally delayed reactions to transfusion is delayed hemolytic transfusion reactions, which typically are detected days after the transfusion. Due to the presence of hemovigilance networks, strategies are emerging to better capture adverse events that occur days after the transfusion. For example, the use of a hemovigilance network in France has successfully increased awareness and recognition of delayed hemolytic transfusion reactions through the dissemination of information through the network.<sup>10</sup>

### Reported data, investigations, and assessment

Adverse reactions are investigated to establish the diagnosis and likelihood or imputability that the adverse event was related to the transfusion or donation. Reporting to the hemovigilance system requires sufficient information to allow the assessors to verify the type of reported reaction. In addition, the adverse events are typically rated for severity. Most hemovigilance systems have objective criteria for establishing both imputability and severity so that adverse events can uniformly be evaluated.<sup>11</sup>

A range of adverse events are reported to hemovigilance systems. In some countries, legislation requires only reporting of serious adverse events or fatalities. When only serious adverse events are reported, less serious adverse events or near misses are not always captured. Identification of near misses and all adverse events are key to a robust and effective RLS. However, the number of reports on the hemovigilance system dramatically increases if all adverse events and near misses are reported. Therefore, available resources determine the type of data reported to a hemovigilance system.

Analysis of the hemovigilance data from a country or region requires context and background. Typical background data that are registered for reporting donor complications are the donors' age and gender, the donation type (whole blood or apheresis), the date and time of donation, and if it was a first-time donation. Typical background data for transfusion reactions are patient age and gender, the indication for transfusion, department and/or ward, and time from transfusion to reaction. Other key information includes whether universal leukodepletion of blood components is in place and for transfusion-transmitted diseases, the prevalence of those diseases in that area.

Context and background help the users of a hemovigilance system to understand the frequency of an adverse event. For example, vasovagal reactions may be reported more frequently in young women, but if we do not know what proportion of donors are young females, this information has limited value. In certain cases, more background information may be useful, such as a female donor's parity in cases of TRALI and the patient's cardiovascular status when transfusion-associated cardiac overload (TACO) or transfusion-associated dyspnea (TAD) is suspected. Also, follow-up testing for antibodies for human leukocyte antigens or platelet antigens can help confirm a diagnosis.

### Hemovigilance data analysis, assessment, and reporting

Reporting to a centralized system allows for the analysis of systemic risk in order to derive recommendations for the improvement of practice and prevention of future errors and incidents and to accurately determine objective risk. From an analysis of hemovigilance data, risk and likelihood of recurrence can be combined to support prioritization of a particular problem for detailed analysis and preventive measures. This can be performed at a system or national level, but also at a local or institution level. Mistakes or errors at the moment of transfusion may have several latent causes, such as lack of training, poorly designed processes, inadequate software, or understaffing. Facilities should assess such causes and supply sufficient information to the hemovigilance system to allow analysis of recurrent problems and weak "links" in the transfusion chain.<sup>12,13</sup> A number of methods for analyzing and classifying contributing

causes have been developed.<sup>12</sup> A practical toolkit based on techniques recommended by the (former) UK National Patient Safety Agency is available on the SHOT website ([www.shotuk.org](http://www.shotuk.org)).<sup>14</sup>

In order for learning and improvement to take place, the collected information is made available to the professionals in all aspects of the transfusion chain. Recommendations for improvement can be made, and ideally incorporated in practice through changes in blood donor care, the production of blood components, recommended practices laid down in testing or transfusion guidelines, or other mechanisms. Through ongoing reporting, the effects of measures can be evaluated and trends can be tracked. Where possible and relevant, peer-reviewed publication should also be pursued to strengthen rigor and ensure international accessibility of the results for incorporation in meta-analyses.

### **Adverse events not captured by hemovigilance systems**

Table 43.2 lists the typical types of adverse events associated with blood product transfusions that are reported to hemovigilance systems. While monitoring and reducing these typical transfusion complications is important, there are many other adverse events associated with transfusion that are not routinely captured by most hemovigilance systems. Most of these other adverse events were discovered through randomized controlled trials that showed an increase in a particular adverse event in the transfused group as opposed to the control group. Without these trials, most of the adverse events would otherwise be attributed to the patient's underlying disease state. For example, pooling of 21 randomized trials involving 8735 patients showed that the intervention of transfusing red blood cells was associated with serious infection, especially in patients undergoing orthopedic surgery or presenting with sepsis.<sup>15</sup> Without these data, the development of an infection would otherwise be attributed to the patient's underlying condition.

Another example was a randomized controlled trial in patients with liver disease presenting with an upper gastrointestinal bleed which identified that the transfusion of red blood cells at hemoglobin threshold of 7 g/dL versus 9 g/dL significantly reduced mortality and bleeding, presumably by not increasing portal pressures.<sup>16</sup> The link between transfusion and mortality applies to platelet transfusions as well. A prospective randomized trial found that platelet transfusions in patients with intracerebral hemorrhage while on antiplatelet therapy were significantly more likely to have serious adverse events and death.<sup>17</sup> Without either of these studies, the effect of the transfusion on mortality would not have been appreciated.

Though not derived from randomized-controlled data, the analysis of a prospective registry data of patients undergoing surgery found that intraoperative transfusion was associated in a

dose-dependent manner with the risk of a developed postoperative clot that needed an intervention.<sup>18</sup> As we gather more information and study transfusion in more detail, it is clear that adverse events and the risk-to-benefit ratio for transfusion have not been fully appreciated. Unfortunately, many of these significant risks of transfusion are not currently captured by most hemovigilance systems. Ideally, as electronic health records become more sophisticated, reporting of these other adverse events could be captured and reported to hemovigilance systems.

### **What have we learned from hemovigilance systems?**

Hemovigilance system reporting and analysis has increased our understanding of adverse reactions that occur in both blood donors and recipients of blood transfusion. The large data sets from hemovigilance systems are invaluable to identify trends from infrequent events. Many adverse reactions are very rare, and a single-institution would never transfuse enough blood products to experience enough events to identify meaningful trends or information. For example, the analysis of 10 years of SHOT data found that leukoreduction likely does reduce the risk for transfusion-associated graft-versus-host disease, a finding that would be impossible with analysis from a few institutions given the low incidence.<sup>19</sup>

Similarly, even though donating blood is considered safe, the analysis of up to 11 years of data from the International Haemovigilance Network was able to quantitate the risk of adverse events, including very rare complications such as cellulitis and air embolism.<sup>20</sup> As hemovigilance systems for donors become more robust, long-term risks, if any, might be identified and could also be extended to donors of gametes, embryos and tissues.<sup>21</sup>

Hemovigilance data have also made it possible to compare transfusion reactions to differently manufactured blood products. The effect of introducing male-only plasma to reduce the incidence of TRALI is one such example.<sup>22,23</sup> Another study using hemovigilance data accumulated from 23 countries found that there was a statistical difference in allergic reactions among recipients of apheresis plasma versus whole-blood-derived plasma.<sup>24</sup> The effect on transfusion reactions by switching from fresh-frozen plasma to solvent-and-detergent treated pooled plasma in Finland is another example.<sup>25</sup> In a health technology assessment (HTA) in Norway, comparing SDplasma, single-donor pathogen-reduced plasma, quarantine FFP, and FFP, data from different hemovigilance systems proved to be valuable.<sup>26</sup> In this HTA, the data from large countries that have different plasma products in use and a comprehensive hemovigilance system like France's were useful in a field dominated by scientific studies too small to detect differences in infrequent complications.

Overall, hemovigilance systems have demonstrated that blood transfusion is generally safe. However, there are preventable errors that still occur. An example from SHOT proves this while it still points at areas for further improvement. Over a 10-year period, during which time 30 million blood components were issued from UK blood services, SHOT received 3770 reports, of which 2717 (72%) were of an incorrect blood component transfused. Ninety-five percent of these patients survived with no serious effects, but 24 deaths were attributed wholly or in part to avoidable transfusion errors, and 100 patients suffered major morbidity.<sup>27</sup> Through the use of the SHOT hemovigilance system, the risk of incompatible transfusion errors continues to decrease, with the wrong blood in tube highlighted as a major cause, indicating labeling and patient identification of blood specimen samples need to be addressed.<sup>28</sup>

**Table 43.2** Examples of Adverse Events Reported to Hemovigilance Systems

<b>Respiratory Complications</b>	Transfusion-related acute lung injury Transfusion-associated circulatory overload Transfusion-associated dyspnea
<b>Allergic Complications</b>	Urticaria/Hives Anaphylaxis
<b>Hemolytic Complications</b>	Acute hemolytic transfusion reaction Delayed hemolytic transfusion reaction Delayed serologic transfusion reaction
<b>Immune Complications</b>	Transfusion-associated graft-versus-host disease Post-transfusion purpura Febrile nonhemolytic transfusion reaction
<b>Infectious Complications</b>	Transfusion-transmitted infections

With the implementation of pathogen reduction technologies, hemovigilance systems will be very important in detecting and documenting a presumed reduced rate of transfusion-transmitted infections. The United States based National Healthcare Safety Network Hemovigilance Module recently reported 54 cases of transfusion-transmitted infections that met their criteria out of 7.9 million transfused components.<sup>29</sup> Given the low rate of recognized transfusion-transmitted infections, hemovigilance systems will be invaluable to make sure that the benefit of pathogen reduction outweighs any possible risks that have been associated with pathogen reduction such as an increase in platelet refractoriness, an increased exposure to platelet transfusions, and lower corrected-count increments.<sup>30</sup>

## Discussion

Hemovigilance results combined with published research are leading to real improvements in transfusion safety. Both SHOT and the French hemovigilance systems have reported a lower rate of ABO-incompatible red blood cell transfusions in recent years. Comparison of hemovigilance system data can give useful information on local, regional, national, and international levels, which can be used in local improvement work as well as in making national and international guidelines and regulations.

Limitations of hemovigilance systems include not capturing harm to patients because of failure to provide blood or other adverse events such as thromboembolism or infection that could be related to transfusion. Another limitation includes differences in system and in practice or reporting, which restricts the ability to

investigate differences in reported incidences between systems or even regions.

Hemovigilance systems help determine that both blood donation and blood transfusion are generally safe, but that there are opportunities to further improve safety. Knowing the incidence and seriousness of complications is very valuable in this respect. Giving correct information on risks to donors and patients is necessary for donors and patients to trust the transfusion service. In the future, international agreement on definitions and on recommended background data to collect will improve benchmarking as will more sophisticated electronic health reporting systems that have the potential to capture more transfusion-related adverse events.

# Transfusion-transmitted viral infections (TTVIs)

Eric A. Gehrie

The American Red Cross, Biomedical Services Division, Washington, DC, USA

## Introduction

Ever since the advent of the global human immunodeficiency virus (HIV) epidemic, transfusion medicine has maintained a heightened awareness of the potential risk of transmitting infection through blood transfusions. This has paradoxically increased despite the actual infectious risks of blood transfusion being lower than ever in developed countries. The enhanced level of safety has resulted from a series of stepwise interventions and policies in blood services throughout the world. Microbial risks were once mainly related to persistent infections such as HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV), where viral carriage and latency were the key factors predisposing an agent to transmission by transfusion. More recently, several acute infections have posed a threat to blood safety when they have occurred at high incidence in certain populations. West Nile virus (WNV) in North America is a good example of this, but other infections such as Chikungunya virus and the specter of emerging respiratory viruses such as SARS-CoV-2 have made transfusion microbiologists widen their areas of vigilance. These issues are reflected in this chapter.

## Hepatitis virus infections (A, B, C, D, and E)

### Hepatitis A virus infections

Hepatitis A (formerly known as infectious hepatitis) is an acute infectious disease of the liver caused by the hepatitis A virus (HAV).<sup>1</sup> The HAV is a nonenveloped picornavirus and contains a single-stranded RNA in a protein shell. Many cases have little or no symptoms, especially in youth. The risk of symptomatic infections is directly related to age, with more than 80% of adults with symptoms of acute viral hepatitis.

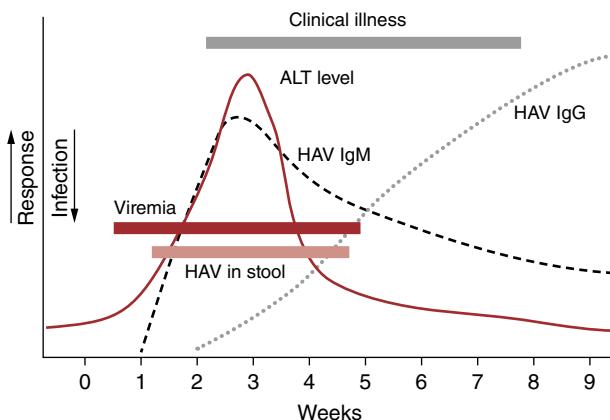

The time between infection and symptom development is between two and six weeks.<sup>2</sup> Clinical symptoms are nausea, vomiting, diarrhea, jaundice, fever, and abdominal pain.<sup>3,4</sup> Acute liver failure occurs rarely, mostly in elderly people. It is usually spread by contaminated food or drinking water with infected feces. It can also be spread through close contact with or blood products from an infectious person. Children are often asymptomatic and can infect

others.<sup>5</sup> After an infection, people develop an immune response for the rest of their lives. The diagnosis requires blood tests for antibodies or nucleic acid amplification (NAT).<sup>6–9</sup> Vaccinations are effective prevention.<sup>10,11</sup> Other preventive measures include handwashing and cooking food properly. A specific antiviral treatment is currently not possible. Patients are treated for nausea or diarrhea. The human body is usually able to eradicate the virus without severe liver disease. The treatment of acute liver failure is a liver transplantation.

Worldwide, approximately 1.5 million symptomatic cases occur each year with probably millions of asymptomatic infections. About 40% of all acute viral hepatitis is caused by HAV. It is resistant to detergent, acid (pH 1), solvents (such as ether and chloroform), drying, and temperatures up to 60 °C. It can survive for months in fresh and salt water. HAV infections are more common in regions of the world with poor sanitary conditions and limited resources of clean water. In developing countries, about 90% of children have already been infected at the age of 10 years.<sup>12</sup> In developed countries, on the other hand, the infection primarily strikes susceptible young adults, most of whom get it when traveling to countries with a high incidence of the disease or by contact with infectious people.

After ingestion, HAV will be transported into the bloodstream through the epithelium of the oropharynx or intestines. The blood carries the virus to its target, the liver, where it multiplies within hepatocytes and Kupffer cells (liver macrophages). Virions are excreted into the bile and bloodstream. HAV is secreted in large amounts from about 11 days before the onset of symptoms or appearance of anti-HAV IgM antibodies in the blood (Figure 44.1). Therefore, donors could be asymptomatic but still viremic. The incubation period is 15–50 days and mortality of less than 0.5%.<sup>13,14</sup> Within the liver hepatocytes, the RNA genome is released from the protein coat and converted by its own ribosome in the cell.

A serotype and six genotypes have been described. The human genotypes are numbered I–III. Genotypes IV–VI are found in non-human primates.<sup>15</sup> A single isolate of genotype VII isolated in man was also described. Genotype III has been isolated from human and monkey.<sup>16</sup> Most human isolates are from genotype I.

**Figure 44.1** Scheme of HAV infections and immune response.

While the virus spreads by the fecal–oral route and infections often occur in areas of poor hygiene and overcrowding.<sup>17</sup> HAV can also pass through the parenteral route via contaminated blood or blood products. Recently, a large producer of plasma-derived therapies reported an increasing incidence of HAV RNAemia among plasma donors in the United States, with a peak incidence of 5.8 cases/100,000 donors in October 2019.<sup>17</sup> A 10 person subset of these donors underwent additional testing and had detectable RNAemia for a mean of 95 days, which was noted to be significantly longer than is generally believed (see Figure 44.1 for a more traditional model).<sup>17</sup>

During the acute phase of infection, the liver enzyme alanine transferase (ALT) is in the blood at significantly elevated concentrations. The enzyme is derived from the liver cells destroyed by the virus.

There is no specific treatment for hepatitis A. Patients are advised to rest, avoid fatty foods and alcohol, eat a balanced diet, and stay hydrated.

In the United States in 1991, there was a low mortality rate for hepatitis A of four deaths per 1000 cases for the general population, but a higher rate of 17.5 per 1000 in those aged 50 years and older. The risk of death from acute liver failure by HAV infection increases with age and underlying chronic liver disease.<sup>18</sup>

### Keynotes: hepatitis A virus

Virus	Region	Transmission	Screening	Inactivation	Vaccination
Picornaviridae, RNA, and six genotypes	South America, Africa, and Asia	Fecal-oral and blood components	NAT and antibody screening	Reduced efficiency	Yes

### Hepatitis B virus infections

The hepatitis B virus (HBV) has a complex coiled genomic structure.<sup>19,20</sup> An envelope embeds the core of the virus. The virus belongs to the virus family Hepadnaviridae. Based on the replication cycles, the DNA virus is close to the retroviridae. Therefore, they are named DNA retroviruses. The surface antigen of HBV was first described in 1963 by B.S. Blumberg as a new serum protein in Australian Aborigines.<sup>21–23</sup> He named the new antigen the Australia antigen. In 1968, a correlation was made between the Australia antigen and the transmission of hepatitis B. Therefore, the antigen was renamed HBsAg for *hepatitis B surface antigen*. HBsAg is embedded by lipid envelopes, and approximately 25 µm round or filamentous subviral particles can be present in huge numbers of up to  $10^{13}$  particles/mL or  $10^6$  ng/mL in serum. The complete HBV particle diameter is from 45 to 52 µm. Inside the HBsAg envelope, the hepatitis B core antigen (HBcAg) is located.<sup>24,25</sup> Inside of that is the HBV genome, with a length of 3200 base pairs. The HBV genome is a complex virus particle with round structure and characteristic properties (Figure 44.2).

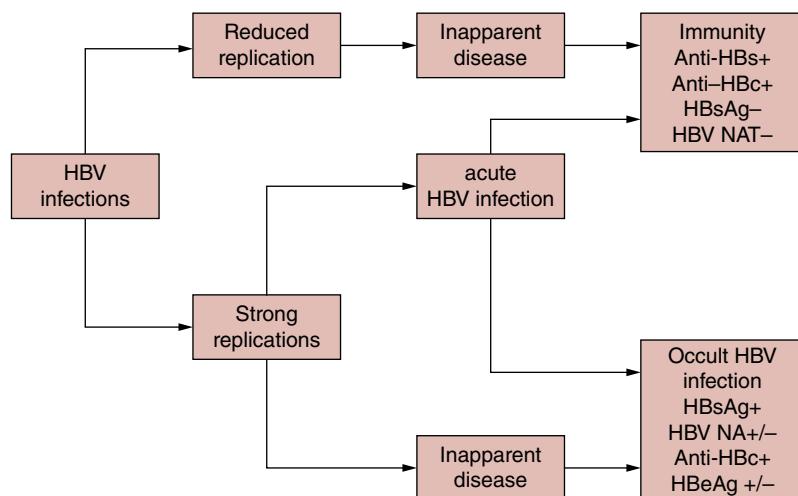

### Characteristics of DNA molecules of hepatitis B genomes

Open circular open-coiled structure with overlapping ends of the double-strand DNA (dsDNA) genome:

- Single-string gap, place for the endogenous DNA-polymerase
- Covalent linkage of the virus protein coding DNA minus strand
- (5'-position) with the virus DNA-polymerase
- Lineages of the DNA plus strand with a RNA primer

### HBV infection pathomechanism

The virus infects liver cells by the bloodstream.<sup>26,27</sup> Via currently unknown receptors, the virus genome is transported into the

**Figure 44.2** Different HBV forms.

liver cells. Cellular repair enzymes build a covalently closed circular DNA (ccc-DNA) that activates the cellular gene expression, producing messenger RNA (mRNA). The mRNA represents the complete genome and works as a matrix for the core protein and the viral DNA-polymerase. Those proteins assemble together to the core particle and embed the mRNA (self-assembly).<sup>28,29</sup> In the next step, the viral DNA-polymerase transcribes the core particles of the RNA into DNA. The RNA is cleaved after producing the viral DNA plus strand. The residual 18 5'-terminal bases of the RNA pregenome represent the primer for the plus strand. In parallel to the genome maturation, subgenomic mRNA molecules are expressed. They are named as 3-DO-carboxy-terminal HB proteins, S (small), M (middle), and L (large), with preS1, preS2, and S protein structures.<sup>30</sup> The HB proteins are released into the endoplasmic reticulum. Within the endoplasmic reticulum, the HB particle embeds the circlet core particle and builds the final HB virus. The HBsAg and the HB virus are released via Golgi apparatus into the bloodstream.

In addition, HBV is coding for two nonstructure proteins, named HBeAg and HBx.<sup>31-33</sup> HBeAg is a nonessential form of HBcAg and has an immune modulating function. HBx has several effects on viral and cellular gene expression. Based on this transcription-regulating mechanism, including a reversed transcription enzyme, HBV is at risk of new genomic variants based on the mutation of viral enzymes. The reason is caused by the missing proofreading function of the reversed transcriptase enzymes. Nevertheless, due to a longtime adaptation between the host and virus without selection pressure, HBV viruses are characterized by eight stable wild-type viruses. Currently, their genotypes are known as HBV genotypes A to H. The most predominant genotypes in Asia are B and C, whereas the most predominant genotypes in Europe are A and D.<sup>34</sup> With an immune selection pressure, HBeAg negative mutants, named *escape mutants*, with mutation within the HB proteins can develop.<sup>35-37</sup>

### **HBV pathogenesis between virus and host**

HBVs are strictly species specific and hepato-autotrophic.<sup>38</sup> Other cells like leukocytes are rarely infected. The reason for the species specificity is currently unknown. HBV and all genome products are usually under nonpathogenic conditions; therefore, HBV-infected persons produce virus copies in a high concentration without showing clinical symptoms or damage of liver cells. HBV is not directly cytopathic, and liver cells are usually a privileged region of the human body, where immune cells can be unable to attack the infection for months or years or indefinitely. Newborns, children, or immunodeficient patients usually cannot produce efficient immune reactions. Therefore, an asymptomatic infection with a high viral concentration can persist.<sup>39</sup> Chronic HBV infections are defined with the detection of HBsAg or HBV-DNA over a period of six months.<sup>40,41</sup> About 10% of all HBV infections become chronic. Seroconversion from HBeAg to anti-HBe antibodies reduces HBV replication and concentration. Nevertheless, patients with anti-HBe antibodies and HBsAg that sometimes still had a high viral concentration were observed. Patients with a chronic HBV infection are at high risk for liver cirrhosis and liver cancer, approximately 10% for each.<sup>42-45</sup>

After an HBV infection, a liver disease of three different phenotypes may be observed:

- 1 Immunotolerance and high infectivity
- 2 Partial immune control with HBsAg positivity and low-level infectivity
- 3 Natural acquired immunity

The humoral and cellular immune response can depress virus replication in most cases, but the ccc-DNA form of HBV is rarely completely eliminated in the hepatocytes. Therefore, patients infected with HBV can reamplify the virus, especially when their immune situation is changed, such as after immunosuppression. Stopping immunosuppression puts patients at high risk of a severe immune reaction including a fulminant hepatitis B reaction. Liver cell carcinoma develops most frequently in HBV-infected middle-aged patients from Asia and Africa after longtime virus persistence. The probability of liver cell cancer is increased with exposition of aflatoxin or by a coinfection with hepatitis C virus.<sup>46-51</sup>

### **HBV transmissions**

Infected patients contain HBV virus in blood, saliva, semen, breast milk, vaginal, and sore secretions, which all can cause infection by percutaneous or transmucosal route. In high epidemic regions, transmissions from mother to child are important, especially because most child infections have no clinical symptoms.<sup>52-55</sup> The vertical infection from mother to child usually accrued in utero, at the end of pregnancy or during nativity. Transmissions by sexual contact are reported. Contaminated, inefficiently sterilized medical devices like endoscopes are possible infection sources as are personal devices such as toothbrushes, razors, and so on. Also, thorns and branches accidentally contaminated with blood have transmitted HBV during sport activities such as orienteering races.

To prevent transfusion of infections by blood components,<sup>56-59</sup> all blood components are screened in most countries for HBsAg, and blood donations in developed countries are in addition screened by HBV nucleic amplification technique (NAT).<sup>9,60,61</sup> In countries with low epidemic prevalence, anti-HBc screening has been implemented for the detection of chronic infected HBV donors (occult hepatitis infections [OBI]).<sup>35,62,63</sup>

Approximately 50% of the world population has been exposed to HBV. World Health Organization (WHO) estimates that approximately 350 million HBsAg-positive people exist. Major epidemic regions are Africa north of the Sahara, Southeast Asia, and major regions of Russia. Middle risk accrued in Southeast Europe, South America, India, North America, Australia, and Northern, Central, and Western Europe. The prevalence of HBV infection is age dependent, approximately 15% of the world population older than 60 is affected.<sup>64</sup> Although exact data regarding the prevalence of HBV exist, data regarding hepatitis B incidents are still limited or missing. Most patients die due to long-term clinical diseases of liver cirrhosis and liver failure.<sup>65,66</sup>

The clinical symptoms of HBV infection depend on the immunopathogenesis and demonstrate a broad range:

- 1 Light liver damage only detectable by a small increase of transaminases and spontaneous healing. Chronic hepatitis decompensated liver cirrhosis and hepatitis cellular carcinoma are possible if viral replication continues.
- 2 Liver disease with extrahepatic manifestation such as arthritis, exanthema, glomeruli nephritis, and polyarteritis nodosa caused by immune complex with high concentration of HBV.
- 3 Acute hepatitis with high levels of liver enzyme (ALT values grossly increased).
- 4 Fulminant hepatitis with complications of liver cirrhosis and liver carcinoma (less than 1%).

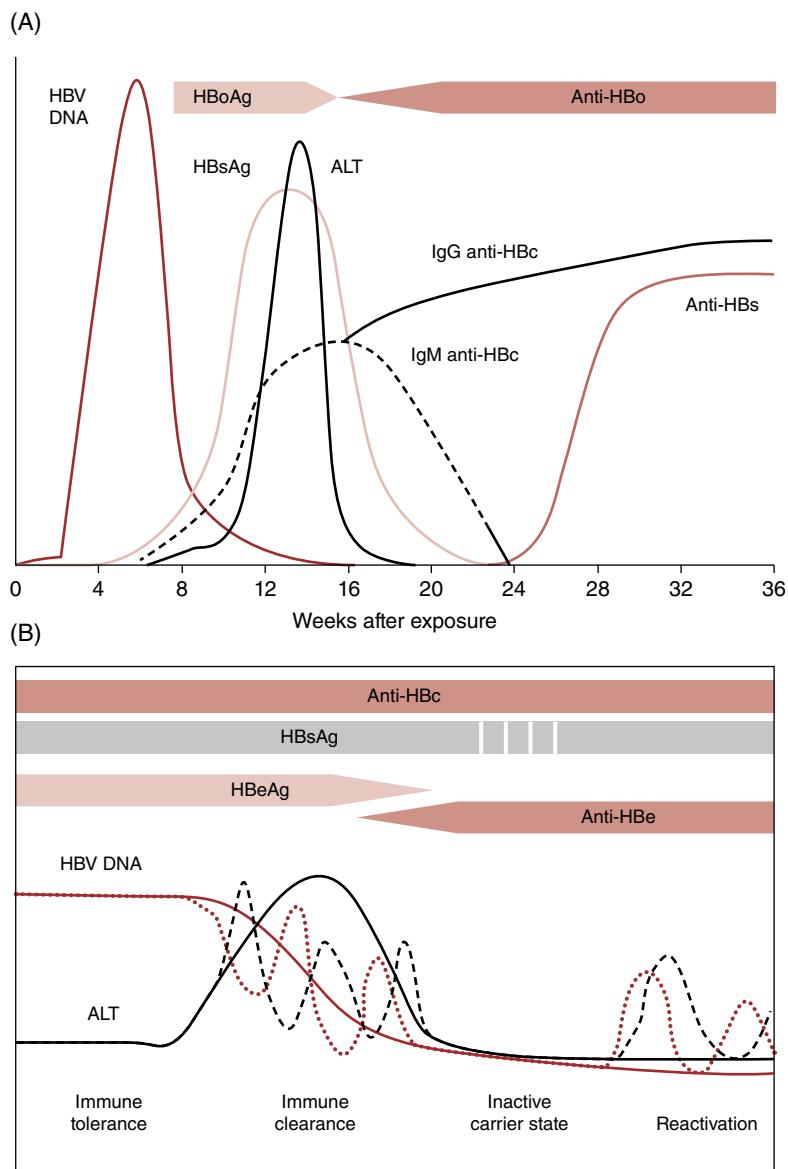

Most cases achieve immunity against HBV within three to six months, but virus replication can continue at a low level over many years. Only highly sensitive NAT assays could detect these low-level carriers (NAT sensitivity should be less than 10 IU/mL). A chronic

HBV infection with only mild symptoms should also be treated, to prevent severe clinical complication such as liver cirrhosis and carcinoma, which can develop after more than 10 years, or to protect others from HBV infections.

### Diagnostic opportunities

Important for HBV diagnostics are HBV antigens (HBsAg and HBeAg), HBV antibodies (Anti-HBc, Anti-HBs, and Anti-HBe) in patient serum and plasma,<sup>63</sup> and HBV detection by NAT,<sup>58,60,67–69</sup> as shown in Figure 44.3.

Finally, histopathological investigations can amend diagnostics of serum/plasma. There is no correlation between the detection of virus parameters (antigens or antibodies) and inflammation activity. Antibodies against HBV, especially anti-HBc, can be detected lifelong in most cases.<sup>24,25,70</sup> The antibody titer against HBsAg (anti-HBs) represents one's immunity status. Vaccinated people should have an anti-HBs titer higher than 100 U/L to have a sufficient response against HBV. Breakthrough infections were reported in the United States with people with a reduced anti-HBs titer of less than 100 U/L.<sup>71,72</sup> The most important parameter is the analysis of

**Figure 44.3** Clinical, serologic, and virologic course of acute and chronic HBV infection. (A) Schematic profile of serologic and virologic markers of a typical acute resolving hepatitis with the average timing of detection of serum HBV DNA, HBsAg, and HBeAg, and their corresponding antibodies, with respect to the ALT elevation reflecting immune-mediated liver cell destruction after HBV replication (as reflected by serum HBV DNA levels) has been mostly controlled by noncytolytic mechanisms. (B) Course of chronic hepatitis B after perinatal or early-childhood-acquired infection. The four distinct phases shown are immune tolerance (high-level HBV replication with normal ALT levels), immune clearance (high ALT level, lower HBV DNA levels, and frequent hepatitis flares, depicted with dashed lines for both HBV DNA and ALT, which may lead to loss of HBsAg and anti-HBe seroconversion), inactive carrier state (normal ALT, presence of anti-HBe, and low or even undetectable HBV DNA), and reactivation phase after many years of inactive carrier state (lower and fluctuating HBV DNA and ALT levels in the presence of anti-HBe), commonly associated with selection of core or precore HBV variant. Reproduced from Figure 46.2 in Alter & Esteban-Mur, Chapter 46, *Ross's Principles of Transfusion Medicine*, 4th Edition.

HBsAg in serum/plasma. Commercial enzyme immunoassays (EIA) for HBsAg are very sensitive (detection limit less than 0.1 ng/mL) and very specific (higher 99.9%). The diagnostic window for HBsAg is approximately 32–38 days.<sup>69,72–74</sup> HBsAg can be detected after vaccination for up to one week in the serum. Recently, the utility of HBsAg testing was questioned, as one study reported that elimination of the testing from the US donor program would have a negligible impact on transfusion transmission of HBV.<sup>75</sup> False negative results due to escape mutants are rare. In some cases, HBsAg will be negative in the acute infection period. Therefore, the detection of hepatitis B should be supplemented by anti-HBc IgM and HBV NAT.<sup>60</sup> Patients with detectable HbsAg for more than six months are considered to have developed a chronic occult hepatitis B infection (OBI).<sup>35</sup> NAT can be positive or negative in OBI patients. The last decade observed improvement in NAT systems, which now have an analytical sensitivity of approx. 2 IU/mL, which represent a diagnostic window of approximately 20 days for HBV infection. Most NAT systems detect HBV, HCV, and HIV-1 simultaneously in a multiplex assay. Therefore, blood donor screening by NAT follows these three parameters, although in some countries, HBV NAT screening is voluntary. As shown by Roth *et al.*,<sup>76</sup> screening of more than 114 million blood donations for HBV by NAT detected 1728 NAT only positive blood donors (negative for HbsAg, Anti-Hbc, anti-HBs, and anti-Hbe). HBV concentration can increase, especially in immunosuppressed patients, up to  $10^{10}$  genome equivalents per mL (geq/mL). In OBIs, the HBV-DNA concentration is reduced to low levels, 1–10 geq/mL, or under the detection limit of the NAT system. The doubling time of HBV in a mouse model is very long, approximately 2.56 days. Therefore, the diagnostic window is much longer compared to hepatitis C (approx. 11 hours) or to HIV-1 (approx. 18 hours).<sup>77</sup>

### HBV therapy

In principle, the eradication of HBV might be possible because the virus infects only the human population and a sufficient vaccine is available. If more than 95% of the human population can be vaccinated, the virus will not be able to survive in order to find nonvaccinated humans. Unfortunately, only monoclonal agents are used for vaccines. They induce an efficient immune protection against genotype A. Therefore, high anti-HBs titers are necessary to protect against other HBV genotypes.

At the end of the 1970s, interferon- $\alpha$  (IFN $\alpha$ ) was detected as efficient against HBV. Treatment with IFN $\alpha$  reduced the viral load within a few days.<sup>78</sup> Unfortunately, it increased again after IFN $\alpha$  therapy was ended. Interferon has nasty flulike side effects; a continuation of therapy can be justified when its antiviral effect is proven by follow-up of HBV DNA. A permanent cure can be assumed if an initially positive HBeAg and HBV NAT has negative six months after the end of therapy. Considerably more tolerable than interferon is the nucleoside analog lamivudine therapy known from the HIV therapy.<sup>79,80</sup> Lamivudine inhibits reverse transcriptase of HBV DNA, causing chain termination. Of special significance is lamivudine for prophylaxis of reinfections after liver transplantation and in case immunosuppression causes HBV reactivation. Nucleoside analogs effective against herpes viruses, such as famciclovir and ganciclovir, have only a small effect on HBV. If the treatment is not perfect or widely applied, the HBV infection can cause liver failure or hepatocellular carcinoma formation. In these cases, a liver transplant might be the only valid therapy, and even then, one must prevent an HBV reinfection of the transplanted organ.

### Keynotes: hepatitis B virus

Virus	Region	Transmission	Screening	Inactivation	Vaccination
Hepadnaviridae, Worldwide DNA, retrovirus, and eight genotypes (A–H)	Blood components, sexual activities, and blood-infected utensils	NAT, antigen (HBsAg) and HbeAg), and AB (anti-HBc, anti-HBe, and anti-HBs)	Possible up to 6 log	Yes, titer should be >100 IU/L	

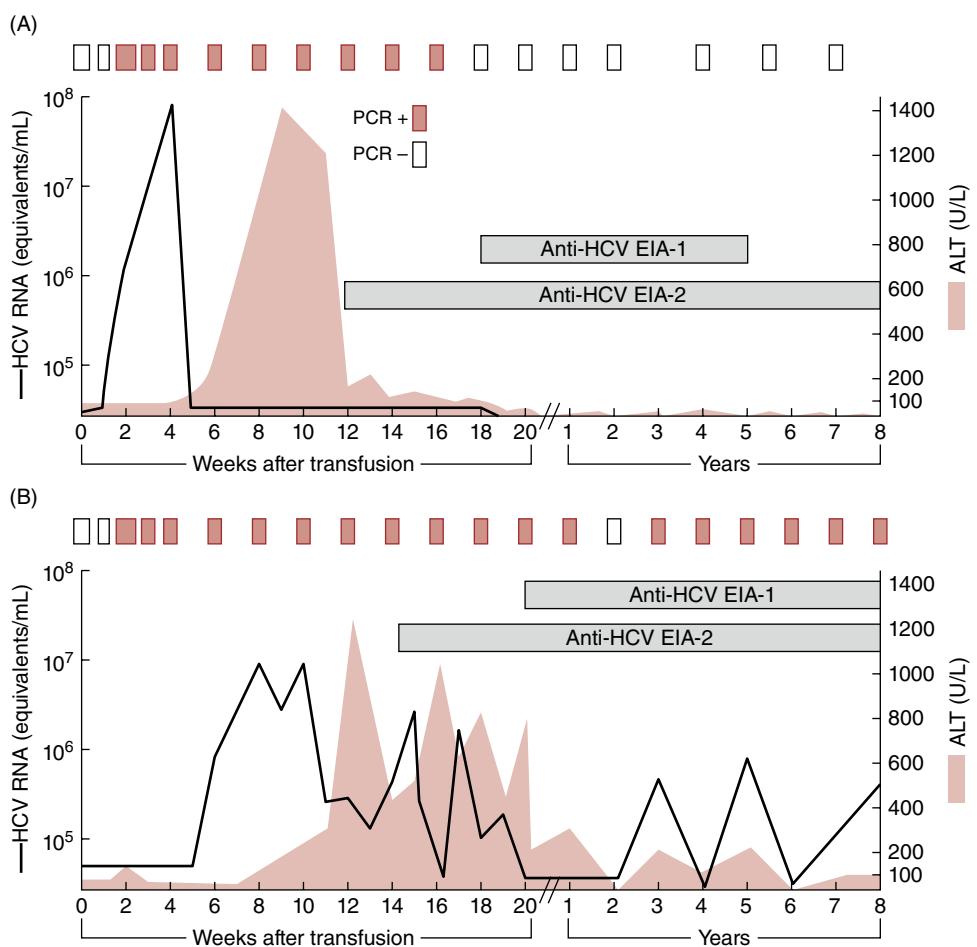

### Hepatitis C virus

The 1989 genetic methods were able to identify hepatitis C virus (HCV), which was shown to be responsible for most blood-borne cases of non-A, non-B (NANB) hepatitis (Figure 44.4). HCV has a genome of approximately 9600 base pairs,<sup>81,82</sup> which is a single-strand RNA (ssRNA) with a plus strand polarity. From the viral RNA, a continuous open reading frame of 3010–3033 amino acids long poly-protein is synthesized. Resulting from a post-translational cellular signal peptidase and two viral proteases, 10 different structural or nonstructural proteins are produced. By sequencing of HCV genome, so far six different genotypes with numerous subtypes can be identified.<sup>83</sup> Due to taxonomic characteristics, the HCV genome belongs to the Flaviviridae family. Worldwide, the incidence of HCV is dropping, approximately 58 million people are currently infected with HCV with about 1.5 million new infections annually.<sup>84–86</sup> Historical epidemiological data indicate a high HCV prevalence in certain risk groups, such as hemophiliacs (60–90%), dialysis patients (30–40%), and intravenous drug users (>80%). Compared to HBV, the risk of HCV transmission through sexual or close family contact is considered low. In approximately 40% of all HCV infections, the transmission pathway cannot be detected. The diagnosis of HCV infection is essentially based on the detection of antibodies against the core protein and the nonstructural proteins NS3 to NS5.<sup>87</sup> However, the presence of antibodies does not provide information about whether a self-limiting or chronic HCV infection occurred. Also, the determination of IgM antibodies cannot differentiate between acute or chronic infection. HCV antibodies usually occur within the transaminase peak of an acute infection which will be in a range of 50–70 days.

The antibodies are stable over 10–15 years after the hepatitis C infection. Screening by NAT and HCV antibodies can differentiate between an acute HCV infection (NAT positive and HCV AB negative) and a chronic HCV disease (NAT positive and HCV AB positive). The quantitative HCV RNA determination is suitable for the control of the antiviral treatment.<sup>88,89</sup>

The efficiency of the HCV antiviral therapy depends on the HCV genotype.<sup>90</sup> Genotype knowledge is essential for recognition of epidemiological correlations and detection of HCV infection chains. The diagnostic window for HCV is long for antibody development, still about 55 days.<sup>91,92</sup> That window could be cut, however, by the introduction of NAT in the blood donor screening. Depending on different NAT methods, the current diagnostic window is between 6 and 8 days if the virus is in the replication process (ramp-up period). Roth *et al.* found, in a worldwide donor screening of more than 300 million investigations,<sup>76</sup> 680 HCV-infected donors with only NAT positive screening.

Hemovigilance data from Germany clearly showed the efficiency of blood donor screening by NAT for HCV (Figure 44.5). Before

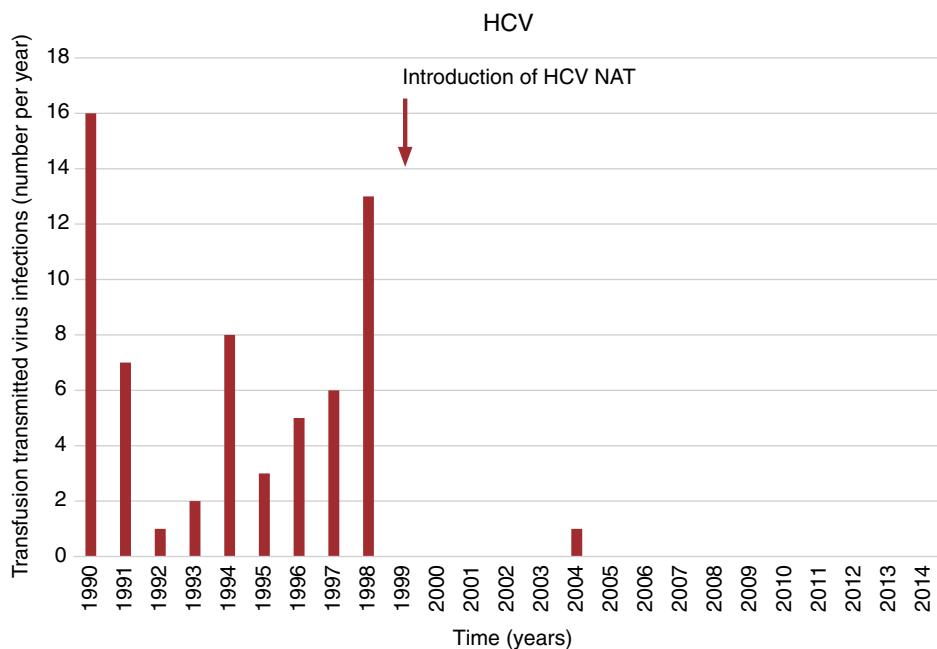

**Figure 44.4** Biochemical, serologic, and molecular biologic profile of acute and chronic transfusion-associated hepatitis C virus (HCV) infection. Acute, resolving hepatitis C is shown in (A) and chronic hepatitis C is shown in (B). Resolving disease cannot be differentiated from progressive disease by the time of onset of detectable HCV RNA by means of polymerase chain reaction (PCR), the magnitude of HCV RNA elevation as measured by means of branched DNA assay, the interval to the first elevation in the level of alanine aminotransferase (ALT), the magnitude of ALT elevation in the acute phase, or the interval between exposure and the first appearance of antibody. Progression to chronic disease cannot be predicted in the acute phase, and the only distinguishing features in these patterns are the persistence of ALT elevation and the persistence of HCV RNA in persons with chronic hepatitis C. The acute, resolving pattern (A) occurs in 10–15% of patients with transfusion-associated hepatitis C and the chronic pattern (B) in 85–90%. Note: (1) HCV RNA is detectable soon after exposure. Here, the PCR results was positive two weeks after exposure, but it can become positive even sooner. (2) HCV RNA may be detected by means of branched DNA assay coincident with PCR reactivity, but the reaction may be delayed, as shown here. (3) The major peak of viral replication (assessed with HCV RNA level) occurs before the first increase in the ALT level and before any clinical or biochemical evidence of hepatitis; it is presumed that persons might be most infectious in this interval before the acute phase. (4) In acute resolving infection, HCV RNA levels increase rapidly before the decline in the serum ALT level. (5) In chronic infection, the HCV RNA level diminishes and can remain low, fluctuate, or become undetectable; HCV RNA levels sometimes show a periodicity that parallels the fluctuations in the ALT level; in (B), the level of HCV RNA increases a short time before the ALT level does and decreases before the decline in ALT. (6) Second-generation anti-HCV assays shorten the seronegative window in HCV infection much more than do first-generation assays; nonetheless, anti-HCV was not detectable for 12–15 weeks after exposure and for six to seven weeks after the first significant rise in the ALT level. Antibody to HCV (detected with second-generation assays) almost always persists in chronic cases and generally persists in acute resolving cases. Antibodies detected with the first-generation assay (anti-C100 and anti-5-1-1) generally disappear in resolving cases. Reproduced from Figure 46.4 in Alter & Esteban-Mur, Chapter 46, *Rossi's Principles of Transfusion Medicine*, 4th Edition.

1999, approximately 6–8 transfusion-transmitted HCV infections were reported annually in Germany. In 1999, all blood donations began to be screened by minipool NAT. Since then, only one additional HCV transmission has occurred, in 2005. The virus concentration in the infective donor was only 10 IU/mL, and below the detection limit of the minipool screening method.<sup>93</sup>

Even a reduction from minipool to individual donation NAT might not have prevented this HCV transmission. Due to the high doubling time in the ramp-up phase of about 11 hours, diagnostic window for HCV differs only about one to two days between blood

donor screening in minipools of 96 samples or testing on an individual NAT basis. The long-disputed question of whether early treatment of acute HCV infections can prevent chronicity of the disease was solved in 2001 when Nakamura *et al.* reported the kinetics of the HCV during interferon therapy.<sup>94</sup> They showed that high concentrations of interferon alpha could prevent a chronic disease.<sup>95</sup> The coupling of interferon with a branched-chain polyethylene glycol molecule (Peg-interferon) leads to a compound with prolonged action compared to unmodified interferon through a longer absorption, a slower clearance, and a correspondingly

**Figure 44.5** HCV transfusion-transmitted infections in Germany. Source: Funk *et al.* Hemovigilance Report 2011, Paul-Ehrlich-Institute, Germany, Frankfurt. Reproduced with permission.

higher half-life.<sup>95–97</sup> In the past several years, numerous oral HCV medications have been approved in the United States, including sofosbuvir, sofosbuvir-velpatasvir, elbasvir-grazoprevir, glecaprevir-pibrentasvir, and ledipasvir-sofosbuvir.<sup>96</sup>

#### Hepatitis D virus infections

Hepatitis D virus was discovered by M. Rizetto 1975 in liver biopsies from patients with chronic hepatitis B infection.<sup>97</sup> By immunofluorescence analysis, he found a new antigen of HBV. At that time, only three were known: HBsAg, HBeAg, and HCcAg. The new antigen was named HBV-D antigen. Later, it was shown that the D-antigen referred to a new hepatitis virus, hepatitis D virus (HDV).<sup>98,99</sup> The D-antigen is embedded in HDV with proteins of HBV. HDV genome contains a small (approximately 1700 bases long), covalently closed, circular, single-stranded RNA that is complementary to itself over a wide range and therefore looks like a partial double-stranded virus.<sup>100–104</sup> Such genomic structure had then been found only in viroids. In addition to this viroid-like behavior, HDV genome segment had a gene that encoded HDAg. HDV are approximately 38 nm large round particles with an HBsAg envelope. HDAg exists in a short form (SHDAg) with 195 amino acids and a longer form (LHDAg) with 214 amino acids. SHDAg is necessary for the regulation of the HDV genome replication, whereas LHDAg inhibits the replication process. LHDAg is required for the translation of the envelope of

HDV ribonucleoprotein. The HDV ribozyme has become an important tool in molecular biology because it can cut RNA molecules precisely. The helper virus HBV essentially determines the host and cell tropism of HDV. HDV can replicate intracellularly without HBV and spread from cell to cell, but cannot develop a complete infection.

Superinfections of HDV in chronic HBV carriers (HDV infection after HBV infection) often lead to persistent chronic HDV infection.<sup>105–107</sup> In coinfecting patients (who have HBV and HDV at the same time), the HDV infection is often mild.<sup>105,108–110</sup> The pathogenicity of HDV is controversial because some studies show a high cytotoxicity of SHDAg, but SHDAg-producing cell cultures are viable. In patients with severe HDV/HBV infection, a microvesicular steatosis is found in liver tissue. Coinfection with HDV and HBV sometimes leads to a biphasic course. Often both viruses multiply in parallel. The HB viremia is reduced by HDV in general. However, the course of acute hepatitis is not necessarily more difficult than for HBV monoinfection. The persistence rate in HBV/HDV coinfections is not increased. HDV superinfection of HBsAg carriers is unfavorable. The HDV genotype is also important for the course of the infection. HDV seems to be dominant in this constellation to HBV. Patients with chronic HDV/HBV infection are three times more likely (60–70%) to develop liver cirrhosis and liver cancer than patients with HBV monoinfection. The overall mortality is about three times higher in superinfected HDV/HBV patients.

HDV virus concentration reaches high levels in the acute infection period:  $10^{11}$  geq/mL (genomic equivalents/mL). In this period, patients are very infectious. In the next phase, the virus titer usually decreases to concentrations of  $10^6$  geq/mL. Prenatal infections are possible if HBV is transmitted. Typical transmission pathways are unsanitary injections (intravenous drug use) and contact with open wounds in tropical regions. Worldwide, approximately 350 million people have HBV, and approximately 12–15 million are coinfecting or superinfected with HDV (relation is 1:23).<sup>111–114</sup> Epidemic areas are the Mediterranean, Southeast and Eastern Europe, Central and East Asia, and local areas in tropical South America and Africa. With intravenous

drug users often coinfections by HDV with HCV and HIV are reported. In many countries, the incidence rate of HDV has decreased. Since blood donations are tested for HBV infections in general, a special screening for HDV for blood products is not required because HDV infections are observed only in conjunction with HBV. The most sensitive and reliable detection of HDV is done by NAT.<sup>115</sup> No antiviremic therapies for HDV yet exist. Its treatment with interferon and/or lamivudine has little effect on its chronicity.<sup>116–119</sup> For fulminant hepatitis D cases with terminal liver failure, a liver transplantation is the final therapeutic approach.<sup>120–122</sup> After transplantation, a graft reinfection with HBV is lower than with HBV mono-infections compared to HDV/HBV infections. When HBV reinfection is suppressed by lamivudine and/or hyperimmune globulin, the overall prognosis is favorable. Otherwise, reinfections of HDV are also possible.

#### Hepatitis E virus infections

In 1980, hepatitis E virus (HEV) infections were first reported in studies of oral–fecal transmitted hepatitis in India.<sup>123</sup> The experimental transmission in nonhuman primates and the virus visualization and characterization became possible in 1983. In the early 1990s, the HEV genome sequenced and serological and molecular screening tests were developed.<sup>124–128</sup> HEV is an ssRNA with a diameter of 32–34 nm. It is a nonenveloped spherical particle with a genetic heterogeneity. The importance of these genetic variants of clinical courses is currently not clear. Type 1 genotype was found in Asia and North Africa, Type 2 was isolated in the United States, Type 3 was found in Europe, and Type 4 was detected in isolates from China and Taiwan. To date, the taxonomic classification of HEV is not entirely clear. Similarities exist to the caliciviruses.<sup>129–131</sup>

HEV is generally transmitted via the fecal–oral route, and mainly through contaminated drinking water. According to WHO, the

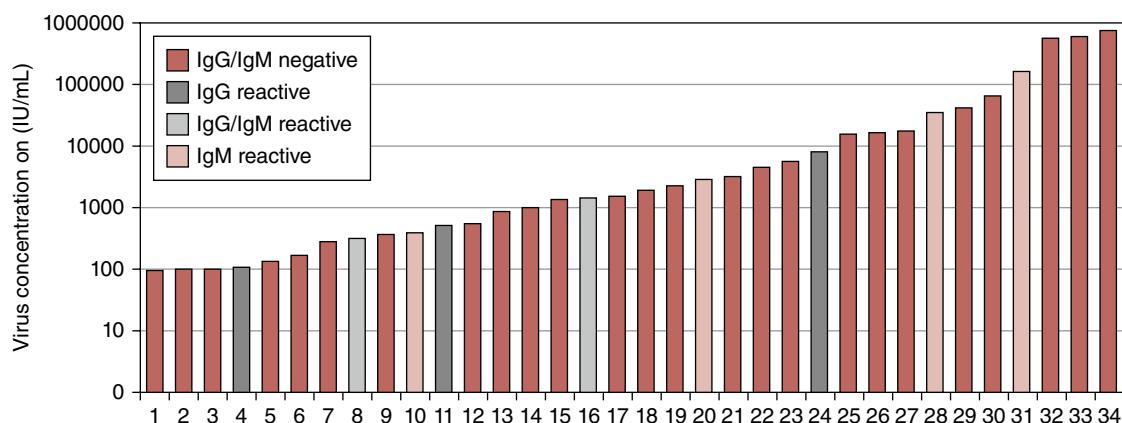

incubation period ranges from three to eight weeks, with a mean of 40 days. The period of communicability is unknown. HEV causes acute sporadic and epidemic hepatitis, which is usually self-limiting. Symptomatic infection is most common in adults between 15 and 40 years. It is frequent in children, but then mostly asymptomatic. In rare cases, fulminant hepatitis with liver failure and death can occur. Severe clinical courses with mortality between 0.5% and 4% mainly occur during pregnancy.<sup>132–135</sup>

WHO estimates 20 million HEV infections, 3 million acute cases of HEV, and 56,000 HEV-related deaths annually worldwide. Highest seroprevalence rates are observed in regions with low development index. WHO estimates indicate that over 60% of all HEV infections and 65% of all HEV related deaths occur in East and South Asia, where seroprevalence rates of 25% are common in some age groups; in Egypt, half of the population aged over five years is serologically positive for HEV. Investigations by Baylis *et al.* show high incidence rates in Japan, the United Kingdom, Germany, and Sweden, between 1:4500 and 1:8500.<sup>136–138</sup> HEV antibodies are usually developed in infected patients after 3–4 months (Figure 44.6). Because neutralizing antibodies' concentration can wane over time, reinfection with HEV might be possible.

In addition to the nutritional infection pathway, HEV transmission by blood products is clearly confirmed in several publications.<sup>3,139–143</sup> However, general blood donor screening for HEV is not universally performed, although some countries, notably Japan, started in 2014 with a 100% blood donor screening for HEV by NAT. Reassuringly, a recent report identified that HEV viremia was only 0.002% in the US source plasma donor population, suggesting that additional mitigation measures may only have a negligible effect on transfusion safety.<sup>144</sup> Pathogen reduction of HEV is limited because the virus is not protein embedded or lipid coated. A licensed vaccine has recently been developed in China.

## Hepatitis F virus

Indian scientists found virus particles that could not associate with the known hepatitis A through E. Therefore, it could be a new standalone virus (hepatitis F) or a mutation and new genotype of the hepatitis B virus. It is believed that hepatitis F can cause liver inflammation. Since the existence of the hepatitis F virus is currently not clearly understood, it is only assumed that the main transmission pathway could equal that of a hepatitis A or hepatitis E infection via the fecal–oral route through contaminated drinking water or food. (Note to reader: Keynotes for hepatitis F are currently not available.)

## Hepatitis G virus/GBV-C

Hepatitis G virus or GBV-C is an enveloped RNA virus and a member of the Flaviviridae family (which also includes HCV).<sup>145–147</sup> The viral genome is similar to HCV in structure but has only 25% homology with it. Several genotypes are reported, mainly restricted to the various continents. GBV-C was discovered in patients with sporadic “non-A, non-B” hepatitis. This led to the conclusion that GBV-C was the cause of viral hepatitis, but further study found it was not, nor did it have any other hepatotropic or pathological role. It was just a “passenger” virus isolated at random. Although parenteral transmission is highly efficient for GBV-C/HGV (58% of recipients of GBV-C/HGV RNA-positive blood products and 32% of aplastic anemia patients), it appears that sexual and vertical transmission are the most common transmission routes.<sup>148</sup>

The prevalence of GBV-C RNA in blood donors ranges from 1% to 5% depending on geographic location. Antibodies, such as anti-E2, are usually three to four times more likely than viral RNA.<sup>149–152</sup> Blood screening is not recommended.

## Retroviruses

Retroviruses are lipid coated and widely distributed in nature, with examples in insects, reptiles, and almost all mammals. There are four main pathogenic human retroviruses—namely, HIV-1 and HIV-2, belonging to the lentivirus group of the retrovirus family, and human T-cell lymphotropic viruses (HTLV-I and HTLV-II) belonging to the oncoa group. It is generally accepted that HTLV-I and HTLV-II evolved from simian T-lymphotropic retroviruses that were transmitted to humans centuries ago. HIV-1 is also thought to have derived from a simian ancestor as simian immunodeficiency viruses are endemic in chimpanzees in Central Africa. HIV-2 originated from sooty mangabey monkeys in West Africa. It is thought that transmission to African natives occurred only over the last century.

Retroviruses are membrane-coated, ssRNA viruses that require the essential enzyme, reverse transcriptase, to transcribe their RNA to complementary double-stranded DNA that will be integrated into the host cell chromosome. The host cell enzymes aid the virus to complete its life cycle by synthesizing virions that bud from the plasma membrane to infect other cells or organisms.

## Lentivirus diseases

Lentiviruses constitute the basis of their genetic features of a subset of the family of retroviruses and are responsible for a variety of neurological and immunological disorders. Typical representatives are visna-maedi virus of sheep (VMV), infectious anemia virus of horses (EIAV), arthritis-encephalitis virus of goats (CAEV), and the immunodeficiency viruses of monkeys (SIV), bovine (BIV), and cats (FIV).

### Human immunodeficiency virus-1

Human pathogenic lentiviruses are the human immunodeficiency viruses of types 1 and 2 (HIV-1 and HIV-2). Due to a distinct genetic entity in the variable Env gene (V3 loop) and the Gag protein (p17), they are subdivided into groups and subtypes. HIV-1 is classified into four groups with a total of 12 known subtypes (Figure 44.7):

- Group M (major): subtypes A–K
- Group O (outlier): subtypes 1 and 2
- Group N (new)
- Group P (pending the identification of further human cases)

In 1983, an unusual accumulation of rare skin tumors (Kaposi's sarcoma), and atypical pneumonia (pneumocystis pneumonia carni, PCP), was observed in homosexual men in the United States.<sup>153–155</sup> It turned out that the cause of these diseases was a reduced cellular immune defense, probably caused by a viral infection. This hypothesis was confirmed in 1983 by Luc Montagnier<sup>156,157</sup> and 1984 by Robert C. Gallo,<sup>158,159</sup> who isolated a novel human retrovirus from affected patients. In addition to the genetic information for the structural proteins, Gag, Pol, and Env genes encoded a number of proteins with regulatory and accessory functions.<sup>160</sup> In HIV-1, the following proteins are included:

- Tat
- Rev
- Nef
- Vif
- Vpr
- Vpu

After activation of the integrated proviral DNA by cellular transcription factors that bind to the 5'-LTR, a de novo synthesis of viral mRNAs starts. These transcripts are spliced twice in the nucleus and transported into the cytoplasm for translation to the regulatory proteins Tat, Rev, and Nef.<sup>161,162</sup> After the splicing process, Tat is transported again into the nucleus and increases the viral RNA synthesis rate by a factor of 100–1000.

The Nef protein can interact with different kinases to bind to the lambda chain of the T-cell receptor and cause a downregulation of the CD4 receptor on the surface of the host cell. Thus, the Nef protein has multiple interactions in signal transduction and in the

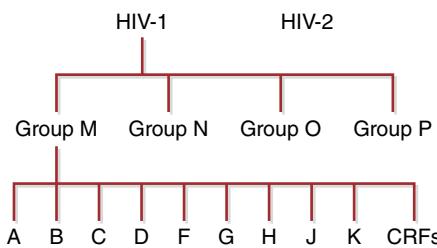

Figure 44.7 Taxonomic of HIV-1 and HIV-2. Source: Prof. M. Schmidt, German Red Cross, Frankfurt. Reproduced with permission.

metabolism of the host cell. Experiments show that HIV-1 can infect a variety of cells: other B lymphocytes, natural killer cells, endothelial cells, megakaryocytes, astrocytes, and glial cells. Nevertheless, CD4 T-lymphocytes, macrophages, and dendritic cells (DCs) are its primary targets. Besides the CD4+ surface marker, which acts as the primary HIV-1 receptor, other coreceptors are necessary for a successful infection. The CCR5 molecule was identified as an HIV-1 coreceptor on CD4+ positive macrophages and dendritic cells.<sup>163,164</sup>

Acquired immunodeficiency syndrome (AIDS) was first described in 1981 in the United States and later in Western Europe as striking at-risk male homosexuals and drug users. These groups were early excluded from blood donation due to indications for transmission of AIDS by blood transfusions.

Indeed, HIV strongly challenged transfusion medicine and the safety of blood products. In addition to blood component recipients, patients with coagulation disorders (hemophilia A and B) were infected in the 1980s (and 1990s) by contaminated factor concentrates.<sup>165–167</sup> This led nations like Germany to classify blood products as medical products, subject to the regulatory requirements of the Medical Act. Even after introduction of highly sensitive blood testing for HIV, lifelong exclusion of men who have sex with men from blood donation persisted for decades. Recently, the FDA has changed its guidance for the first time since 1992, allowing some men who have sex with men to enter the blood donor pool.<sup>168</sup>

Blood products can be screened for antibodies to HIV-1/2, the p24 antigen, and in addition to HIV NAT. Roth *et al.*<sup>148</sup> reported more than 270 million investigations in which 244 samples turned up only NAT positive, preventing HIV-1 transmission by blood components. The diagnostic window depends on the analytical sensitivity of the detection method and is calculated for NAT systems between 6 and 8 days. Despite the high level of blood safety, a calculated residual transfusion HIV-1 infection risk of 0.5–1:1,000,000 remains in the literature. Schmidt *et al.*<sup>169</sup> described an HIV-1 transmission by blood components after introduction of blood screening of HIV-1 by NAT. The cause of the transmission was a false negative HIV-1 NAT test result based on mutations in the primer/probe region of the detection method. The mutations reduced amplification efficiency. In 2012, Chudy *et al.*<sup>170,171</sup> reported further cases with false negative NAT screening results. One case was an HIV-1 transmission by a red blood cell concentrate. The reason for these negative HIV NAT results is that the reverse transcriptase from RNA into cDNA does not have a proofreading function. Errors in transcription are therefore neither registered nor corrected. Blood donor screening for HIV-1 by NAT should be done on a dual target basis, with amplification in at least two independent genome regions, to reduce the risk of mutations in one of the primer/probe areas.

A recent area of emerging concern is regarding the impact of highly active antiretroviral therapy (HAART) on blood donor behavior and education. It has recently been reported that HIV+ individuals on HAART, as well as individuals taking antiviral medication as pre exposure prophylaxis, have been donating blood, potentially increasing the risk of transfusion transmitted HIV.<sup>172</sup> The blood collection industry will need to continue to develop strategies to ensure that donation procedures and testing keep pace with these developments.

### HIV-1 therapy

The current applied antiretroviral therapy (ART) focuses on the inhibition of viral protein reverse transcriptase (RT) and protease (PR).<sup>173–175</sup> Furthermore, various drugs are emerging that pursue

the inhibition of various viral and cellular functions. With the use of a combination therapy (highly active antiretroviral therapy [HAART]), the rate of severe illness has decreased remarkably.

Patient discipline is necessary because drug side effects are frequent. Incomplete medication leads viruses to build up resistance; this leads in time to treatment failure.

### Human immunodeficiency virus-2

Most HIV-2-infected people are living in Central and West Africa. The first case in the United States was reported in 1987.<sup>176</sup> There are eight different subtypes known for HIV-2 (A to H). Subtypes A and B are epidemic. Subtype A is particularly common in West Africa, but also in Angola, Mozambique, Brazil, India, and very limited in Europe or the United States. Subtype B is mainly restricted to West Africa.<sup>177</sup>

HIV-2 is closely related with the simian immunodeficiency virus in sooty mangabeys (*Cercocebus Atys Atys*) (SIVsmm), a species of monkeys that inhabit the forests of the coast of West Africa. Phylogenetic analyses show that the SIVsmm is most related to the two strains of HIV-2, which are connected to spread in humans (A and B HIV-2 groups). SIVsmm is found in sooty mangabeys of the Tai Forest, west of Ivory Coast.

HIV-2 was found to be less pathogenic than HIV-1. The pathomechanism of HIV-2 is not clearly understood, but its transfer rate is much lower than HIV-1. Both infections can lead to AIDS in individual patients, and both viruses can mutate to resist drugs. HIV-2 infections had lower mortality than HIV-1 infections, but coinfection is also possible. The progress of coinfections depends on which virus was first. Coinfection seems to be a growing problem globally as time progresses, with most cases identified in West African countries, but some in the United States.<sup>178,179</sup>

### Human T-cell lymphotropic virus

Human T-cell lymphotropic virus (HTLV-I) was identified and isolated in a Japanese patient in 1978.<sup>180</sup> The virus was found that causes adult T-cell leukemia and lymphoma (ATL) and tropical spastic paraparesis (TSP), which can also be found as HTLV-I-associated myelopathy. The virus is now known worldwide, but endemic in Japan, the Caribbean, South America, and West and

Central Africa, where infection rates are often more than 1%. HTLV-II was originally identified in 1982 in a patient with hairy cell leukemia.<sup>181,182</sup> HTLV-I and HTLV-II show 65% homology. HTLV-II is found in Native American populations and in some populations of injecting drug users.

The overall prevalence in blood donors in the United States is about 9.6/100,000 person years and the incidence is 0.239/100,000. HTLV-II is more common than HTLV-I in blood donors.<sup>183</sup> Current HTLV donor screening tests offered only on antibody detection by ELISA or chemiluminescent (ChLIA). The more sensitive assays use recombinant HTLV proteins in a sandwich assay format. Assays test both HTLV-I and HTLV-II in parallel.

Confirmatory testing of reactive HTLV donation is more complex than a confirmatory test for HIV, in part because of the relatively poor Western blots, which are commercially available. NAT could be an alternative to confirm reactive HTLV-1/HTLV-2 antibody screening results, but no commercial test is currently available.<sup>73,184</sup>

Most British HTLV-positive blood donors have been shown to be of Afro-Caribbean origin or sexual partners of someone Afro-Caribbean origin. Therefore, it is important that sexual partners and other family members are also tested for HTLV in a clinical follow-up.

The diagnostic window for HTLV antibodies is about 51 days. A study by the US transfusion recipients estimated a residual risk of HTLV infections at 1:128,000.<sup>185</sup> In general, transfusion-transmitted infectious risk for HTLV is transmitted by cellular components (leukocytes). Therefore, leukocyte depletion is able to improve blood safety.<sup>186</sup>

Although most HTLV-positive donors show no clinical signs of disease, a small percentage (2–4%) can develop an acute T-cell leukemia (ATL) up to 40 years after infection.<sup>187,188</sup> HTLV-I is also associated with uveitis.

## Flaviviruses

### Dengue virus infections

Dengue virus infections pose a major international public health concern. According to WHO, approximately 2.5 billion people in more than 100 countries are at risk of infection, 50–100 million dengue virus infections occur every year, and approximately 1.25 million people may die due to dengue fever, dengue hemorrhagic fever (DHF), or dengue shock syndrome (DSS).<sup>128,189–191</sup> A very recent study suggests that dengue infections are underreported and that annual infection rates may be even three- to fourfold higher than estimated by the WHO. Dengue fever can therefore be considered to be the most important mosquito-borne viral disease.<sup>192–194</sup> As an arthropod-borne infection, the major transmission pathway occurs by mosquitoes from the *Aedes* genus;<sup>195</sup> however, transmission by blood components or organ transplants has also been documented.<sup>196–198</sup>

Dengue virus is an ssRNA virus belonging to the Flaviviridae family. The mature virion has three structures (core, membrane, and envelope) and seven nonstructural (NS1, NS2a, NS2b, NS3, NS4a, NS4b, and NS5) proteins. There are four serotypes classified according to their immunological properties: DEN-1, DEN-2, DEN-3, and DEN-4.<sup>199–202</sup> The primary vector is *Aedes aegypti*, but other vectors, like *Aedes albopictus* or *Aedes polynesiensis*, are also possible. Female mosquitoes acquire the virus by biting infected humans during the viremic period and become infective after an incubation period of 7–14 days. Subsequently, infected mosquitoes can transmit the virus during every feeding.

Laboratory diagnosis can be carried out using NAT, antibody screening, or dengue antigen tests. The diagnostic window is 3–5 days for IgM antibodies and 2–3 days for NAT.<sup>203,204</sup> The diagnostic window for the NS1 antigen test may also be very short. IgG antibodies are detectable after approximately 9–10 days. Crossreactivity with other flavivirus infections is possible and can be explained by sharing common antigenic epitopes. Commercial NAT systems for blood donor screening are available with a 95% level of detection of 14.9 geq/mL.

Fever is the predominant symptom in adults, whereas people younger than 15 often have asymptomatic infections or an undifferentiated febrile illness with maculopapular rash. Dengue fever (DF) and dengue hemorrhagic fever (DHF) are characterized by severe headaches, sudden onset of high fever, hemorrhagic manifestations, thrombocytopenia, and evidence of plasma leakage. Dengue shock syndrome has a high mortality rate and often acts as a pathway to disseminated intravenous coagulation (DIC). There are no specific antivirals currently available for dengue; therefore, its management is symptomatic and supportive.

In Germany, 594 total imported cases of dengue fever were reported in 2010; 75% were imported from Asia, and 21% came from South and Central America.<sup>205</sup> The last dengue epidemic in Continental Europe occurred from 1927 to 1928 in Greece. Since then, Europe has been the only populated continent without autochthonous dengue virus infections until in 2010, when cases of autochthonous dengue virus infections were reported from southern France and Croatia.<sup>206,207</sup>

In both countries, *Aedes albopictus* mosquitoes have become domestic and were the implicated vectors in the transmission cases. *Aedes albopictus* has become increasingly established in the European Union. It is assumed that the import of mosquito larvae during the transport of car tires, in combination with rising average temperatures in Europe due to climate change, is an important factor of this process.

Today, *Aedes albopictus*, the so-called Asian tiger mosquito, is established in many European countries, such as Greece, Albania, Italy, Croatia, Montenegro, and Spain, and it is spreading further. During mosquito monitoring activities in 2011, *Aedes* species were also detected in the Upper Rhine Valley in Baden-Württemberg.

*Aedes albopictus* is not only a very efficient vector for dengue virus, but also for numerous other arboviruses, such as the Chikungunya virus. Consequently, if travelers with arboviral infections acquired abroad return home, where *Aedes albopictus* has become domestic, there is the risk of causing a local outbreak. Likewise, infected tourists could import infections, as happened during the Chikungunya outbreak in northern Italy in 2007, which was probably caused by a tourist from India.

Although the primary pathway for dengue virus is through the mosquito vector, vertical transmission through intrapartum transmission, nosocomial transmission through needlestick injury,

transmissions by organ and bone marrow transplantation, and transfusion of blood components have all been reported. Even though the diagnostic window is assumed to be very short, asymptomatic donors could be the source of such transmissions. In some cases, however, the differentiation between nonmosquito transmission and mosquito-borne infection is difficult in endemic areas where the vector is widespread.

Transfusion-transmitted dengue virus infection has been confirmed in two cases from Hong Kong and Singapore.<sup>208–212</sup> As a first step to improve blood safety, with regard to dengue virus, many countries have implemented a temporary donor deferral program for travelers returning from highly endemic areas. These deferral strategies might be helpful if only a few donors will be affected (e.g., less than 1%). If more than 5% of the donor population will be involved, there is a high risk of unnecessary donor deferral because donors might not come back, even if the deferral is temporary.

Testing for dengue virus is also an option. In the most recent outbreak of dengue fever on Madeira, in the Atlantic Ocean, Portuguese authorities implemented blood donor screening by NAT for dengue virus RNA. Additionally, an ELISA test for the NS1-antigen of dengue virus is available that allows early detection of an infection. Another approach is the implementation of pathogen-reduction methods.

For Germany, however, the main strategy should be the implementation of strict vector control measures, such as insecticiding and reducing potential breeding sites, in order to avoid the spread of *Aedes* species throughout the country.

#### Keynotes: dengue virus infections

Virus	Region	Transmission	Screening	Inactivation	Vaccination
Flaviviridae, RNA, and genotypes 1–4	Japan, Caribbean, and South America	Vector-transmitted (arbovirus) blood components	NAT and antibody screening	Possible, 4–6 log	Not available

#### West Nile virus infections

The WNV is known since 1937. It has a structure similar to dengue fever virus, and both belong to the genus *Flavivirus* within the family *Flaviviridae*. WNV is an enveloped RNA virus with a positive-sense, single strand of RNA, which is between 11,000 and 12,000 nucleotides long.<sup>213,214</sup> The virus occurs in tropical as well as temperate areas. It mainly infects birds, but can spread to humans, horses, and other mammals.<sup>215,216</sup> The vector of the virus is through mosquitoes of different genera, such as *Culex*, *Aedes*, or *Ochlerotatus*. The European/Asian tiger mosquito, *Aedes albopictus*, can transfer it to human and birds.

From 1999 to 2003, there was a large spread of a new strain (strain New York, lineage 1) of West Nile virus in the United States from the East Coast to the West Coast.<sup>217,218</sup> A huge number of infections, some fatal, led the FDA to mandate blood donor screening for West Nile virus by NAT in 2003. The virus concentration in humans was in a range between  $10^1$  and  $10^5$  geq/mL. Thus, a blood donor screening in small pool sizes (1–8 donations per minipool) was required to reduce the diagnostic window to a minimum of three days.<sup>210,211,219–224</sup> After about 11–12 days, infected patients developed IgM antibodies and got a natural protection against the virus infection. In recent years, the incidence of WNV disease in

Europe increased from year to year (data by ECDC), particularly in Greece, Russia, Hungary, and northern Italy.<sup>225–227</sup> All donors who visited a country with WMV infections have to be deferred from blood donations for 28 days. As an alternative, blood donors can be screened for WNV by NAT with a sensitive method or antibody assays. But the diagnostic window for antibody assays is 11–15 days. Therefore, they are not feasible to detect infected blood donors in the early infection period, and the specificity of the commercial antibody tests is limited. Crossreactivities with other flaviviruses cannot be ruled out.

#### Keynotes: West Nile virus infections

Flaviviridae, RNA and five lineages	USA, Greece, Russia, and Hungary	Vector-transmitted (arbovirus) blood components	NAT and antibody screening	Possible, 4–6 log	Not available

#### Alphavirus infection

##### Chikungunya virus infections

Chikungunya virus (CHIKV) is an enveloped ss (+) RNA virus and belongs to the genus Alphavirus in the family Togaviridae, a group of arboviruses. Infection is mostly transmitted by the bite of arthropods. The pathogen was discovered in 1953.<sup>228</sup> In humans, the virus causes chikungunya fever.<sup>229,230</sup> The virion has a diameter of about 60 nm, making it one of the smaller viruses. It has a length of about 11,700 base pairs that code for 2474 amino acids. The protein NSP4 takes presumably over the function of an RNA polymerase.

Chikungunya occurs in Africa, Asia, and the Indian subcontinent. In 2005/2006, there was a CHIKV epidemic on the island La Réunion, with a total of 270,000 infections (about 35% of the population) and a total of 254 documented, related deaths.<sup>231,232</sup> A year later (2007), an epidemic occurred in northern Italy in Ravenna.<sup>233,234</sup> Here, 197 suspected cases of chikungunya fever were registered. Currently, there is a local epidemic of CHIKV in the Caribbean, Latin America, and the northern part of South America. WHO reports indicate that by October 2014 over 776,000 suspected cases of Chikungunya have been recorded in the Caribbean islands, Latin American countries, and some south American countries.<sup>152</sup> 152 deaths have also been attributed to this disease during the same period. In El Salvador, the Food and Drug Administration reported more than 30,000 suspected cases this year, and about 1700 have been registered in Venezuela.<sup>235–237</sup> Most infections are in the Dominican Republic. According to the reports of the Pan-American Health Organization OPS, CHIKV has spread to at least two dozen countries and territories in the Western Hemisphere since the first case was detected on the Caribbean island of St. Martin at the end of 2013.<sup>238</sup>

Survivors develop usual neutralizing IgG antibodies that protect them from a second infection for their lives. In the early infection period, an asymptomatic viremic phase may occur; therefore, CHIKV epidemics represent a challenge for blood donor services in endemic countries. Blood donor screening can be made by NAT, and the performance characteristics appear to be favorable, either in the detection of CHIKV alone or in combination with DENV or Zika.<sup>239,240</sup>

### Herpesvirus infections

Herpesviruses are spread all over the world and can infect all creatures. Humans are known as the host for various herpesviruses. All human herpesviruses (HHVs) have the ability to rest in tissues after acute infection. Depending on the immune system and stress factors, the replication of herpesviruses can start again and cause a reinfection. Human cytomegalovirus (CMV or HHV-5) is the most transfusion-relevant herpesvirus infection for humans.<sup>241–243</sup> Herpes simplex (HHV-1 and HHV-2) and herpes varicella zoster (HHV-3) have limited target cells, but CMV can manifest itself in many different organs. CMV represents a major challenge in immunosuppressed patients exposed to transfusion therapy. Special patient groups at risk are the following:

- Transplant recipients
- Patients with severe immune deficiency
- Fetuses (intrauterine transfusion)
- CMV-negative pregnant women
- Low-birthweight premature infants and neonates
- Multitransfused patients

It is important to distinguish between CMV infection by serological tests or viral isolation and CMV disease by laboratory evidence of infection in connection with specific symptoms that identify the virus. Most CMV infections are asymptomatic, but high fever, sore throat, and symptoms similar to flu and glandular fever occur. Reactivation of CMV can occur when the immune system is weakened.

The target cells of CMV are monocytes and macrophages. Therefore, leucocyte depletion is effective at reducing residual infection risk. The main infection risk is during childhood or the early adult years via sexual activities. At the age of 40, about 60–70% of all donors in Western Europe have anti-CMV IgG antibodies as a sign of a past CMV infection.

Most blood transfusion services are using ELISA-based assays to test blood for the presence of anti-CMV.<sup>244–249</sup> Hemagglutination assays can detect both classes of antibodies, and some commercial tests can now be performed on automated blood group analyzers (PK7300 systems).

CMV transmission by transfusion is now relatively rare in developed countries, particularly those in which all blood components are leukocyte reduced. It is believed that only 12–62% of CMV-seropositive blood units infect CMV-seronegative recipients depending on the interval to the last seronegative donation.<sup>250</sup> The incubation time of the primary CMV infection varies between four and eight weeks. The residual risk of CMV transmission from properly leukoreduced blood products is difficult to establish with certainty, but is sufficiently low that many transfusion services have abandoned the historical practice of providing CMV seronegative products in favor of leukoreduction.<sup>251</sup>

In marrow transplantation, CMV is one of the most important infections and responsible for about 15% of mortality before the introduction of good antivirals.<sup>252–254</sup>

Antiviral drugs, active against CMV, include ganciclovir, foscarnet, cidofovir, and valacyclovir.<sup>255–258</sup> Drugs may be prescribed for prevention, suppression, or treatment.

Epstein–Barr virus (EBV or HHV-4) is responsible for infectious mononucleosis, Burkitt's lymphoma, and nasopharyngeal cancer, and may also be transmitted by transfusion.<sup>259</sup>

*Human herpesvirus 6* effects (HHV-6) is *roseola infantum* or *sixth disease*—a childhood rash. Primary infection in adults is rare.

*Human herpesvirus 8* (HHV-8) is the causative agent for Kaposi's sarcoma and other tumors such as Castleman disease. Infections with HHV-8 are also associated with polyneuropathy, organomegaly, and endocrinopathy. As with CMV and EBV, HHV-8 appears to cause a persistent infection within the host immune cells.<sup>260–262</sup>

Transfusion-transmitted EBV infections are usually asymptomatic, but some present as infectious mononucleosis with a slight fever, loss of appetite, and nausea. Most HHV-4 infection is benign with a low frequency of disease development.<sup>263–265</sup>

### Parvovirus B19 infections

The parvoviruses still form the only family of viruses whose genome consists of single-strand, linear DNA, and the only known human pathogen is parvovirus B19. It was isolated in 1975 by Yvonne Cossart and employees from blood associated with the clinical picture of erythema infectiosum, also known under the names of *fifth disease* or *slap-cheeked syndrome* in young children.<sup>266–268</sup>

Parvoviruses, as the name indicates, are among the smallest known viruses. The virus capsids have a diameter of only 18–26 nm and are not surrounded by a membrane or an envelope. They have an iso-octahedral structure and consist of 60 capsomeres, which are 95% the structural protein VP2 and 5% VP1 protein. VP2 is identical to the carboxy-terminal region of VP1 sequence. The capsids mediate the absorption of the parvovirus B19 to its target cells. The linear DNA single strands of parvovirus B19 is 5600 bases long. The genome has two large open reading frames: the first location is for the nonstructured protein NS1 (MW 71,000). The protein activates the promoter and has important functions in the replication of virus DNA. Furthermore, after the replication, the protein induces apoptosis of the infected cells. The second reading frame is located in the 5' half of the genome and is coding for the structural proteins VP1 and VP2.

Parvovirus B19 infects erythropoietic precursors<sup>269,270</sup> (red blood cells in different stages of differentiation in the BFU-E [erythrocyte-forming unit], CFU-E [erythrocyte colony-forming unit], and the erythroblasts in the bone marrow, as well as pronormoblasts in the fetal liver) by binding to the P antigen, a glycosphingolipid, which is the membrane receptor on the target cells.<sup>271</sup> Various other cell types also contain this receptor explaining the widespread manifestations of parvovirus B19 infection. Individuals lacking the P blood group antigen are naturally immune to parvovirus B19 infection.

Parvovirus B19 is usually transmitted by droplet infection. In the bloodstream of infected persons, the virus concentration can increase to very high concentrations of  $10^{11}$ – $10^{13}$  geq/mL.<sup>272–275</sup>

Infections by parvovirus B19 mainly occurred in the early childhood. Therefore, 40–50% of adolescents aged 15 years already have virus-specific antibodies. The percentage grows up to 80% at the age of 40, which could explain why few transfusion-transmitted cases are reported.

After parvovirus B19 infection, the body forms IgM and IgG antibodies directed against the capsid proteins VP1 and VP2. The first IgM antibodies appear approximately 6–10 days after infection with B19. From the 12th day, IgG antibodies are detectable. The virus concentration will be diminished under the NAT detection limit within 3–4 weeks after infection in about 80% of all cases. Low B19 virus concentration can be detectable up to 12 months. CD4-positive T lymphocytes are in addition involved in the elimination of B19 virus.

The clinical symptoms of B19 infections are manifold. The course of the infection and severity of the disease depend on the patient's hematological and immunological status. Possible clinical manifestations include acute anemia, arthritis, transient aplastic crisis, chronic arthritis, thrombocytopenia, neutropenia, pure red cell aplasia, hydrops fetalis, pancytopenia, chronic anemia, myocarditis, pericarditis, hepatitis, acute liver failure, meningitis, acute liver failure, uveitis, vasculitis, and pneumonia. About 33% of children have no symptoms.<sup>276–279</sup> Generally, clinical symptoms are mild also. In adults, however, complications can occur, especially in women. In 50% of adults, pains in the small joints of both hands and feet can occur. In immunosuppressed patients, such as those with congenital immunodeficiency, transplant and cancer patients, and HIV-infected persons, parvovirus B19 can cause a long, life-threatening infection persistent over months or years. B19-associated mortality in transplant patients is estimated to be about 7%. Before parvovirus-B19-specific antibodies are formed, large amounts of B19 virus (up to  $10^{13}$  geq/mL) can be detected in the blood.

Despite the high virus concentration, many infections are asymptomatic so that infected people can come to a blood donation and be accepted as donors. The virus may also be present in the final blood components products such as factor VIII and IX in relevant concentrations because chemical or physical pathogen inactivation methods are less efficient since B19 virus has no lipid or protein membranes. Commercial NAT systems are available and should detect all three genotypes of B19 viruses. Some blood transfusion services have introduced screening for plasma products by NAT.<sup>138,280–283</sup> Pools of source plasma for fractionation are only acceptable with less than 10,000 geq/mL of parvovirus B19. This level of activity is ascertained by considering the level of parvovirus antibodies that are also present in the pool and by their ability to neutralize small concentrations of the virus.

At present, there is no effective vaccine against parvovirus B19 or antiviral chemotherapeutic agents for the treatment of the infection.

### Keynotes: parvovirus B19 infections

Virus	Region	Transmission	Screening	Inactivation	Vaccination
Parvovirus B19, DNA, small virus, and three genotypes	Worldwide	Droplets and blood components	NAT antibody screening	Yes, but less efficient	Not available

### Filoviridae

#### Ebola virus infections

Marburg virus (MBG) and Ebola virus (EBOLA) are nonsegmented negative-stranded RNA viruses and belonged to the family of Filoviridae within the order Mononegavirales.<sup>284–286</sup> The species Ebola virus can be subdivided into subspecies from Reston, Sudan, and Zaire. The virions are filamentous and extremely polymorphic. The total length is up to 14 μm compared to the uniform diameter of about 80 nm. The lipid envelope surrounding the nucleocapsid consists of genomic RNA and four structural proteins.

- Nucleoprotein
- Viral structural protein (VP) 30
- Viral structural protein (VP) 35
- Viral polymerase

The viral polymerase controls the transcription and replication in the cytoplasm of the cell. VP 35 appears to be a cofactor of the viral polymerase.<sup>287</sup> The nucleoprotein envelopes the RNA and interacts with VP30, which in the case of Ebola acts as a transcription factor.

Filovirus-related hemorrhagic fever was first diagnosed in 1967 in Europe (Marburg, Frankfurt, and Belgrade). The first patient was a lab worker who had contact with monkeys imported from Uganda (*Cercopithecus aethiops*). A total of 26 primary and six secondary infections were registered, with seven death cases. The Ebola virus hemorrhagic fever was first described in 1976 during two outbreaks in Sudan and the Democratic Republic of Congo (Yambuku).<sup>288,289</sup> A total of 602 cases were registered, and the mortality rate was 88%. The natural hosts are humans and other primates. Experimental hosts, including guinea pigs, hamsters, and mice, are often the primary infection. The initial transmission pathway (zoonosis) is currently unclear. The transmission from humans to humans occurs through close contact with infected people and their excretions (often nosocomial). Sexual, neonatal, and airborne transmissions are possible, but epidemiologically of minor importance. The incubation period is usually between 1 and 21 days.<sup>290,291</sup> Animal studies indicate that Ebola viruses are very infectious, so small viral concentrations might be sufficient to infect new people. The disease progresses with severe clinical symptoms such as high hemorrhagic fever and loss of fluid (up to 10 L/day). Therefore, patients will have numerous medical complications, including renal insufficiency. Secondary bacterial infections can be added. In the acute period, patients need intensive medical care. Since clinical symptoms begin immediately at the time of viremia, Ebola infection is believed to be avoidable through donor deferrals, including travel deferrals to affected regions, as well as routine donor assessment. Asymptomatic infectious patients have not been observed. Of particular importance to medical transfusion is the care of Ebola patients since crossmatching must be carried out under high secu-

rity and safety conditions. A challenge for blood transfusion service is to produce convalescent plasma from patients with neutralizing antibodies against Ebola virus infections, although demand for this service in the future may be lessened by data showing that this therapy is ineffective.

#### Keynotes: Ebola virus infections

Virus	Region	Transmission	Screening	Inactivation	Vaccination
Filoviridae, Ebola virus, and RNA	West Africa	Human-to-human contacts, droplets, and blood products	Commercial NAT available	Probably yes, no data available	Not available

#### Pandemic influenza

Influenza viruses are lipid enveloped negative-stranded RNA viruses of the orthomyxoviridae family. There are three types of influenza virus, A, B, and C, which give rise to each their type of influenza. Influenza C gives few clinical symptoms and infects only humans. Influenza B generally only infects humans, whereas influenza A can infect a number of species. Influenza A and B can cause serious disease and are the two virus types that cause epidemics each winter.

Influenza pandemics are a persistent threat due to frequent mutations in the genetic code of the virus. Therefore, a persistent efficient immune response is not possible. The lethal influenza viruses that have infected humans have so far been managed by the existing public health measures. This was helped by the relative inability of the “bird flu” virus (H5N1) to infect people.<sup>292–294</sup> However, there is concern that eventually a mutation or mixed infection of these deadly viruses will spread into the public. Since there have been a series of bird flu cases in humans involving H5N1, it is assumed that any new influenza threat will probably be closely related. Vaccines have been prepared; but like normal human flu vaccines, they have good efficacy in immunocompetent individuals, but are of limited use to those at highest risk from such a pandemic (the old and the very young). It is believed that transfusion-transmitted influenza is relatively rare but theoretically possible. But the timeframe of an asymptomatic viremia is very limited, probably only a few hours. At the height of each epidemic, the use of blood is probably severely limited because of the cancellation of planned operations, but also because of the shortage of health workers and blood donors. Commercial NAT detection systems are available, but a routine blood donor screening is not recommended. Only in the case of a global pandemic, this question should be raised again to improve blood safety.

#### Keynotes: influenza infections

Virus	Region	Transmission	Screening	Inactivation	Vaccination
Orthomyxo virus, and influenza virus, and RNA	Worldwide	Human-to-human contacts, and human contacts with birds, pigs, and other animal	Antibody screening and commercial NAT available	Possible	Yes, but vaccination has to be updated annually

#### Other viruses

##### Lymphatic choriomeningitis (LCMV)

LCMV was first described in 1931 as one of the main causes of meningitis.<sup>295,296</sup> LCMV is a lipid enveloped ssRNA virus and one of the Arenaviruses. Its main reservoir is mice, but it can infect other animals or humans. Eight solid organ transplants have been infected with LCMV from two organ donors, raising the concern that LCMV can also be a transfusion-transmitted virus.<sup>297,298</sup> A French study found a low prevalence in the blood donor population, suggesting a low risk of transmission. However, the researchers suggest that the history of the last rodent contact should lead to a temporary deferral of potential donors. This could have an important impact on donor deferrals. Based on the low prevalence rate, a general blood donor screening is currently not recommended.

#### Keynotes: lymphatic choriomeningitis virus

Virus	Region	Transmission	Screening	Inactivation	Vaccination
Arenavirus, LCMV, and RNA	World wide	Contacts with rodents and mice, and blood components not proven	In development	No data available	Not available

##### TT virus (TTV)

TTV was discovered in the search for the elusive reason for the smaller (non-C) component of the “non-A to E” post-transfusion hepatitis. The virus was discovered in a post-transfusion hepatitis patient with the initials TT and first reported by T. Nishizawa in 1997.<sup>299,300</sup> TTV is a small (18–50 nm), nonenveloped DNA virus and belongs to the family Anelloviridae. Isolates have been classified into five main clades numbered 1–5. TTV genogroup 3 also includes the eight virus strains known as SENV-A to H.<sup>301</sup> TTV can be transmitted by transfusion and has a prevalence of TTV RNA between 5% and 80%; there are again significant geographical differences in infection rates with higher prevalence in Africa (up to 80%). It is assumed that 50% of African children of one year have been infected with TTV. Sensitive NAT assays demonstrate a high percentage of viral infections in blood donors. The relevance of TTV in transfusion is limited due to the absence of clinical symptoms.

#### Keynotes: TT virus

Virus	Region	Transmission	Screening	Inactivation	Vaccination
Anelloviridae, TTV, and RNA	Worldwide	Blood components possible	In development	No data available	Not available

#### Summary

Blood safety is an important topic in transfusion medicine with subtopics such as prevention of the incorrect blood transfusion,<sup>302</sup> prevention of transfusion-related acute lung injury (TRALI),<sup>303</sup> and of course prevention of transfusion-transmitted virus infections.<sup>304</sup> After the AIDS scandal, blood safety was improved regarding transfusion-relevant viruses such as HIV-1, HBV, and HCV. The introduction of NAT and serological screening assays comprised big milestones in hemovigilance and reduced the residual infectious risk to less than 1:1,000,000 for HIV-1 and HCV.<sup>305</sup>

But viruses are not stable. They change their genetic information and sequence due to mutation pressure. RNA viruses have no proof-reading function for reverse transcriptase. Therefore, risks of mutation within the primer and probe binding region exist and were the cause for several cases of transfusion-transmitted HIV-1 with NAT-negative blood. Therefore, manufacturers of diagnostic assays must be on alert to adapt their system to new genotypes.

Second, people travel the world. A new virus can be spread around the world within 48 hours. Therefore, new pathogens can become relevant for all countries or for some regions like West Nile virus for the United States and probably for Europe within the next years.

Nevertheless, blood safety is a global challenge for all transfusion services. The scientific exchange within international societies is inspiring, and cooperation within WHO is a necessity. Safe blood products should be available on the same safety level to all patients in the world.

## CHAPTER 45

# Transfusion transmission of parasites and prions

Bryan R. Spencer<sup>1</sup> & Paula P. Saá<sup>2</sup>

<sup>1</sup>American Red Cross Scientific Affairs, Dedham, MA, USA

<sup>2</sup>American Red Cross Scientific Affairs, Gaithersburg, MD, USA

### Summary

Blood recipients in the United States (US) face low risk for transfusion of a component contaminated with parasites. Quantifying the risk was historically challenging given several unknown or poorly characterized parameters. Estimates from 15 to 30 years ago suggest one transmission of parasitic infection per million transfusions.<sup>1,2</sup> Enhanced diagnostics and mitigation efforts have delineated the risk while simultaneously reducing it considerably.

A 2009 review of 68 pathogens by the AABB's Transfusion Transmitted Diseases (TTD) Committee<sup>3</sup> identified four protozoan parasites among the agents of greatest concern. For *Babesia microti* and other *Babesia* species, recent data suggest that transfusion transmission was historically undercounted. Screening for *Trypanosoma cruzi*, the etiological agent of Chagas disease, significantly curbed the risk of transmission associated with immigrants from Latin America, while raising questions about autochthonous transmission within the US. Transfusion of malaria parasites continues to be rare, with prevention based on deferral of at-risk donors.

Prions, the causative agent of transmissible spongiform encephalopathies, represent a small but nonzero risk for transfusion recipients, and like parasitic agents require the attention of blood collectors and regulatory authorities. This chapter discusses parasitic and prion agents potentially found in blood donors, associated risks, and strategies for mitigating these risks.

### Babesiosis

Concern for transfusion-transmitted babesiosis (TTB) recently culminated in regulatory guidance in the US after years of documenting expanded transmission and refined estimates of transfusion risk. *B. microti* is primarily responsible for clinical cases and transfusion transmission events in the US, but is one of at least three distinct genotypes transmitted to humans. In Europe, *Babesia divergens* causes most human illness. Multiple *Babesia* species have been documented in Asia, which together with isolated reports from Africa, Australia, and South America indicate the emergence of human babesiosis as a global phenomenon.

Transmitted primarily by ixodid ticks, over 100 species of these intraerythrocytic protozoan parasites infect many vertebrate species

worldwide.<sup>4</sup> *Babesia* infection is often clinically silent, with symptomatic infections more common with advancing age.<sup>5</sup> Clinical infections begin 1–6 weeks following tick bite and are frequently nonspecific, presenting with fever, headache, and myalgias. Risk for severe disease is higher in the elderly, the immunocompromised, and the asplenic; complications include thrombocytopenia, hemolytic anemia, and renal, heart, or respiratory failure.<sup>6</sup> The case fatality rate ranges from 5% to 10% for *B. microti*<sup>6</sup> to 42% for *B. divergens*.<sup>7</sup> That nearly all reported cases of *B. divergens* occurred in asplenic hosts<sup>7</sup> contributes to this disparity.

Human babesiosis is an emerging disease within the US and globally. Since the first US case of human babesiosis in 1966,<sup>8</sup> fewer than 2000 cases were reported over the next four decades, concentrated in seven states considered "endemic" (Massachusetts, Connecticut, New York, Rhode Island, and New Jersey in the Northeast, and Minnesota and Wisconsin in the Upper Midwest).<sup>9</sup> Since babesiosis was made a nationally notifiable disease in 2011, the number of states reporting cases and the number of reported annual cases have doubled (see Table 45.1), reflecting its expanding endemic range.

The primary agent responsible for human babesiosis in the US is *B. microti*. It is transmitted by the black-legged deer tick (*Ixodes scapularis*), the vector of Lyme disease. Heightened awareness and scrutiny, together with increased molecular characterization of patient isolates of *Babesia* parasites, present a complex picture of *Babesia* transmission in nature. *B. microti* is considered a species complex composed of three clades with identical morphology but partly distinct vertebrate hosts and potentially differing levels of pathogenicity for humans.<sup>10</sup> *Babesia duncani*, first recognized in the Western US in the early 1990s, is morphologically identical to *B. microti* but antigenically and genetically distinct.<sup>11</sup> *Babesia* sp. MO1 was originally thought to be the primary European parasite *B. divergens*, but it is distinguished by genetic sequence difference and in vitro characteristics and is often referred to as "divergens-like." Its isolation from asplenic patients in five mostly noncontiguous states (Missouri, Kentucky, Washington, Arkansas, and Michigan) portends future documentation elsewhere.<sup>12–14</sup> Finally, the first human case in Tennessee, found in an immunocompromised hunter with heavy tick exposure, has been characterized as "genetically distinct" from previously identified zoonotic

agents,<sup>15</sup> but detailed characterization of the patient's isolate remains unpublished.<sup>15,16</sup> Outside of *B. microti*, little is known about the geographic distribution, vertebrate reservoirs, tick vectors, or virulence in humans of other *Babesia* species.

A similar picture of increasing complexity is seen elsewhere. In Europe, reports of human babesiosis are rare, with about 50 human cases reported since 1957 and a fatal case in a splenectomized Yugoslav farmer.<sup>7</sup> European cases are mostly attributed to *B. divergens*, a bovine pathogen.<sup>23</sup> Risk for human infection correlates geographically with the presence of infected cattle and areas infested by the *Ixodes ricinus* tick; little is understood about the role that spleen-intact human populations and silent carriage of *B. divergens* might play in terms of TTB risk.<sup>23</sup> A variant isolated from asplenic patients in Italy, Austria, and Germany has been designated *B. venatorum*<sup>7</sup> and is associated with three human cases. Two cases of autochthonous *B. microti* have been identified in Europe, one likely by blood transfusion,<sup>7</sup> although entomologic<sup>24</sup> and serologic<sup>25</sup> evidence suggests that transmission is much more common than recognized.

In Asia, autochthonous human babesiosis has been confirmed in Japan (due to transfusion-acquired *B. microti*-like infection),<sup>26</sup> Taiwan (also *B. microti*-like),<sup>27</sup> and Korea (designated KO1).<sup>28</sup> More than 100 cases have been newly reported from China, in both healthy and immunocompromised populations, primarily from *B. microti* and secondarily from a *B. crassa*-like organism.<sup>29,30</sup> Isolated reports from Africa, Australia, and South America reflect the ubiquity of *Babesia* worldwide.<sup>31</sup>

The two most important characteristics of *B. microti* infection driving transfusion risk are the preponderance of clinically silent infections<sup>32</sup> and the ability of immunocompetent persons to carry infection for lengthy periods.<sup>33</sup> There is little direct evidence for the proportion of infections that are asymptomatic, but one review suggests that one-half of children and one-fourth of immunocompetent adults have no symptoms with *B. microti* infection.<sup>5</sup> Confirming early studies,<sup>33</sup> a large follow-up study in blood donors documented parasite carriage of more than two years in 2 of 56 subjects; across all subjects the median time to PCR-negative sample collection was 4.7 months and 86% had cleared infection within a year's time.<sup>34</sup>

Together with prolonged parasitemia, storage of red cells contributes to year-round risk despite the overwhelming majority of tick-borne cases reported in June through August.<sup>20</sup> In vitro studies indicate that while cold storage reduces viability, some parasites survive storage at 4 °C and remain infective for 21–31 days.<sup>35–37</sup> A review of 162 transfusion cases in the US from 1979 to 2009<sup>22</sup> showed all but 3 were due to *B. microti*. Most occurred in the seven “endemic” states, but 13% occurred in 21 other states due to interstate movement of blood donors or blood components. Overall mortality was 18%, consistent with the advanced age (median age 65) and the compromised immune status of recipients. The median range from transfusion to diagnosis was six weeks but extended up to seven months. Nearly all implicated components were red cells,

with a median storage age at the time of transfusion of 16 days and four cases where red cells were between 35 and 40 days old. Three cases were caused by *B. duncani* and occurred in California and Washington. Subsequent reports show consistency in epidemiologic patterns with several dozen additional cases reported by CDC or blood collectors from 2010 forward.<sup>38,39</sup> Additional transfusion cases of *B. microti* have been documented once each in Canada, Germany, and Japan.<sup>40</sup>

Traditional diagnosis of *Babesia* infection relied on microscopic exam of Giemsa-stained blood films. Serological methods including immunofluorescent assay (IFA) diagnosis are both sensitive and specific for measuring exposure, and automated IFA assays improved throughput.<sup>41</sup> Real-time polymerase chain reaction (PCR) is highly sensitive and a valuable complement to serological methods which has received regulatory licensure.<sup>42–45</sup>

Human babesiosis was historically treated with clindamycin and quinine (CQ), but atovaquone with azithromycin is now the first-line recommendation in the US given the fewer collateral effects.<sup>5</sup> Treatment with CQ continues to be recommended for severe cases. In severe cases, partial or whole blood exchange transfusion might be indicated, especially for severe infections of *B. divergens*.<sup>5</sup>

Until licensure of a screening assay, the prevention of transfusion-transmitted babesiosis long relied on a health history question asking whether the donor ever had babesiosis. In 2019, the US Food and Drug Administration (FDA) released guidance recommending year-round nucleic acid testing (or pathogen reduction) in 14 states at highest risk, plus Washington, DC. A two-year deferral is recommended for NAT-reactive donors as is maintenance of a screening question in areas not performing NAT testing.<sup>46</sup>

As with other protozoan infections, pathogen inactivation methods hold promise in reducing the risk from transfusion-transmitted babesiosis. Photochemical treatments currently under development indicate parasite reductions of 5 logs in whole blood.<sup>47</sup> Equivalent efficacy has been shown in platelets and plasma.<sup>48</sup> Given that transfusion risk of *Babesia* parasites is associated almost entirely with red cell components, eventual regulatory approval of red cell/whole blood pathogen inactivation technologies will be a hallmark milestone in risk mitigation.

## Chagas disease

Risk for transfusion transmission of *Trypanosoma cruzi* infection declined in the United States following the implementation of donor screening in 2007. Concern had grown from the late 1980s forward with documentation of a small number of transfusion transmissions along with recognition of the potentially large human reservoir population of Hispanic residents. Endemic in Central and South America and in Mexico, this protozoan hemoflagellate is transmitted in nature by reduviid bugs or triatomines. These bugs often bite on the face (and hence are called *kissing bugs*) but do not directly inject the parasite in their bite. Rather, the insect vector

deposits the infective metacyclic forms of trypanosomes in its feces during or after the blood meal, which is rubbed into the wound or transferred to susceptible membranes in the eye or mouth by the sleeping host. Triatomids competent for transmitting *T. cruzi* are widespread in the Americas, including in the US, where autochthonous transmission occurs.<sup>49</sup> The agent is readily transmitted by blood transfusion, solid organ transplantation, and congenital transmission.<sup>50</sup> Occasional outbreaks from contaminated food or drinks have been reported, especially in Brazil.<sup>51</sup> Symptoms during the acute phase last four to six weeks and are characterized by fever, malaise, edema of the face, lymphadenopathy, and hepatosplenomegaly.<sup>52</sup> The fatality rate in the acute phase is usually less than 5%, and many cases go unrecognized. During this period, parasites are readily detectable in peripheral blood.<sup>50</sup> The ensuing chronic phase is lifelong, with infections that remain asymptomatic and parasitemia that is low grade and intermittent.<sup>52</sup> Ten to thirty years later, 20–30% of carriers develop serious sequelae involving cardiac and/or digestive features (megacolon and megaesophagus). Chagas is estimated to kill about 14,000 people annually, mostly due to cardiac complications.<sup>53</sup> Acute stage treatment with benznidazole or nifurtimox leads to cure in 80–99% of cases, but treatment during the chronic phase is less effective at eliminating infection. Therapies for slowing disease progression once symptomatic are under active investigation, but indications vary with the patient's age and severity of morbidity.<sup>54,55</sup>

Public health authorities have achieved considerable success in reducing risk and morbidity from Chagas disease. In the 1980s, an estimated 17 million residents of Latin America were infected and 100 million lived in areas with transmission risk; current estimates are roughly 6 million infected and 70 million at risk for insect transmission.<sup>53</sup> Annual incidence of cases has dropped more sharply, from 700,000 new cases annually to 30,000, a 96% decline.<sup>52,53</sup> This success began in 1991 with the Southern Cone Initiative, which sought to eliminate domestic infection by *Triatoma infestans* and to interrupt transfusion transmission through universal donor screening.<sup>56</sup>

The adoption of universal blood screening in Latin American countries dramatically lowered the risk for transfusion transmission in endemic countries. In the 1990s, only 4 of 17 Latin American countries with available data screened all donors, but now all 21 have universal testing.<sup>53</sup> Estimates within the last 20 years were that 2000 transfusion transmissions occurred annually,<sup>57,58</sup> but universal screening using high sensitivity assays<sup>59</sup> suggests a sharply lower risk today.

Clearly, the risk in the United States and other receiving countries of Latin American immigrants depends on their immigrants' risk for acquisition of infection extending decades into the past. Recent census figures estimate that 60.5 million Hispanics live in the US, of whom 37.4 million are of Mexican origin,<sup>60</sup> 5.6 million are Central American, and 4.0 million are of South American origin. Roughly one-third of these residents are foreign born, and more than 25% of them arrived to the US prior to 1990,<sup>60</sup> before the intensification of control programs in endemic countries. Current estimates project that up to 350,000 Hispanic immigrants in the US may be infected with *T. cruzi*.<sup>55</sup> Canada and Australia are estimated to have more than 1000 *T. cruzi*-infected immigrants each,<sup>57</sup> and Europe between 68,000 and 123,000, nearly entirely undiagnosed.<sup>56,61</sup>

Until licensure of a screening test in December 2006, there were seven reported cases of *T. cruzi* transfusion transmission in the United States and Canada,<sup>62</sup> and five cases of transmission associated with solid organ transplantation.<sup>63,64</sup> The actual number of transfusion cases was undoubtedly higher, in that all seven cases

were detected in immunocompromised patients.<sup>65</sup> Although platelet products were implicated in six of these seven events, robust estimates for infectivity of different blood components were not available until recently. Prior estimates of ≈20% risk of transmission from a *T. cruzi*-infected donor were based on studies conducted in endemic countries where the transfusion of fresh whole blood is common.<sup>57</sup> Lookback studies based on large numbers suggest that the risk of transmission by blood is less than 2% overall, ranging from 0% in PRBCs or plasma to 13% in platelets.<sup>65</sup> A higher inoculum of parasites in platelet concentrates compared to plasma and whole blood might partially explain this difference.<sup>66</sup>

The approach for screening blood donors for *T. cruzi* is different in endemic countries with active transmission than those where risk is associated with an immigrant population. All endemic countries in the Americas have adopted universal screening. In nonendemic countries, a recent survey of blood centers from 22 countries showed that 17 countries employed one or more mitigation strategy, with 15 countries using health history questions to identify risk and 10 using *T. cruzi* serology.<sup>67</sup>

In the US, testing following licensure of the first serological screening test clarified the prevalence and distribution of Chagas. A 2009 FDA Blood Products Advisory Committee (BPAC) meeting<sup>68</sup> resulted in an endorsement of selective testing for US donors where one negative donation would qualify a donor for all future donations and also a recommendation to discontinue requiring the health history question on Chagas disease. These recommendations were formalized in guidance issued by the FDA in 2010 and finalized in 2017.<sup>69</sup> An online AABB Chagas Biovigilance network that was in operation from January 2007 to 2019 evaluated more than 2400 confirmed positive cases from 15,000 reactive donations. Cases were widely distributed but concentrated in California, Florida, Texas, and other states with large Hispanic populations.<sup>70</sup>

Interesting findings triggered by investigations of seropositive donors included documentation of several presumed autochthonous cases. Of 11 reduviids found across the southern US, 4 major and 7 minor triatomine species maintain enzootic cycles of *T. cruzi*.<sup>55</sup> Although domestically transmitted cases had previously been documented,<sup>54</sup> they were rare and the number has now increased from 7 to 42.<sup>55,71</sup> Hence, unlike in other countries that have embraced selective testing strategies, risk in the US includes that from local transmission in addition to that from migrants. A study of nine million donations from 2007–2015 identified an overall confirmed-positive prevalence of 1:15,000 (up to 1:2700 in southern California), with only 5 of 585 radioimmunoprecipitation assay-positive donors classified as due to presumed autochthonous transmission.<sup>72</sup> The same report found zero incident cases from six million person-years of follow-up, which together with low estimates of transmissibility from seropositive donors<sup>73</sup> supports the updated guidance from FDA.

Aside from testing, additional options for risk reduction include donor exclusion, pathogen removal, and pathogen inactivation. Exclusion of donors on the basis of residence and travel history in endemic areas is not specific and is feasible only where these donors constitute a small portion of the donor pool. Leukoreduction filters have been shown to lower the concentration of trypanosomes in blood,<sup>74</sup> but at least one case of transfusion transmission in platelets was from a leukoreduced, and irradiated, product.<sup>62</sup> A variety of photochemical treatment methods in platelets,<sup>75</sup> plasma,<sup>76</sup> and red cell components<sup>77,78</sup> all show promise in reducing the parasite load by several logs.

## Malaria

Human malaria is caused by five species of protozoan parasites: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, *Plasmodium ovale*, and *Plasmodium knowlesi*.<sup>79,80</sup> There are ≈229 million clinical cases annually and 400,000 malaria deaths, and it is especially severe among young children in sub-Saharan Africa.<sup>79</sup> Natural infection occurs through the bite of an infective female *Anopheles* mosquito. Parasites are less frequently transmitted through blood transfusion, organ transplant, parenteral exposure, or mother-to-child transmission.<sup>81</sup> The US recorded an average of three cases of transfusion-transmitted malaria (TTM) per year between 1963 and 1989.<sup>82</sup> More recently, there were 14 cases recorded during the 1990s and 11 from 2000 to 2017.<sup>83</sup> The current risk of 1 per 20 million donations compares favorably to historical estimates of 0–2 cases per million donations in nonendemic areas and 50 cases per million in endemic countries.<sup>84</sup>

In malaria-endemic settings, where frequent boosting by infective mosquito bites helps induce and maintain protective immune responses, severe infection is rare for those who survive early childhood.<sup>85</sup> In a nonimmune population, such as in the US, clinical malaria presents as a febrile illness with paroxysms, possibly at regular intervals, with accompanying flulike symptoms. Complications can include severe anemia, hepatic involvement, cerebral alterations, renal failure, and shock.<sup>86</sup> The case fatality rate for malaria is generally low (less than 1% in developed countries)<sup>87,88</sup> but can surpass 10% in recipients of blood products.<sup>82</sup>

Once endemic throughout much of its territory, malaria in the US is now almost exclusively due to imported infections. The most recent year with published surveillance data (2017) reflects a decade-long trend of increasing cases, with 2161.<sup>89</sup> More than 98% were found in US civilians who visited endemic areas and in foreign civilians from endemic countries. A review of TTM in the US from 1963 to 1999 indicates that many of these infections were preventable, with >60% occurring due to deviations from prevailing deferral guidelines.<sup>82</sup> *P. malariae* has a disproportionate effect, accounting for 65% of transfusion cases where donor exclusion guidelines were followed compared to representing only 4% of cases diagnosed in US travelers. This reflects the ability of *P. malariae* to remain at sub-clinical levels for lengthy periods, even up to 40 years.<sup>90</sup> Because malaria parasites from the four primary *Plasmodia* remain viable in blood stored at 4 °C for at least one week, there exists risk from these species,<sup>81</sup> and presumably from *P. knowlesi* as well. *P. falciparum* malaria has been transmitted in blood stored for 19 days.<sup>91</sup> Interval to onset in transfusion cases varies by species, with *P. falciparum* developing in about 10 days, *P. vivax* taking 16 days, and *P. malariae* taking 40 days.<sup>81</sup> Where a donor has been implicated, recent history in the US implicates semi-immune visitors from endemic areas. Over a 40-year period, only one US civilian without previous residence in malaria-endemic countries has been implicated in transfusion transmission, in contrast to 40 former residents of endemic countries.<sup>83</sup>

In the absence of an FDA-approved blood-screening assay, the prevention of TTM in the United States relies on exclusion of presenting donors with elevated risk for malaria infection. The criteria are oriented to determining risk on the basis of prior infection with malaria, prior residence in a malarial country, or recent travel to a malaria risk area. In 2013, the FDA issued new guidance.<sup>92</sup> Continuity of policy included deferral for

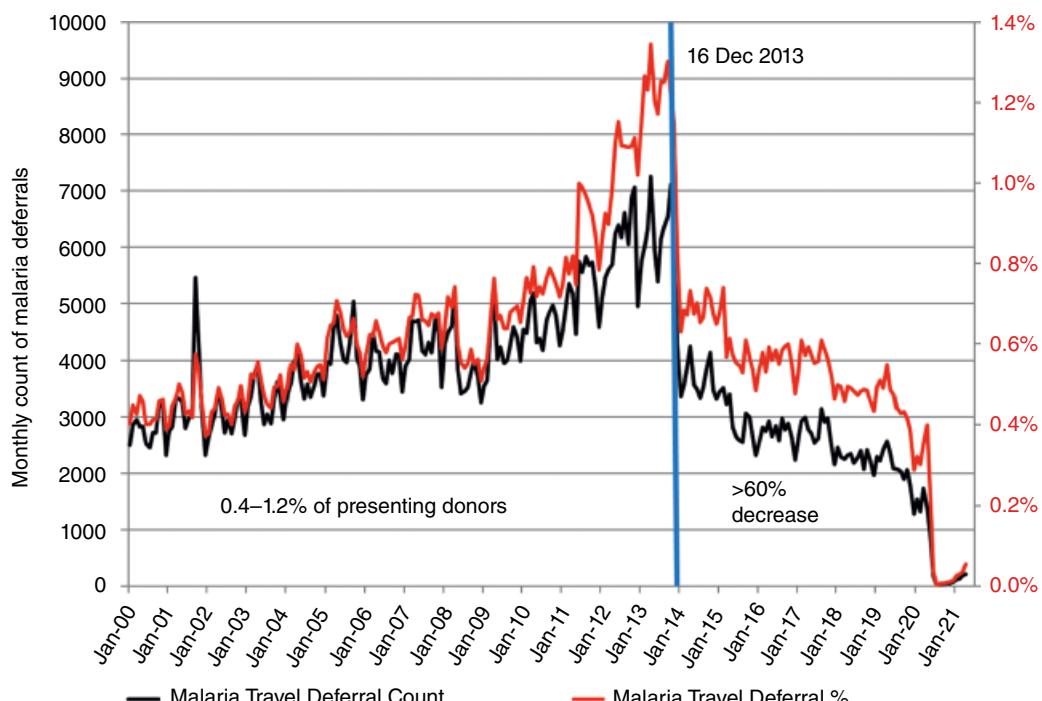

- 1** history of malaria within three years;
- 2** residence in a malaria-endemic country within three years; and
- 3** travel to a malaria-endemic area within one year.

Important clarifications or definitions included the following:

- 1** A *malaria-endemic* area was defined as any area with malaria where CDC recommends antimalarial chemoprophylaxis in travelers in *The Yellow Book*, whereas previously any nonzero risk was considered *endemic*.
- 2** *Travel to a malaria-endemic area* was now defined as travel of duration between 24 hours and 5 years, whereas previously even the briefest exposure—including land travel through a risk area—could trigger deferral.
- 3** *Residence in a malaria-endemic country* was now defined as a continuous stay of longer than five years in a country or countries having any malaria-endemic areas.
- 4** Donors who meet the definition of a *resident in a malaria-endemic country* will be deferred for three years following travel to a malaria-endemic country unless they have lived for three continuous years in a nonendemic country.

These first two changes followed published evidence showing a vanishingly small risk for infection for most donors receiving the one-year travel deferral, but a significant impact on availability equivalent to ≈1% of presenting donors.<sup>93,94</sup> The third change acknowledges the lengthy exposure typically required to acquire partial immunity that allows for asymptomatic carriage, whereas the final change reflects caution against the possibility that partial immunity may be boosted and sustained by return to endemic areas.<sup>85</sup> During the COVID-19 pandemic, an April 2020 update was published that reduced the deferral period to three months for residents of nonendemic countries who traveled to a malaria-endemic country.<sup>95</sup> Figure 45.1 shows the dramatic impact on malaria deferrals from the new guidance in 2013 following implementation at the American Red Cross, compounded further by the COVID-19-related changes in April 2020.

Advances in diagnostics have created opportunities for nonendemic countries to implement strategies that lessen the impact of malaria deferrals while minimizing risk of transfusion transmission. Council of Europe regulations endorse the use of validated serological tests to shorten the deferral period of donors with potential malaria risk who test negative.<sup>96</sup> Donors who lived for six months or more in a malaria-endemic area are acceptable as blood donors if they test antibody negative at least four months after their return from a malaria area. Likewise, donors with less than six months duration in an endemic area can shorten the deferral period from one year if they test antibody negative at least four months after their return.<sup>96</sup> The lengthy use of serological testing in England, France, and Australia indicates a strong safety profile resulting in TTM incidence of approximately 1 per 10–20 million RBC units transfused despite background rates of imported malaria at least fourfold greater than the US (25–40 per million residents, vs. 6 in US). With selective testing algorithms that have been refined over time, donor loss has been kept acceptably small.<sup>97,98</sup> Direct methods for detection of malaria infection include Giemsa- or Wright-stained blood films, although their use is not practical for mass screening in nonendemic areas. Assays detecting circulating parasite antigens such as histidine-rich protein 2 (HRP) and lactate dehydrogenase (LDH) offer sensitivity equivalent to microscopy for *P. falciparum* but are less sensitive for *P. vivax* below a parasite density of 200 parasites per microliter,<sup>86</sup> still insufficient to prevent transfusion transmission. Nucleic acid tests (NATs) have considerably higher sensitivity than microscopy and may be suitable in certain endemic areas,<sup>99</sup> but with an infectious dose as low as 1–10 parasites per unit of blood may not reduce the risk to zero. NAT testing technologies

Unpublished data. Vertical line shows date of implementation of 2013 deferral guidance.<sup>92</sup>

**Figure 45.1** Trends in malaria travel deferrals at American Red Cross, 2000–2021 (Q1).

successfully deployed for *Babesia* might prove suitable to *Plasmodium* as well.<sup>45</sup>

Pathogen reduction technologies have shown promise against *P. falciparum* in both in vitro studies<sup>100</sup> and in a field-based randomized trial in Ghana.<sup>101</sup> While phase 3 trials are in process, no pathogen-reduction platform for red cells or whole blood is licensed in the US.

### Leishmaniasis

*Leishmania* species are protozoan parasites with broad distribution worldwide. *Leishmania* are transmitted in nature by the bite of a female phlebotomine sandfly, but can be transmitted in blood components and, rarely, congenitally or sexually.<sup>102,103</sup> Clinical manifestations can vary widely, ranging from asymptomatic infection to severe illness with visceral, cutaneous, or mucosal involvement. The visceral form (kala-azar) is characterized by fever, wasting, hepatosplenomegaly, and pancytopenia, and if untreated is usually lethal.<sup>103</sup> Cutaneous forms involve progressive skin lesions that become ulcerative, sometimes with mucosal involvement. Although endemic in about 90 countries, the public health burden is hardly uniform. New visceral cases are concentrated in Brazil, South Asia, and East Africa, while the heaviest burden of cutaneous leishmaniasis (CL) is in the Americas, Mediterranean, Middle East, and Central Asia.<sup>104</sup> The World Health Organization estimates that 0.6–1.0 million new cutaneous and 50,000–90,000 visceral leishmaniasis (VL) infections occur annually and 12 million people worldwide are infected.<sup>104</sup> The United States is home to both phlebotomine sandflies and *Leishmania* parasites, but autochthonous transmission is limited to infrequent and isolated outbreaks.<sup>105,106</sup>

The infective form of *Leishmania* parasites in the sandfly is the flagellated promastigote; in humans and other vertebrates, the parasite takes the form of an oval amastigote found in phagocytic vacuoles of macrophages and other mononuclear phagocytes.<sup>103</sup> Diagnostic methods include microscopic visualization of amastigotes in tissue aspirates or biopsies from spleen, bone marrow, or lymph nodes, or in the peripheral blood buffy coat. The duration of parasite circulation in the blood can vary across the >20 *Leishmania* species, but rarely lasts more than one year.<sup>107</sup> The immunological response differs according to the clinical syndrome, with VL leading to a stronger and more enduring antibody production than CL.<sup>108</sup> The conventional treatment of leishmaniasis has been pentavalent antimony, but new strategies include lipid formulations of amphotericin B, injectable paromomycin, and miltefosine.<sup>108</sup>

The risk for transfusion transmission of *Leishmania* may be underreported, with only 14 probable or confirmed cases reported over 60 years.<sup>102,109</sup> About half of the cases were in infants and 80% in children six years old or younger.<sup>109</sup> The average incubation period was over seven months, with fever and hepatosplenomegaly being most common symptoms.<sup>109</sup> Studies from endemic areas and of US military personnel returning from southwest Asia highlight the potential risk. Viscerotropic *L. donovani* and *L. tropica* isolated from US servicemen were shown to survive 25 days in whole blood or PRBCs stored at 4 °C, five days in platelet concentrates at 24 °C, and 35 days in glycerolized RBCs frozen at -70 °C. Further, *L. tropica*-spiked whole blood stored at 4 °C for 30 days retained infectivity to healthy mice. Fresh-frozen plasma did not support parasite survival.<sup>110</sup>

Because transfusion transmission would likely be mistaken for sandfly transmission in endemic areas, and because infection may be subclinical and intermittent in immunocompetent individuals, assessing transfusion risk is difficult. Studies performed on blood donors across Southern Europe and Brazil indicate rates of detectable parasitemia reaching 10% or more,<sup>111</sup> whereas a recent review compiles several reports documenting asymptomatic infection in healthy populations.<sup>112</sup> Numbers of this magnitude suggest that the actual transfusion risk might be higher than indicated by published reports, which represent cases detected in largely immunosuppressed individuals. In contrast, one group in the Balearic Islands has found that despite active surveillance and high prevalence of infection in donors, they have yet to confirm transfusion transmission to patients.<sup>109</sup>

The options to blood banks to prevent distribution of *Leishmania*-contaminated blood are limited. Targeted donor exclusion was practiced selectively in the United States during military operations in Iraq, but the 12-month deferral has been retired. Donors in the US are now currently deferred indirectly via malaria deferral requirements for areas coendemic for malaria. Because serological status correlates poorly with asymptomatic infection,<sup>107</sup> antibody tests hold little promise for donor screening. A recent survey of 28 countries showed that no country employed laboratory testing to mitigate risk, while several employed risk factor questions relating to travel, birth, vector exposure or history of disease.<sup>113</sup> Photochemical inactivation of different *Leishmania* species has shown 4-log reduction of amastigote and promastigote forms in platelets,<sup>114</sup> and another study demonstrated 5-log to 6-log reductions in both platelets and plasma.<sup>115</sup> Another study utilizing riboflavin and ultraviolet light was only partially effective in whole blood, with a 2.3-log reduction in parasite load.<sup>116</sup> Furthermore, the filtration of leukocytes at both the point of collection and the bedside has been shown to dramatically lower free and intracellular *Leishmania* parasites.<sup>117</sup>

## Toxoplasmosis

*Toxoplasma gondii* is an obligate, intracellular protozoan that has felines as a definitive host but can grow in any mammalian or avian organs or tissues.<sup>118</sup> Felines become infected in nature by consuming intermediate rodent hosts with infective *Toxoplasma* cysts in the brain or skeletal muscle. The parasite is ubiquitous in nature and can infect a wide variety of animals, developing into cysts that remain infective for years. Human infection occurs through multiple modes of transmission. Most common are consumption of raw or undercooked meat containing *Toxoplasma* cysts, and accidental ingestion of *T. gondii* oocysts from soil or cat litter contaminated with excreted oocysts. Increasingly, water is implicated as a vehicle for transmission.<sup>118</sup> There are rare reports of infection acquired via solid organ transplantation and blood transfusion.<sup>118</sup> Finally, congenital transmission can occur when the mother acquires primary infection during pregnancy, but the probability of transmission to the fetus depends on the timing of infection.<sup>118</sup>

Up to one-third of the world's population is infected with *T. gondii*. About 90% of primary infections are subclinical, and they appear to be lifelong. Symptomatic infections are usually nonspecific and self-limiting, typically involving fever and isolated swollen lymph nodes. More rarely, infection can lead to myocarditis, pneumonitis, hepatitis, or encephalitis.<sup>118</sup> Toxoplasmosis is often severe

in immunocompromised hosts, and it is a common opportunistic infection of persons with AIDS. Estimates of seroprevalence across countries vary from 10% to 90%, and the acquisition of infection depends on local and household factors that include hygiene and sanitation, source and preparation of food, exposure to felines, and climatic factors influencing the survivability of oocysts in nature.<sup>118</sup> In the US, a representative study from 1999 to 2004 indicated an age-adjusted seroprevalence <10%, with foreign-born residents three times as likely as US-born residents to be antibody-positive, 24.8–8.2%.<sup>119</sup>

Transfusion transmission of toxoplasmosis was reported 50 years ago, in a case where patients with acute leukemia were transfused with leukocytes from donors with chronic myelogenous leukemia.<sup>120</sup> Despite the scarcity of reports of transfusion transmission, the risk is well documented in heart, liver, and kidney recipients.<sup>118</sup> Seroprevalence studies in healthy blood donors indicate antibody prevalence ranging from 7.4% in Durango, Mexico,<sup>121</sup> to 75% in northeastern Brazil.<sup>122</sup> Antibody presence is long-lived and does not necessarily denote infectivity. Little information is available, however, on the long-term kinetics of antibody development and patent parasitemia, and parasite isolation or detection by PCR is generally not useful in immunocompetent patients.<sup>123</sup> The ability of the parasite to survive 50 days at 4 °C<sup>120</sup> and isolated reports of transfusion transmission in the literature both establish an element of risk.

Prevention of transfusion-transmitted toxoplasmosis is not feasible with either donor exclusion or serologic screening.<sup>124</sup> In most places, discarding units from seropositive donors would heavily prejudice blood availability, with unclear indications that positive antibody status of the donor implies risk for parasitemia. In high-prevalence countries, many blood recipients are likely to have been previously exposed. In an immunocompetent recipient, transfusion transmission is likely to go undetected. Given the parasite's ability to readily invade and replicate in leukocytes,<sup>125</sup> leukocyte filtration might diminish the risk in similar fashion as with cytomegalovirus. Whether inactivation treatments being evaluated for other protozoa might be of use for *Toxoplasma* remains unknown.

## Microfilariasis

Filarial worms are arthropod-borne macroparasites that include several different organisms. *Wuchereria bancrofti* and *Brugia* spp. cause lymphatic filariasis; *Loa loa*, *Onchocerca volvulus*, and *Mansonella streptocerca* cause nonlymphatic, subcutaneous filariasis; and *Mansonella ozzardi* and *Mansonella perstans* cause nonlymphatic infections of different body cavities and are typically asymptomatic or mild.<sup>3</sup> The filariases occur in more than 72 countries, and the health and socioeconomic burdens from lymphatic filariasis and *O. volvulus* are particularly severe, with an estimated prevalence of 51 million and 21 million infections, respectively.<sup>126,127</sup> These organisms share similar life cycles and are all transmitted by hematophagous arthropods. In each, adult female worms produce larvae called *microfilaria*, which for most species circulate in the bloodstream, sometimes with periodicity timed to their primary vector's feeding habits. The microfilaria are the infective form for insects, but when transmitted by transfusion they are incapable of propagating further.<sup>128</sup>

The lymphatic forms of filariasis, which cause elephantiasis, have been targeted by the World Health Organization as potentially eradicable, primarily by eliminating the human reservoir of microfilaria that infect the mosquito vectors through repeated mass administration of curative drugs.<sup>126</sup> Estimates indicate a 75% decline in prevalence of human infections, including elimination from several countries and reversing the pathology associated with infection.<sup>127</sup>

There is little published information on the risk for transfusion transmission of filariasis. Limited studies from Nigeria showed prevalence of microfilaria of 3.5% with *Loa loa*,<sup>129</sup> 15.6% with *M. persans* and 1.3% with *L. loa*,<sup>130</sup> and 1.3% with unspecified microfilaria.<sup>131</sup> One report found an American blood donor with microfilaria.<sup>128</sup> Isolated case reports of transfusion transmission exist from Italy<sup>132</sup> and India,<sup>133</sup> in both cases indicating that the outcome in blood recipients might be no more severe than mild allergic reaction to microfilarial antigens. The microfilaria of both *W. bancrofti*<sup>134</sup> and *L. loa*<sup>135</sup> survive routine storage conditions for blood. Those from *M. ozzardi*<sup>136</sup> and from *B. malayi* and *W. bancrofti*<sup>137</sup> have been recovered following cryopreservation. Given the modest clinical consequences even with direct transfusion, most countries appear to consider the risk to blood recipients too small to merit donor or component screening.<sup>138</sup>

### Prion diseases

The term prion was originally coined by S.B. Prusiner to denote a small proteinaceous infectious particle, which is resistant to most procedures that inactivate nucleic acids.<sup>139</sup> Prions are the causative agent of transmissible spongiform encephalopathies (TSEs), a group of fatal neurodegenerative disorders characterized by a long incubation period, short clinical duration, and transmissibility to susceptible mammalian species. Prions can be transmitted through several routes of infection, which determine the length of the silent incubation period in an infected host. Usually, peripheral extra-neuronal exposures result in incubation phases that are longer than direct intracerebral routes. TSEs can cause infections of epidemic proportions in humans (kuru) and animals (bovine spongiform encephalopathy [BSE]) and be endemically present in domestic (scrapie) and wild animals (chronic wasting disease [CWD]).

Human TSEs have different etiologies: sporadic, genetic, and environmental (i.e., infectious). Sporadic Creutzfeldt–Jakob disease (sCJD) is the most common TSE, occurring with a frequency of one case per million people per year worldwide.<sup>140</sup> Genetic TSEs are inherited in an autosomal dominant fashion and are associated with more than 30 pathogenic mutations in the prion protein gene (PRNP);<sup>141</sup> they represent 10–15% of all TSEs and include familial CJD (fCJD), Gerstmann–Sträussler–Scheinker syndrome (GSS), and fatal familial insomnia (FFI).<sup>142,143</sup> The infectious forms include variant CJD (vCJD), resulting from dietary exposure to meat unknowingly sourced from BSE-infected cattle,<sup>144</sup> iatrogenic CJD (iCJD),<sup>145</sup> and kuru, an almost eradicated disease described in cannibalistic tribes of New Guinea.<sup>146,147</sup> iCJD has been linked to therapeutic treatments with human pituitary hormones (growth hormone and gonadotropin), dura mater, cornea or pericardial grafts obtained from CJD-afflicted individuals, and to neurosurgical procedures performed with ineffectively decontaminated instruments previously used on CJD-afflicted patients.<sup>145</sup> The most common TSEs in animals are scrapie in sheep and goat, BSE

(commonly called “mad cow disease”) in cattle, and CWD in cervids. BSE is the only animal form of TSE that has been causatively linked to a human disease, vCJD.<sup>144,148</sup>

TSEs are a clinically heterogeneous group of diseases, each presenting with a distinctive phenotype characterized by differences in the age of onset, clinical symptoms, brain pathology and disease duration, and by different patterns of PrP<sup>TSE</sup> deposition.<sup>140,143,147,149</sup> Polymorphisms in the host PRNP gene influence the phenotypic differences and individual susceptibility to certain forms of the disease<sup>150,151</sup> and partially explain the origin of biochemically distinct PrP<sup>TSE</sup> strains exhibiting a range of strain-specific phenotypes in infected humans<sup>152–154</sup> and animals.<sup>155</sup>

### Molecular mechanisms of prion conversion

These diseases share a common mechanism that involves a conformational change in the structure of the membrane-bound prion protein (PrP<sup>C</sup>) leading to self-replicating propagation and accumulation within the central nervous system (CNS) of a misfolded form, termed PrP<sup>TSE</sup>. Specifically, PrP<sup>TSE</sup> results from conformational changes in the secondary structure of the PrP<sup>C</sup> protein leading to an increase in the proportion of beta-pleated sheet from 3–4% to 40%, and a decrease in the proportion of alpha-helix from 40% to 30%, with the concomitant acquisition of new biochemical properties, namely, insolubility in nonionic detergents and resistance to proteinase K (PK) degradation.<sup>156</sup> This transition occurs under unknown circumstances, but once initiated, PrP<sup>TSE</sup> propagates in a self-catalytic way by imprinting its aberrant conformation onto new molecules of PrP<sup>C</sup> via a seed-mediated polymerization process.<sup>157</sup> Temporal and spatial deposition of PrP<sup>TSE</sup> aggregates, which are devoid of detectable informational nucleic acid,<sup>158</sup> coincide with a series of pathological events in the brain, resulting in spongiform degeneration, neuronal loss, and gliosis (proliferation of glial cells), which constitute the diagnostic markers of these diseases.<sup>159</sup>

### The nature, concentration, and distribution of infectivity in blood and tissues

PrP<sup>C</sup> is a highly conserved cell-membrane sialoglycoprotein that is expressed in all tissues in mammals. In blood, PrP<sup>C</sup> is primarily found in plasma, but it is also present in cellular components, specifically, white blood cells and platelets.<sup>160,161</sup> Our current understanding of the pathogenesis of TSEs is largely predicated on animal studies. Biochemical and biological assays link the accumulation of high concentrations of PrP<sup>TSE</sup> and infectivity in the CNS with the neurodegenerative changes observed in all TSEs. Animal models of peripherally transmitted prion diseases<sup>162,163</sup> point to follicular dendritic cells (FDCs)<sup>164,165</sup> in the germinal centers of lymphoid tissue as the key cell in the establishment of infection, and not B lymphocytes as previously suggested.<sup>166,167</sup> The presence of PrP<sup>TSE</sup> accumulation in the FDCs in tonsil, spleen, and lymph nodes of 89 vCJD-afflicted patients examined postmortem suggests a similar pathophysiology for CJD in humans following primary (e.g., cattle BSE to humans), or secondary, and higher order (human-to-human) transmission.<sup>168</sup> Although less frequently, PrP<sup>TSE</sup> and/or infectivity can also be found in non-neuronal tissues from sCJD patients, including the spleen, muscle,<sup>169</sup> and bone marrow.<sup>170</sup> A survey of 32,441 de-identified archival appendix tissue samples that

had been removed during operations performed in the United Kingdom (UK) between 2000 and 2012 revealed an estimated prevalence of PrP<sup>TSE</sup> accumulation of 1 per 2000. This finding was thought due to exposure of the community to beef contaminated with BSE prions and to indicate a vCJD carrier status in the general population.<sup>171</sup> Multiple studies showed that TSE infectivity and PrP<sup>TSE</sup> are present in the blood of experimental rodents, sheep with scrapie and experimental BSE, and deer affected with chronic wasting disease (CWD).<sup>172–180</sup> PrP<sup>TSE</sup> has been successfully detected in buffy coats and plasma of hamsters and sheep experimentally infected with scrapie,<sup>181–183</sup> as well as in plasma of mice with scrapie and white-tailed deer naturally and experimentally infected with CWD.<sup>184–187</sup>

The exact nature of TSE infectivity in peripheral blood and tissues is uncertain. Likewise, it is still not fully understood in what blood component infectivity and/or PrP<sup>TSE</sup> reside and whether and how blood contributes to the spread of the disease from the periphery to the brain. Recent work in this area, particularly relating to the physicochemical characteristics of the infectious prion in plasma, is of relevance, with one study providing evidence of the presence of PrP<sup>TSE</sup> in plasma-circulating extracellular vesicles (EVs) isolated from the blood of preclinical and clinically sick mice infected with mouse-adapted vCJD,<sup>188</sup> lending additional support to the concept that EVs contribute to the spread of misfolded proteins.<sup>189–194</sup>

The spatial distribution of infectivity also varies between models. Brown *et al.*<sup>195,196</sup> mimicked clinical blood separation processes and demonstrated a four- to fivefold higher concentration of infectivity in the buffy coat (per unit volume) compared to plasma. Gregori *et al.* studied purified blood components and concluded that red cells and platelets have very little infectivity, and that approximately 40% of infectivity is associated with leukocytes, with the remainder residing mostly within the plasma.<sup>197,198</sup> In contrast, studies in sheep<sup>174,199–201</sup> and in humans<sup>202</sup> suggest that infection can be transmitted by all blood components.

The temporal development of infectivity in peripheral tissues during the incubation period is similarly uncertain. In rodent models, a variety of patterns of change in infectivity and PrP<sup>TSE</sup> concentration have been observed.<sup>182,203</sup> In humans, the pattern of development of infectivity in peripheral blood and tissues during CJD infection is unknown, although abnormal PrP has been detected in an appendix sample removed two years before the development of clinical variant CJD.<sup>204</sup>

Overall, the current working assumption is that the level of infectivity in the peripheral blood of donors during the subclinical phase of variant CJD infection is likely to be in the order of 1 ID per unit of infected red cells prior to leukodepletion.<sup>205</sup>

## Transfusion Transmissibility of variant and sporadic CJD

Blood and plasma from sCJD and iCJD patients have been shown to harbor infectivity and cause disease following intracerebral inoculation into animals, including humanized transgenic mice.<sup>202,206,207</sup> Likewise, infectivity was demonstrated to be present in bone marrow isolated from sCJD patients.<sup>170</sup> PrP<sup>TSE</sup> can be detected in whole blood of patients with vCJD,<sup>208–210</sup> and similar levels of PrP<sup>TSE</sup> have been found by Western blot in spleen, tonsils, and lymph nodes of patients afflicted with vCJD and sCJD.<sup>211</sup> Based on the ubiquitous expression of PrP<sup>C</sup> and the accumulation of PrP<sup>TSE</sup> and infectivity in non-neuronal tissues, it was speculated that prion diseases could be

transmitted via blood transfusion. In the UK, vCJD was confirmed in four transfusion recipients of nonleukoreduced red blood cell concentrates prepared from 18 donors who subsequently developed vCJD.<sup>212–214</sup> A hemophilia patient, who died of unrelated causes five years after transfusion, showed PrP<sup>TSE</sup> deposits in lymphoid tissues but not in the brain, and probably represents a case of preclinical or subclinical infection.<sup>215</sup>

The data on peripheral blood infectivity in sCJD are open to interpretation,<sup>216</sup> although recent studies suggest that infectivity can be detected in the peripheral blood of patients with sCJD using transgenic mice overexpressing bovine PrP.<sup>202</sup> Even though experimental evidence indicates that blood from some sCJD patients harbors infectivity, epidemiological data from several case-control<sup>217,218</sup> and lookback studies<sup>219</sup> show no evidence of transfusion-transmission of sCJD. The American Red Cross, in collaboration with the US Centers for Disease Control and Prevention, is conducting a lookback study on the risk of transmission of the nonvariant forms of CJD through blood transfusion. The study has been active since 1995 and recently extended to 2024, with the most recent results published in 2017.<sup>220</sup> At the time of the last report there were 65 CJD donors who gave 1816 components to the blood supply. Eight-hundred and twenty-six traceable recipients were identified for the study. Of these, 27 had insufficient information to track using the National Death Index (NDI) search. Of 799 other recipients, a total of 154 were alive and 645 were deceased. Recipients contributed 3934 person-years of follow-up in the study and no transfusion-transmitted cases of CJD have been recognized.<sup>220</sup> The Transfusion Medicine Epidemiology Review (TMER) study from the UK<sup>219</sup> similarly demonstrates a lack of evidence for transfusion transmission of CJD. Together, these two studies represent more than 5100 person-years of follow-up of patients exposed to blood from donors who subsequently manifested CJD. To date, neither study has found any recipient who has died of CJD. A recent study utilizing the SCANDAT<sup>221</sup> database in Denmark/Sweden added an additional 7617 person-years of follow-up and evaluated potential clusters of sCJD cases among recipients of blood components that could be attributed to a single donor, even if that donor was never diagnosed with sCJD, of importance since TSEs continue to be underdiagnosed and underreported. No aggregation of sCJD cases among blood recipients was found that could be attributed to an individual donor. The results of these three studies strongly demonstrate a lack of evidence for transfusion transmission of sCJD.

## Regulatory measures to reduce the risk of transfusion transmission of sCJD and vCJD

There is currently no donor screening method that can identify individuals who will later develop TSEs. The data summarized above indicate that of all TSEs, vCJD poses the highest risk to the blood supply. In most cases, the likelihood of vCJD in a country that has no BSE in cattle depends upon the extent to which people were either exposed outside the country or consumed BSE-contaminated imported beef products.<sup>222</sup> Therefore, it is essential that measures implemented to reduce TTvCJD be proportionate to the risk.

In Europe, the region with the largest number of vCJD cases, accounting for 220 of the 229 cases worldwide, the current directive as regards technical requirements for blood and blood components recommends that persons who have a family history which places

them at risk of developing a TSE, or persons who have received a corneal or dura mater graft, or who have been treated in the past with medicines made from human pituitary glands be permanently deferred from donating blood. For vCJD, further precautionary measures are recommended.<sup>223</sup> To consider appropriate measures authorities should seek two kinds of information regarding the risk of vCJD:

- Prevalence of BSE infection in native and imported cattle populations and potential BSE agent contamination of products.
- Potential human exposures to the BSE agent.

With respect to plasma-derived medicinal products, recommendations to minimize the risk of transmission are based on the country of residence. As such, residence in the UK is a recognized risk factor for vCJD. Consequently, donors who have spent a cumulative period of one year or more in the UK between 1980 and 1996 are excluded from donating blood/plasma for fractionation. No requirement for leukoreduction of plasma is recommended since animal models fail to provide clear evidence that leukoreduction of plasma significantly reduces the risk of TSE transmission. Moreover, available data indicate that the manufacturing processes for plasma-derived medicinal products would reduce TSE infectivity if present in human plasma.

In the US, the first recommendations to reduce the possible risk of transfusion transmission of sCJD and vCJD by blood and blood products issued by the Food and Drug Administration (FDA) date back to 1987. In its first memorandum, the FDA recommended the deferral of individuals who received human cadaveric pituitary growth hormone injections. Following the publication of the first guidance in 1999, the Transmissible Spongiform Encephalopathy Advisory Committee held several meetings to review the newly published scientific evidence and the risk assessment of donor deferrals and TTvCJD and issue new recommendations, including the following:

- Donor deferral for receipt of human growth hormone (hGH), dura mater transplant, or injection of bovine insulin, the latter since 1980, and the potential risk of iCJD development.
- Donor deferral for having a blood relative with CJD and the potential risk of fCJD development.
- Donor deferral for geographic risk of BSE exposure, including deferral for potential exposure to UK-sourced beef on US military bases, and the associated risk of vCJD development.
- The unproven value of leukoreduction based on experimental data showing that a substantial portion of blood-borne infectivity remained in plasma following filtration.

In April 2020, the FDA released final guidance<sup>224</sup> that takes into consideration the most recent experimental and epidemiological findings highlighted above and data collected using FDA risk assessment models. The main revisions involved changes to deferral recommendations for geographical risk of exposure to BSE prions, including potential exposure to UK-sourced beef on US military bases. Under the new guidance, indefinite deferral is restricted to US donors who spent extended periods of time in the UK, Ireland, and France. Risk-ranking models indicated that this change in deferral combined with voluntary leukoreduction would reduce the TTvCJD risk by 89.3% while allowing blood donations by approximately 100,000 currently deferred donors.<sup>225</sup> Given the absence of reported cases of vCJD among 4.4 million military personnel and civilians who might have ingested UK-sourced beef on US military bases in Europe, the FDA no longer recommends deferral for time spent in US military bases in

Europe. The new guidance also recommends the removal of hGH from the medication deferral list following the determination that the prevalence of patients who may have been treated with hGH extracted from cadaveric pituitary glands among blood donors is very low and the transmission risk is theoretical. Similarly, due to the absence of vCJD cases in recipients of bovine insulin, the FDA allows the removal of this drug from the medication deferral list. Likewise, under the new guidance donors who have a blood relative with CJD are no longer deferred since most cases reported are sCJD and not familial TSEs, and blood relatives of individuals with sCJD are not at increased risk of developing the disease.

A comparison between the numbers of CJD-related deferred blood donors at the American Red Cross a year prior and a year after implementation of the new FDA guidance showed a 47% reduction in donor loss or 3000 more donor presentations. This number represents 3% of the FDA-projected reduction in donor deferral or 7.5% assuming that the American Red Cross collections represent approximately 40% of the US blood supply.

## Summary

The current risk for transfusion transmission of parasites in the United States is not high, but it may be greater than the prevailing estimate of one per million units. Risk for transfusion transmission of *Babesia* was almost certainly higher than one per million preceding regulatory intervention, but year-round NAT testing in areas of highest endemicity curtails the risk considerably. The mobility of both people and blood products implies nonzero risk under a selective testing paradigm. Licensure of *T. cruzi* screening assays has brought the incident risk to near-zero. Silent infection in semi-immune donors constitutes a small but ineradicable risk for malaria transmission in blood products in the absence of serological and nucleic acid screening.

Other parasites with wide global distribution, including *Leishmania* parasites, *Toxoplasma gondii*, and microfilaria, are of scientific interest and theoretical transfusion risk. Concern is insufficient by the general public or competent authorities to mandate specific interventions given the perceived level of risk and attendant benefit in relation to cost.

For prions, compelling epidemiological data from three national studies strongly indicate that the transfusion transmissibility of sCJD remains theoretical. If sCJD is transmissible via blood, it is undoubtedly less infectious than vCJD. Altogether, the data summarized above highlight the relevance of lookback studies to inform policy changes and the importance of continuing surveillance of human prion diseases to ensure the safety of the blood supply.

## Introduction

Bacterial contamination of blood components is a pervasive but often neglected risk of blood transfusion. Historically, public attention has focused disproportionately on transfusion-transmitted viral infections. With improved donor selection (e.g., risk-based deferral) and advances in laboratory screening, the risk of the major transfusion transmitted viruses (e.g., HIV, Hepatitis B [HBV], and C viruses [HCV]) has diminished, at least in the United States (US) and other high-income countries (HICs).<sup>1</sup> Given the reduction of viral transmission via allogeneic blood, the risk of bacterial contamination has emerged as a leading threat to blood transfusion safety. Adoption of routine measures, such as standardized skin preparation, use of diversion pouches, and bacterial culture of platelets in HICs, has interdicted most cases of bacterial contamination of blood products (notably platelets) and associated septic transfusion reactions. Nonetheless, residual risk remains, particularly for platelets. The latter account for the majority of cases of septic transfusion reactions given their associated storage conditions. Recognition of the potential risk posed by bacterial contamination has led to the development and adoption of novel strategies to contend with this risk. This chapter provides an overview of bacterial contamination of blood components with a focus on approaches to minimize or eliminate that risk.

## Bacterial contamination of platelets

### Epidemiology

Sepsis resulting from transfusion of bacterially contaminated platelets is the most common transfusion-transmitted disease. Platelets are stored at room temperature (20–24 °C), making them an excellent growth medium for bacteria. Historically, aerobic culture surveillance studies have demonstrated that 1 in 1000–3000 platelet units were bacterially contaminated.<sup>1</sup> The observed rates of septic transfusion were much lower at approximately 1 in 25,000 platelet units (range 1 in 13,000–100,000).<sup>1</sup>

The reported incidence of contamination widely varies by location, collection type (e.g., apheresis vs. whole blood derived), and the extent to which mitigation measures have been implemented. For example, the Australian Red Cross reported a rate of confirmed culture positive

and indeterminate results of 0.22% for pooled platelets and 0.11% for apheresis units, respectively; by contrast, Canadian Blood Services documented a frequency of 0.09% and 0.04% confirmed-positive results for platelet pools and apheresis units, respectively.<sup>2,3</sup>

The French National Hemovigilance Program utilizing active surveillance in the period 2000–2008 reported rates of sepsis and fatality of ~1:40,000 (24.7 per million) and ~1:200,000 (5.14 per million), respectively.<sup>4</sup> Following the introduction of measures to limit and detect contamination in 2004 in the US, the American Red Cross described an ~70% decline in sepsis reported to their passive surveillance program, with current rates of 1:107,000 for sepsis and 1:1,016,000 for fatalities.<sup>5</sup> From 2014 to 2018, 22 fatalities caused by blood components contaminated with bacteria were reported to the FDA.<sup>6</sup> From 2010 to 2016, the US National Healthcare Safety Network (NHSN) Hemovigilance Module reported rates of septic reactions of 2.5/100,000 and 0.9/100,000 for apheresis and whole-blood-derived platelets, respectively, based on data collected from 195 facilities.<sup>7</sup> In Canada, the Transfusion Transmitted Injuries Surveillance System Programme Report documented 31 transfusion reactions attributed to bacterially contaminated blood components during the period 2014–2018.<sup>8</sup> Since the implementation of platelet screening for bacterial contamination in 2011, the United Kingdom's Serious Hazards of Transfusion (SHOT) program has documented only one confirmed septic transfusion reaction involving contaminated platelets.<sup>9</sup> Nonetheless, even with culture screening in place, Jacobs *et al.* estimated that at least 550 contaminated units are still transfused in the US each year, based on their bacterial testing on the day of transfusion.<sup>10</sup>

### The challenges surrounding case ascertainment and definitions

The true extent of bacterial contamination of blood products is somewhat uncertain. In large part, this is attributed to definition, whereby disparate risks are compared despite being inherently different.<sup>11</sup> Indices that are frequently reported in the literature include the (1) incidence of positive bacterial culture, (2) transfusion of a blood product that was later found to be culture positive, and (3) septic transfusion reactions and (4) deaths attributed to a contaminated blood product. The risk of each of these entities is enormously

variable, is impacted by the environment in which collection and testing is undertaken, the safeguards in place to mitigate that risk (e.g., arm cleaning and diversion pouches), the blood product type (e.g., RBC vs. platelets), the presence of comorbid factors that may mask (e.g., antibiotics) or confound clinical presentation, and the rigor of follow-up investigation to attribute cause. Collectively, these factors impact the imputability of the findings. An attempt to capture the strength of ascertainment is reflected in contemporary hemovigilance modules such as those published by the US Centers for Disease Control and Prevention (CDC), in which imputability is graded from “definite” to “not determined.”<sup>11,12</sup> While classification of risk is improving and estimates are becoming more specific, periodic changes to classification schemas complicate the epidemiology.<sup>11</sup> Bacterial contamination of blood products may occur anytime from collection to transfusion. Independent of the mode or timing of contamination, as well as the identity of the organism, the presence of detectable bacteria should be viewed with extreme caution. One transfusion of a large inoculum of bacteria into a patient poses high risk for severe sequelae. This is particularly the case with platelet transfusion recipients, given overrepresentation of immunosuppressed and critically ill patients in this population. Even bacteria that are typically perceived to be commensal organisms of low virulence have the ability to seed lines and valves.

### Mode of contamination

Platelets pose the major risk of transfusion associated sepsis. The reasons for this include storage at room temperature (20–24 °C) in oxygen permeable bags with agitation for 5–7 days, thus offering excellent growth conditions for many aerobic and facultative bacterial species. Bacteria most commonly enter the collected blood at the time of phlebotomy, whereby the contamination of the needle with skin commensals and contaminants occurs during venipuncture (Table 46.1). More rarely, contamination occurs through blood collection from a donor with asymptomatic donor bacteremia (e.g., with oral or enteric commensals). Investigation of the donors involved in the donation of contaminated components rarely identifies the origin skin commensal organisms such as *Staphylococcus epidermidis* and the aerotolerant anaerobic organism *Cutibacterium acnes*, which are the organisms most often detected as contaminants using culture methods.<sup>13,14</sup> Prior to the introduction of routine culture screening processes, septic fatalities caused by platelet contamination were predominantly caused by enteric Gram-negative organisms.<sup>15</sup> In blood centers where platelet screening is performed using culture systems, the majority of septic transfusion reactions are caused by Gram-positive bacteria.<sup>2,3,7,16,17</sup> Platelet culture is effective in detecting fast growing Gram-negative species; however, Gram-positive bacteria are slower growers and are therefore more likely to be missed.

### External contamination

Very rarely, cases of contamination of the collection bag, tubing, or anticoagulant have occurred due to improper sterilization during manufacturing or contamination of products after collection due to failure of the closed storage system (e.g., defects in the bags or tubing); these have involved environmental contaminants such as *Serratia* spp. and *Acinetobacter* spp.<sup>18,19,21–23</sup> Reports of transfusion reactions involving platelets contaminated with *Acinetobacter calcoaceticus-baumannii* highlight the potential harm associated with external contamination of platelet units. Investigation of two septic transfusion cases involving pathogen-reduced apheresis platelet units contaminated with *Acinetobacter calcoaceticus-baumannii*

**Table 46.1** Bacterial Species Isolated from Platelet Concentrates<sup>2,3,7,16,18–20</sup>

Species	Potential Origin
<b>Gram positive</b>	
<i>Cutibacterium acnes</i>	Skin flora
<i>Propionibacterium</i> spp.	Skin flora
Coagulase negative staphylococci	Skin flora
<i>Staphylococcus aureus</i>	Skin and upper respiratory mucosa
Diphtheroid bacilli	Pharynx, mouth, and skin
<i>Streptococcus pyogenes</i>	Upper respiratory tract, mouth, skin, and GI tract
<i>Streptococcus bovis</i>	Pharynx, skin, GI tract, and female genital tract
<i>Streptococcus agalactiae</i>	GI tract and female genital tract
<i>Streptococcus dysgalactiae</i>	Pharynx, skin, GI tract, and female genital tract
<i>Streptococcus gallolyticus</i>	Alimentary tract of ruminants
<i>Streptococcus viridans</i>	Upper respiratory tract and oral flora
<i>Streptococcus mitis</i>	Upper respiratory tract and oral flora
<i>Gemella</i> spp.	Upper respiratory tract, oral flora, and GI tract
<i>Bacillus cereus</i>	Environment
<i>Clostridium perfringens</i>	GI tract
<i>Lactobacillus</i> spp.	GI tract
<i>Enterococcus faecium</i>	GI tract
<i>Listeria monocytogenes</i>	GI tract
<b>Gram negative</b>	
<i>Serratia marcescens</i>	GI tract
<i>Escherichia coli</i>	GI tract
<i>Morganella morganii</i>	GI tract
<i>Klebsiella pneumoniae</i>	GI tract
<i>Klebsiella oxytoca</i>	GI tract
<i>Citrobacter freundii</i>	GI tract
<i>Salmonella</i> spp.	GI tract
<i>Pseudomonas aeruginosa</i>	Environment
<i>Acinetobacter calcoaceticus-baumannii</i>	Environment

concluded that the contamination occurred after pathogen reduction treatment due to damage of the platelet containers.<sup>18,19</sup> In the US, *Acinetobacter calcoaceticus-baumannii* has been implicated in multiple septic transfusion reaction cases suggesting a common source.<sup>21</sup>

### Adherence to plastics

Common bacterial contaminants of platelets such as *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Serratia* spp. are able to adhere to platelets and to the inner surfaces of platelet containers where they form surface-attached bacterial aggregates (i.e., biofilms) during platelet storage; this results in reduced numbers of bacterial cells in suspension contributing to missed detection during platelet screening.<sup>17</sup> Biofilm-forming *Staphylococcus aureus* and *Staphylococcus epidermidis* have both been implicated in severe septic transfusion reactions.<sup>24,25</sup> Transfusion of biofilm-forming bacteria compounds risk to platelet recipients given their propensity to colonize biomedical devices, coupled with their resistance to antibiotic treatments and clearance by the immune system.<sup>17,26</sup>

### Final guidance to address risk of bacterial contamination of platelets in the United States

In recognition of the residual risk of bacterial contamination of platelets, in 2016 the FDA issued the first of a series of guidance documents offering a variety of approaches to contend with that risk.<sup>27</sup> The guidance document was ultimately finalized in December 2020, recommending implementation occur by October 2021.<sup>28</sup> Broadly, the mitigation strategies are categorized as

single- or two-step processes. Single-step approaches are confined to large volume delayed sampling and pathogen reduction. Under certain conditions, it may be permissible with certain approaches to extend the shelf life of platelets from five to seven days. The latter is very attractive to transfusing facilities as it minimizes the risk of out-dating and associated wastage. The conditions under which extension of shelf life becomes permissible include delayed timing of sampling of the platelet product for culture, increase in the sample volume (i.e.,  $\geq 8$  mL vs.  $\geq 16$  mL), the use of both aerobic and anaerobic bottles for culture (i.e., rather than aerobic bottles alone), and point of release testing. Pathogen-reduced platelets with seven-day storage are not yet FDA approved in the US but are widely used in Europe. Each approach has both advantages and disadvantages; institutions are best positioned to assess their individualized needs, balancing cost, logistical ease, efficiency, and integration into extant workflow.<sup>27</sup> All of the available approaches are nonetheless effective at addressing the residual risk of bacterial contamination of platelets.

### Strategies to reduce the risk of post-transfusion sepsis (Table 46.2)

Approaches to reduce the risk of post-transfusion sepsis can be categorized as follows: (a) reduction of bacterial contamination, (b) preventing exposure to high concentrations of bacteria, (c) improvement in bacterial detection, and (d) elimination of contaminating bacteria.

#### Reduction of bacterial contamination

##### Donor screening

Donors are routinely asked whether they feel well on the day of donation. Their vital signs are also tested (including temperature). Should the donor report a history of a recent infection, any antibiotic regimen must have been completed for donation to be permitted. The phlebotomy site is inspected to ensure that it is clean and without signs of inflammation or infection. Surgical wounds must be healed and dry. Donor screening also includes asking questions regarding general health, recent dental work, and signs of infection. Unfortunately, asking donors about symptoms suggestive of infections offers limited utility, given a lack of specificity for pathology that poses transfusion-associated risk.

##### Skin disinfection

This is an important step since most bacteria that are found in contaminated blood components are either resident or transient skin

flora; this underscores the need for optimal donor skin disinfection. Yet despite excellent technique, absolute sterility during venipuncture is not feasible given that organisms, which are harbored in sebaceous glands and hair follicles cannot be completely removed or killed and skin fragments, which are drawn up into the collection bag during the initial phase of donation, can also provide a source of infectious organisms.<sup>29,30</sup> Scarring or dimpling of the venipuncture site from prior donation has also been recognized as a risk factor for bacterial contamination because these areas frequently are difficult to disinfect.<sup>31</sup>

The effectiveness of skin preparation depends on the type and concentration of the disinfectant solution utilized, the number (generally one or two) and mode (e.g., scrub and swab) of applications, the dwell time during which the skin is exposed to the disinfectant, and the skill of the operator.<sup>32,33</sup> Blood centers have standard procedures that enforce optimal skin disinfection procedures. The AABB Technical Manual recommends a two-stage method involving disinfection of the venipuncture area with a 0.75% povidone-iodine scrub or a 10% povidone-iodine swab stick for a minimum of 30 seconds followed by the application of a 10% povidone-iodine preparation solution, which should stand for at least 30 seconds.<sup>34</sup> The skin of donors who are allergic to iodine is often cleansed with a chlorhexidine or isopropyl alcohol solution.<sup>35</sup> A one-step swab disinfection method (2% chlorhexidine and 70% isopropyl alcohol) is currently used in the US, the UK, Australia, China, and Canada, which has been shown to be as effective as two-step donor skin disinfection methods.<sup>36-40</sup>

##### First aliquot diversion

Diversion of the first 30–40 milliliters of whole blood during blood collection has been shown to reduce the amount of bacterial contamination from the skin, presumably by capturing skin fragments or a shower of bacteria released at the time of phlebotomy. Bruneau *et al.* collected the first and second 15 mL aliquots of 3385 whole blood collections and cultured these under aerobic and anaerobic conditions.<sup>41</sup> Seventy-three of them were positive in the first 15 mL and 21 in the second, including four species not detected in the initial 15 mL. The overall contamination rate was 2.2%, mainly with Gram-positive *Staphylococcus* spp. and *Bacillus* spp. The residual risk of contamination in the collection was 0.6%, demonstrating that diversion could significantly reduce the overall risk. A study from the Netherlands compared the bacterial contamination rates of whole blood collections with and without the removal of the first 10 mL. The diversion of the first 10 mL resulted in a significant decrease in bacterial contamination (18,263 collections with 0.39% contamination without diversion compared with 7115 collections with 0.21% contamination with diversion,  $p < 0.05$ ).<sup>42</sup> Diversion is most effective at interdicting contamination with skin flora. Similarly, investigators at the American Red Cross reported data comparing the rates of confirmed-positive bacterial cultures during one-arm collections, which incorporated inlet-line diversion, and two-arm collections, which did not, on the same apheresis equipment.<sup>14</sup> There was a 2.2-fold higher rate of skin contaminants with the two-arm procedure compared with the one-arm procedure and this difference was apparent only for skin contaminants. Of note, the majority of bacteria-related fatalities are associated with Gram-negative organisms; the latter are not impacted by diversion, i.e., diversion is intended to interdict skin flora that are introduced at time of collection.

**Table 46.2** Mitigation Strategies to Reduce the Incidence of Septic Transfusion Reactions

Time of Application	
<b>(a) Reduction of bacterial contamination</b>	
Donor questionnaire	Prior to blood collection
Donor skin disinfection	Prior to blood collection
Initial aliquot diversion	During blood collection
<b>(b) Preventing exposure to high concentrations of bacteria</b>	
Reduced PC shelf life	Transfuse early in the platelet shelf life
Point of issue testing	Within 24 hours of transfusion
Cold stored platelets	During platelet storage
<b>(c) Improvement in bacterial detection</b>	
PC screening with culture methods	Early in the platelet shelf life
PC screening with rapid testing methods	Late in the platelet shelf life, close to transfusion
<b>(d) Elimination of contaminating bacteria</b>	
Pathogen reduction methods	Early in the platelet shelf life

## Apheresis versus whole-blood-derived platelet concentrates

Therapeutic doses of platelets can be obtained from a single donor using apheresis technology or from whole blood donations. In the case of whole-blood-derived platelets, four to six platelets concentrate from whole blood donations (i.e., representing multiple donors) are pooled to make a therapeutic dose. Apheresis platelet units (i.e., single donor platelets) have been associated with lower rates of bacterial contamination as compared to pooled platelet concentrates due to reduced donor exposure resulting in lower frequency of bacterial contamination per transfusion episode.<sup>2,3,43,44</sup> This is not uniformly the case: Schrezenmeier *et al.* reported rates of bacterial contamination that did not differ significantly between apheresis and pooled buffy-coat platelet concentrates.<sup>45</sup> Interestingly, a comparison of the incidence of bacterial contamination in apheresis platelets collected in different devices showed that the rate of contamination and septic reactions was significantly higher with apheresis units collected with Amicus than with Trima indicating that apheresis collection technology affects the incidence of bacterial contamination in platelet components.<sup>46</sup>

## Bacterial detection

Bacterial contamination of platelet products is typically attributable to initially very low numbers of bacteria, some of which proliferate to high levels during storage. In vitro inoculation experiments confirm that the growth dynamics differ by bacterial species. In one study, bacterial growth characteristics were reported for 165 platelet units, each inoculated on the day of collection with 1–5 colony-forming units (CFU)/mL of one of the following organisms: *B. cereus*, *P. aeruginosa*, *K. pneumoniae*, *S. marcescens*, *S. aureus*, and *S. epidermidis*.<sup>47</sup> By Day 3 following inoculation, all the units that were contaminated with *B. cereus*, *P. aeruginosa*, *K. pneumoniae*, *S. marcescens*, or *S. aureus* had concentrations  $>10^2$  CFU/mL. By Day 4, all units with these organisms contained  $>10^5$  CFU/mL. Units contaminated with *S. epidermidis* exhibited slower and more varied growth. This study concluded that an assay capable of detecting  $10^2$  CFU/mL on Day 3 of storage would detect the vast majority of bacterially contaminated platelet units.

Based on these and similar findings from other studies, sensitive culture techniques that can detect 1–10 CFU/mL are used soon after platelet manufacture, while rapid, less sensitive detection methods are used closer to the time of transfusion. Examples of FDA approved screening systems with high sensitivity and may be used soon after manufacture includes the BACT/ALERT™ 3D and Virtuo Systems (BioMerieux Inc, Durham, NC) and the BACTEC™ System (BD Medical Device Company, Franklin Lakes, NJ). These can theoretically detect as few as a single viable bacterium in a 4–10 mL sample. In practice, they are validated to detect 1–10 CFU/mL of a range of transfusion relevant bacterial strains. In contrast, there are a number of detection systems that detect bacteria directly, such as the FDA-approved PGD™ assay (Verax Biomedical, Worcester, MA) and BacTx® Bacterial Detection Kit (Immunetics Inc.). There are other tests in use or development, including NAT assays, which typically have a lower analytical sensitivity than culture methods ( $\sim 10^2$ – $10^5$  CFU/mL), but may be performed rapidly (1–4 hours) and so are suitable for use close to the time of issue when bacterial concentrations are likely to be higher.

## Bacterial culture

The BACT/ALERT™ 3D and Virtuo systems use an automated liquid culture system that includes culture broth under aerobic or

anaerobic conditions. Each bottle contains a sensor that changes color as a consequence of increasing CO<sub>2</sub> produced by bacterial proliferation. The system monitors both the absolute color change and rate of change of the colorimetric sensor. The method reliably detects contamination of platelets with inocula of 10 CFU/mL and in many cases  $<5$  CFU/mL (e.g., *B. cereus*, *S. marcescens*, *C. perfringens*, *S. epidermidis*, *S. pyogenes*, *E. coli*, *K. pneumoniae*, *S. aureus*, and *viridans streptococci*) in 12–26 hours.<sup>48</sup>

There are several factors that may affect The BACT/ALERT system culture sensitivity including (a) the delay between collection and sampling, (b) the volume of product inoculated into the culture bottle, and (c) the evaluation of both aerobic and anaerobic culture conditions versus aerobic conditions alone.<sup>49</sup> Wagner and Robinette<sup>50</sup> used a model system of platelets contaminated in vitro with *S. epidermidis* or *E. coli* at 10, 1, or 0.1 CFU/mL and then sampled 0, 6, 24, or 48 hours later; 0.5, 1, or 2 mL were inoculated and incubated in 12 BACT/ALERT™ aerobic bottles for each data point. Their results clearly showed that higher initial concentrations, larger sample volumes, and longer delay before sampling were associated with a greater proportion of inoculated bottles signaling positive at any given time point. Their work was subsequently replicated for a wider range of organisms.<sup>48</sup> Various laboratories around the world have implemented the test in different ways (Table 46.3). False-negative screening BACT/ALERT results are either detected following the investigation of transfusion reactions or while performing quality control testing of expired platelet PC components.<sup>6</sup> False-negative results are associated with a low initial bacterial concentration and slow-growing or biofilm-forming organisms.<sup>3,16,51</sup>

The second culture system is the BACTEC automated culture system, which detects production of CO<sub>2</sub> by growing bacteria, which reacts with a fluorescent dye sensor at the bottom of the culture bottles.<sup>73</sup> Spiking studies have demonstrated the ability to detect Gram-positive organisms, including *B. cereus*, *S. aureus*, *S. epidermidis*, *S. agalactiae*, and Gram-negative species—including *E. cloacae*, *E. coli*, *K. oxytoca*, *Serratia marcescens*, and *P. aeruginosa*—at concentrations ranging from  $<1$  to 335 CFU/mL.<sup>74</sup> The system is routinely used in some European countries.<sup>1</sup> It has also been used in a study aimed at evaluating the incidence of bacterially contaminated PCs prior transfusion in a Ugandan Cancer Centre.<sup>75,76</sup> A study performed by Riedel *et al.* showed faster bacterial detection by the BACTEC system compared to the BacT/ALERT system.<sup>77</sup>

## Secondary culture

Primary bacterial culture of platelets has been in use in the United States and other high-income countries for over 15 years. It has been very effective at reducing the risk of contamination and associated septic transfusion reactions. But as described, risk has not been eliminated. Two root causes for cases of contamination escaping detection are the low inoculum at the time of sampling and insufficient time to allow growth, particularly for slow growing organisms. To contend with the residual risk of bacterial contamination, one approach that has been adopted at selected hospitals is secondary culture, whereby the unit of platelets is sampled at time of receipt at the transfusing institution.<sup>52</sup> This optimizes the probability of detection should there be contamination given the added 2–3-day interval between the donation and secondary sampling. In one institution, the investigators observed no cases of septic transfusion reactions in the three years following implementation.<sup>53</sup> By contrast, in the 13-month period prior to the implementation of secondary culture, there were a total of seven culture positive

\* Universal PR is mandated.

transfusion reactions, including one life-threatening event and one fatality.<sup>52</sup> Secondary culture has been included in the final FDA guidance document pertaining to bacterial control.<sup>28</sup> Secondary culture can be integrated into routine workflow using microbiology instrumentation that is commonly available in hospitals. The approach also allows for seven-day expiration if sampling is performed on Day 4 and both aerobic and anaerobic cultures are inoculated. The costs of secondary culture are also lower than those associated with other approaches that have been proposed to contend with residual risk.<sup>54,55</sup> Nonetheless, secondary bacterial culture has not been adopted widely. In part, this may be ascribed to the burden being placed on the transfusing facility where most might prefer the simplicity of pathogen reduction or high-volume delayed sampling that are undertaken by the collection center. Secondary bacterial culture with a five-day expiration, as outlined by the FDA, requires an incubation period to be defined by the transfusing institution. Of note, in published reports of use, no quarantine was applied following sampling such that when cultures turned positive, transfusion had already transpired in some cases, albeit without observed adverse clinical effect.<sup>53</sup>

### Large volume delayed sampling

In 2011, the National Health System Blood and Transplant (NHSBT) service in the UK adopted a large volume delayed sampling approach with platelet sampling performed at ≥36 hours post blood collection with inoculation of both aerobic and anaerobic culture bottles.<sup>9,17</sup> Using this approach, which remains in effect, platelet products are quarantined for at least six hours after sampling. Implementation of this testing algorithm has significantly reduced the incidence of septic transfusion reactions. A similar approach was adopted by Canadian Blood Services with extension of platelet storage from 5 to 7 days, demonstrating that the LVDS protocol has improved platelet safety. Héma-Québec has also implemented a more stringent LVDS protocol to screen platelets with sampling performed at 48 hours post blood collection and holding of units at least 12 hours post sampling.<sup>56</sup> Theoretical calculations suggest that doubling the sample volume may increase the proportion of contaminated products detected by as much as 25%, and Eder *et al.* found that BACT/ALERT™ culture was 1.54-fold (1.05–2.27) more likely to detect bacteria using an 8 mL sample versus a 4 mL sample.<sup>14,57</sup> Further theoretical calculations have been provided by Tomasulo and Wagner who advocate the use of a sample size that is a constant proportion of the product volume, in order to standardize the sensitivity of

the assay for single, double, and triple collections.<sup>58</sup> Despite a theoretical concern that larger volume products may be less safe if standard sampling volumes are applied, (i.e., a smaller proportion of the product is sampled), Eder *et al.* reported no difference in the septic transfusion reaction rates between single, double, and triple collections.<sup>59</sup> The downside of increased volume inoculation is the loss of product volume for transfusion and decreased splits rates for multiple component collections.

### Aerobic versus anaerobic culture conditions

Many centers inoculate both aerobic and anaerobic culture bottles in order to maximize culture sensitivity. Most clinically relevant bacteria that contaminate platelets grow under both conditions, although specific strains may grow faster in one condition than the other. This was best demonstrated for a single strain of *Streptococcus lugdenensis* implicated in a fatal transfusion reaction.<sup>60</sup> A small number of species are obligate aerobes (e.g., *Pseudomonas fluorescens*) or obligate anaerobes (e.g., *Clostridium* spp.). Utilizing both aerobic and anaerobic conditions enables the detection of a complete range of species, speeds up detection of some strains, and doubles the volume of product cultured, thereby increasing the sensitivity of the overall detection system.<sup>61,62</sup>

Even under optimal conditions that include both aerobic and anaerobic cultures, false-negative screening results continue to occur. Evaluation of outdated cultures suggests that only 25–40% of contaminated products are intercepted, thus accounting for reported septic reactions.<sup>70–72</sup> While culture screening has significantly reduced the risk of bacterial sepsis, especially for Gram-negative organisms, absolute protection from contamination has yet to be attained. Bacterial screening is also logistically burdensome, delaying product release into inventory. Further, there is product loss due to sampling especially when large volumes are used, and there is need for product recalls when culture screenings turn reactive after components are distributed to hospitals. Individual users have optimized the conditions of the culture assay to maximize analytical sensitivity while minimizing impact on logistics and blood availability, leading to the many different approaches as shown in Table 46.3.

### Point of care immunoassays

In September 2007, the FDA approved a rapid immunoassay for the detection of aerobic and anaerobic bacteria in leukocyte-reduced apheresis platelets as an adjunct quality control device. The Platelet PGD™ Test (Verax Biomedical, Worcester, MA) is a qualitative

immunoassay that differentiates between Gram-negative and Gram-positive bacteria through the detection of lipopolysaccharides (LPS) and lipoteichoic acid (LTA), respectively.<sup>10</sup> As approved, it is intended to be an adjunct safety test for leukocyte-reduced apheresis platelets; testing is required within 24 hours of transfusion, after the use of an FDA-cleared bacterial culture method at the time of manufacture. The system is also approved as a quality control test for pooled WBD platelets within four hours of transfusion. In this case, the platelets are not required to be prescreened using a culture method. The Platelet PGD™ Test can detect *B. cereus*, *C. perfringens*, *E. aerogenes*, *E. coli*, *K. pneumoniae*, *P. aeruginosa*, *S. aureus*, *S. epidermidis*, and *S. agalactiae* at a level of  $>10^5$  CFU/mL and *S. marcescens* at a level of  $8.6 \times 10^5$  CFU/mL. The test takes approximately 20–60 minutes to perform and is optimally undertaken after at least 72 hours of platelet storage. In a clinical study, the Platelet PGD™ test detected nine confirmed positive components of 27,620 apheresis platelets (1:3069) that had previously been screened and found to be negative for bacteria using the BACT/ALERT™ or eBDS™ culture systems. These were all Gram-positive organisms that were detected on Days 3 (four occurrences), 4 (two occurrences), and 5 (three occurrences) after collection. In the same study, two false-negative tests of 10,424 tests (1:5,212) were confirmed and the false-positive rate was 0.51%. An enhanced PGD test, the PGDprime test, was recently developed to simplify the workflow and improve specificity and sensitivity.<sup>78,79</sup>

### Nucleic acid testing detection techniques

Several amplification methods have been described for the detection of bacterial contamination, but none are currently available commercially. These comprise universal NAT assays that target genes with multiple copies (e.g., 16S ribosomal DNA or 23S ribosomal RNA) using real-time technology.<sup>80</sup> In theory, polymerase chain reaction (PCR) should be able to detect 1 CFU/mL of bacteria; however, the presence of bacterial DNA contaminating PCR reagents, and even in platelet products themselves, reduces the theoretical sensitivity of the assay to 20–1000 CFU/mL. Schmidt *et al.*<sup>81</sup> reported on the use of PCR to detect 16S ribosomal RNA from *S. aureus*, *E. coli*, *B. cereus*, and *K. pneumoniae* in pooled platelet concentrates. At an inoculum of 10 CFU/mL, the PCR testing detected all four bacteria at 12, 16, 20, and 24 hours after spiking. With a lower inoculum of 10 CFU/bag, the PCR testing detected 60% of *E. coli*, 80% of *B. cereus*, 90% of *K. pneumoniae*, and 100% of *S. aureus* 12 hours after spiking. Another study compared 16S ribosomal DNA PCR with the automated culture system BACT/ALERT.<sup>82</sup> A total of 2146 platelet concentrates were tested by both methods. When compared to the culture method, the PCR had a sensitivity and specificity of 100%. Recently, a Brazilian team reported an optimized RT-PCR method to detect bacterial contamination in platelets by targeting ribosomal 16S genes of common platelet contaminants, including *C. acnes*.<sup>83</sup> This method has enhanced specificity by treating the PCR Master Mix with ethidium monoazide and has a limit of detection of 10 genome equivalents. Given the complexities associated with such tests and the 2–6-hour delay to obtain results, nucleotide-based amplification has not been routinely applied to bacterial screening of platelets.

### Pathogen reduction

The ability to eliminate bacterial contaminants soon after collection as part of a global infection mitigation strategy offers a promising approach for preventing septic reactions completely. The FDA

recognizes that centers that implement approved pathogen reduction (PR) systems meet the requirements of the final FDA guidance for bacterial risk control.<sup>28</sup> Three pathogen reduction systems are described: (1) The INTERCEPT™ (Cerus Corp., Concord, CA) Blood System for Platelets uses amotosalen, a psoralen-based compound, plus ultraviolet-A (UVA) light to crosslink nucleic acids to prevent pathogen replication, (2) the Mirasol™ Pathogen Reduction Technology (PRT) system (TerumoBCT, Lakewood, CO) utilizes the vitamin riboflavin and ultraviolet plus visible light to achieve a similar effect by damaging nucleic acids and forming monoadducts.<sup>84,85</sup> These technologies are CE marked in Europe and are in various stages of implementation in individual European countries and are required for all platelets transfused in France, Switzerland, Belgium, Kuwait, and Iceland in 2021, while the Mirasol™ PRT system is used for all platelets in Luxembourg. At the time of writing, the INTERCEPT™ system is the only technology approved for use in the US. A third technology, (3) the THERAFLEX™ UV Platelets system (Macopharma, Tourcoing, France), is in development and uses UV-C light without any added photoactive compound to cause the formation of DNA pyrimidine dimers. This serves to block the elongation of nucleic acid transcripts and prevent replication.<sup>86,87</sup>

Efficacy in reducing the risk of bacterial contamination and sepsis is predicted by *in vitro* experiments that evaluate the ability to reduce the concentration of bacteria in artificially contaminated platelet products. In brief, components are inoculated with high concentrations of known bacterial species, and the titer is assessed directly before and after pathogen reduction treatment.<sup>84,88,89</sup> Technologies differ in their ability to inactivate various bacterial species, and all three technologies are less able to inactivate spores formed by *Bacillus* strains. PR is performed soon after platelet collection at a time when bacterial concentrations are low. PR treatments must render platelet components “functionally sterile” (defined as negative bacterial cultures at outdate). Since the components are stored for many days after treatment, even single residual viable bacteria may grow to sufficient concentrations to cause severe transfusion reactions. PR technology must be effective against Gram-negative bacteria (e.g., *Klebsiella* spp., *E. coli* etc.) that may grow rapidly after collection to overwhelm the capacity of PR systems.<sup>15</sup> The efficacy of PR is therefore contingent upon how soon after collection the PR process is performed.

Nussbaumer *et al.* inoculated double-dose apheresis platelet components with three different concentrations (1–10, 10–100, and 100–1000 CFU/mL) of each of seven different species of bacteria, performed INTERCEPT™ treatment 18–20 hours later, and compared the outcome to BACT/ALERT™ culture screening on Days 1, 2, and 5 after inoculation.<sup>90</sup> INTERCEPT™ was 100% effective at inactivating all species even when assessed five days after inoculation and treatment. Schmidt *et al.* confirmed these findings with apheresis platelets contaminated with eight different bacterial species and INTERCEPT™ treated 12 hours after contamination. A similar experiment was performed with whole-blood-derived (WBD) platelets with pathogen reduction performed 35 hours after collection and bacterial inoculation with either 100 CFU or 1000 CFU. All replicates were sterile at outdate with 100 CFU inoculation but with 1000 CFU inoculation, three of eight replicates of a strain of rapidly growing *K. pneumoniae*, and two of eight replicates of *B. cereus* exceeded the capacity of the PR system, allowing regrowth of bacteria during storage.<sup>91</sup> Similarly, Wagner *et al.* evaluated apheresis platelets inoculated with low concentrations (3–53 CFU/unit) of five transfusion relevant bacterial strains and treated with the INTERCEPT

System after either 24 or 30 hours of storage.<sup>92</sup> Platelets were stored for seven days and then cultured for sterility. All contaminated units treated with the INTERCEPT process 24 hours after inoculation were culture negative on all days tested. With inactivation performed 30 hours following inoculation, 1 of 15 units (1 of 3 replicates) was culture positive with *Klebsiella pneumoniae* by Day 5 of storage. These data support the use on the INTERCEPT Blood System for Platelets on the day of and the day after collection for both apheresis and WBD platelets.

Using the THERAFLEX UV Platelets system and pooled WBD platelet components spiked with each of 29 strains of bacteria, Gravemann *et al.* evaluated the ability to sterilize platelets contaminated with low levels of bacteria on the day of manufacture (~100 CFUs/unit).<sup>93</sup> They reported a mean  $\log_{10}$  reduction factor after UVC treatment ranging from 3.1 to 7.5, and that this varied between different strains of the same species. All platelets ( $n = 12/\text{species}$ ) spiked with up to 200 CFUs/bag remained sterile until the end of storage when treated six hours after spiking. UVC treatment eight hours after spiking resulted in single breakthrough contaminations with the fast-growing species *Escherichia coli* and *S. pyogenes*. These data support the use of the THERAFLEX UV Platelets system within six hours of platelet component collection.

Goodrich *et al.* inoculated multiple platelet samples with each of 20 different bacterial strains and performed PR using the Mirasol PRT system two hours later.<sup>89</sup> They found that for components contaminated with <20 CFU/mL, PR was 98% effective at inducing functional sterility and substantially more effective than bacterial culture screening, whereas for components contaminated with 20–10<sup>3</sup> CFU/mL, PR was 91% effective and as effective as culture screening. Subsequently, Kwon *et al.* demonstrated that platelets inoculated with low titers (45–147 CFU/bag) of *S. aureus* and *B. subtilis* and immediately treated with the Mirasol PRT system led to regrowth to clinically significant concentrations by Day 5 of storage, suggesting that cases of breakthrough contamination could be detected even when treatment was performed immediately after contamination.<sup>94</sup>

Finally, McDonald *et al.* investigated the inactivation capabilities of the Mirasol PRT and the INTERCEPT Blood System for Platelets, by evaluating the absence of viable bacteria after seven days for terminal sterility.<sup>95</sup> Bacterial count was determined post-spiking, immediately prior to treatment (two hours after spiking), immediately after treatment, and at the end of shelf life (Day 7). Using sterility at the end of platelet shelf life as the outcome, the inactivation capabilities of INTERCEPT and Mirasol PRT treatment were assessed. With INTERCEPT treatment, the inactivation capacity was measured as  $\geq 10^5 \log_{10}$  CFU/mL for *S. aureus*, *S. epidermidis*, *K. pneumoniae*, *S. bovis*, *E. coli*, *S. pneumoniae*, *S. mitis*, *L. monocytogenes*, and *S. dysgalactiae*. For *S. marcescens* and *P. aeruginosa*, the inactivation capacity was 10<sup>3</sup>–10<sup>5</sup>  $\log_{10}$  CFU/mL, and for *B. cereus* (sporulating strain), the inactivation was <10<sup>2</sup>  $\log_{10}$  CFU/mL. For the Mirasol PRT system, the inactivation of *S. pneumoniae* was 10<sup>3</sup>  $\log_{10}$  CFU/mL, and for all other strains tested, it was <10<sup>2</sup>  $\log_{10}$  CFU/mL.

The authors conclude that the inactivation capability of INTERCEPT was greater than that of Mirasol PRT. PR offers a possible alternative to bacterial screening if treatment is performed at an appropriate time dependent on the inactivation capabilities of the system. Mirasol PRT treatment needs to be performed promptly after manufacture to achieve maximum benefit, while INTERCEPT treatment could be applied much longer after donation.

Taken together, these data suggest that while PR systems are promising technologies for preventing septic transfusion reactions, the available technologies differ in their ability to inactivate clinically relevant strains to sterility. Technologies with less robust inactivation should be performed close to the time of collection in order to be as effective as available culture screening techniques.<sup>96</sup>

Blood collectors need to validate each PR technology and how it is implemented, as local practices such as buffy-coat PC preparation and the timing of leukoreduction may influence outcomes.<sup>96</sup> Alabdullatif *et al.* inoculated whole blood (WB) units with one of six *K. pneumoniae* strains, which are generally known to be fast growing, at a concentration of 3–38 CFU/unit, and processed these using the platelet-rich plasma (PRP) method 18 hours after collection.<sup>97</sup> Each spiked PC was pooled with four unspiked units and split into three components, one control, and the other two that were treated with the Mirasol PRT system 26 and 32 hours after collection, respectively. Culture at 5 and 7 days after treatment revealed that Mirasol treatment after 26 hours of WB collection resulted in complete inactivation of all *K. pneumoniae* strains. However, treatment 32 hours post-WB collection resulted in the breakthrough of one clinical isolate in two of the three replicates with ~7.8  $\log_{10}$  CFU/unit detected on Day 5 of PC storage. Although other bacterial strains were not tested and the outcomes may be variable, for *K. pneumoniae* it seems that Mirasol PRT can be performed up to 26 hours after collection under these specific conditions of non-leukoreduced WB storage which are thought to suppress bacterial growth.

Clinical data on the effectiveness of PR system in routine use have begun to be published. Hemovigilance programs in Belgian, Swiss, and French had not documented any septic reactions attributable to transfusion of INTERCEPT platelets with 609,290 platelets transfused (<1.6 per million) up to 2016;<sup>98</sup> further, no subsequent cases have been reported under these hemovigilance programs with over 1.5 million platelets transfused. This rate is significantly lower than those reported with nonpathogen-reduced platelets in the same settings. In the US, two confirmed septic reactions, including one fatality, were reported with PR-treated platelet components.<sup>19,99</sup> In both cases, there is strong evidence that the PR process would have effectively inactivated the implicated bacterial strains if they were present at the time of treatment and that contamination occurred after the PR process was performed. Environmental bacterial strains were implicated and in the fatal case, a defect in the storage container was demonstrated suggesting that bag damage provided a portal for bacterial entry. These reports highlight the need for proper platelet storage bag handling techniques and the storage and transport of platelets in clean environments as sterile platelets can be contaminated after PR treatment through “holes in the bag.”

Pathogen reduction systems are effective at reducing the risk of bacterial sepsis and enjoy the added advantages of providing a level of protection against emerging pathogens and the residual risks of known pathogens, as well as reducing the risk of transfusion associated graft versus host disease. They allow earlier release of platelets into hospital inventories as they do not require the delay before release that is inherent to the use of delayed large volume sampling strategies.<sup>100</sup> Both culture and PR incorporate processing losses of 5–10% of each platelet collection. All three PR technologies lead to lower platelet count increments than conventional platelets; however, multiple studies with the PR system available in the US demonstrate noninferiority with respect to the ability to prevent and treat bleeding.

## Bacterial contamination of red blood cells

Sepsis associated with the transfusion of bacterially contaminated Red Blood Cell (RBC) components is very rare and appears to be declining in incidence. In part, this is ascribed to the storage conditions of RBCs that are unfavorable to bacterial growth. Specifically, RBC concentrates (RBCCs) are stored at 1–6 °C in North America for a maximum of 42 days and at 2–6 °C for up to 35 days in Europe. Most bacteria have poor viability under these storage conditions. However, some psychrophilic (i.e., that grow optimally at refrigeration temperatures) pathogenic organisms can proliferate in RBCCs reaching clinically significant levels. RBCCs are not routinely screened for bacterial contamination; therefore, the incidence of bacterial contamination in RBC units is estimated based on reports of septic transfusion reactions or analysis of data from quality control sterility testing of expired units.

RBC transfusion associated sepsis may be severe. From 2014 to 2018, the US Food and Drug Administration (FDA) reported seven fatalities caused by RBCC contaminated with bacteria.<sup>6</sup> Implicated organisms included *P. fluorescens*, *Pseudomonas veronii*, *Enterococcus faecium*, and the obligate intracellular bacterium *Anaplasma phagocytophilum*. Since 2010, there have been no cases of transfusion-transmitted infections caused by bacterially contaminated RBCCs reported to the United Kingdom's Serious Hazards of Transfusion (SHOT) program.<sup>9</sup> Funk *et al.* reported one fatality in 2018 caused by transfusion of a RBCC contaminated with *E. coli* in Germany.<sup>101</sup>

The major contaminants of RBCCs are Gram-negative bacteria of the Enterobacteriace family, with *Yersinia enterocolitica* being historically the most commonly isolated species.<sup>102–104</sup> Isolation of this species has decreased in recent years, which has been ascribed to the implementation of leukocyte reduction in many high-income countries.<sup>105</sup> However, the risk of *Y. enterocolitica* has not been eliminated. In 2015, Frati *et al.* published a case report of a fatal septic reaction in Italy caused by the transfusion of a RBC unit contaminated with *Y. enterocolitica*.<sup>106</sup> *Serratia* spp. are also Gram-negative bacilli that are ubiquitous in the environment and grow well under RBC storage conditions. In particular, *Serratia liquefaciens* has been implicated in RBC transfusion-associated sepsis, with a high mortality rate.<sup>107,108</sup> In 2016, Héma-Québec reported a fatal RBC transfusion case involving another environmental contaminant, *Aeromonas veronii*.<sup>109</sup> *K. pneumoniae* is a bacterium also often implicated in severe septic transfusion events involving contaminated RBCC.<sup>15,110</sup> An interesting case study was published by Woodring and Farrel involving the transfusion of an RBC unit contaminated with *Pseudomonas poae*. Although Gram-negative bacilli were visualized by Gram staining of the transfused unit, blood cultures of the patient and cultures of the RBC unit yielded negative results given that this organism fails to grow at 37 °C.<sup>111</sup> Other species of *Pseudomonas* have also been implicated as RBC contaminants. For example, *Pseudomonas putida* was identified in a septic reaction in Australia,<sup>2</sup> and *P. fluorescens* was implicated in a transfusion reaction that was reported to the NHSN Hemovigilance Module.<sup>7</sup>

Septic reactions caused by contaminated RBCC are mostly associated with Gram-negative bacteria due to infused endotoxin (lipopolysaccharide of the cell wall), which can provoke an uncontrolled immune response and septic shock. Most severe reactions occur following the transfusion of older RBCC (i.e., that have been stored for more than 21 days) as these are more likely to have a high endotoxin load.

Although infrequent, Gram-positive bacteria, including *S. aureus*, *S. epidermidis*, *S. pneumoniae*, and *Streptococcus mitis*, have also been implicated in septic transfusion reactions associated with

contaminated RBCC.<sup>2,7,112,113</sup> Damgaard *et al.* performed a study in which blood samples that had been collected from healthy blood donors were separated into RBC and plasma; approximately 35% of the samples showed evidence of bacterial contamination in the RBC component with *Cutibacterium acnes* being most commonly identified.<sup>114</sup> Similarly, a spiking study performed by Taha *et al.* demonstrated that bacteria present in whole blood migrate preferentially to cellular fractions (RBC and platelets) during manufacturing of buffy-coat platelet pools.<sup>115</sup> These two studies raise the question as to whether screening of RBCC for bacterial contamination should be considered. Approximately 40% of RBC units associated with bacterially contaminated whole-blood-derived platelets test positive. The most frequent organism isolated in companion RBC units of whole-blood-derived platelets is the aerotolerant anaerobe *C. acnes*. Although *C. acnes* does not replicate during RBCC storage, there is evidence that transfusion reactions caused by this organism are delayed and may go unrecognized and underreported.<sup>116</sup>

## Clinical presentation

The clinical sequelae following transfusion of bacterially contaminated blood products are highly variable, spanning asymptomatic infection, low grade fever (which may be indistinguishable from a nonhemolytic transfusion reaction) acute sepsis, hypotension, and death.<sup>11</sup> In general, the clinical manifestations are less severe following platelet transfusion than those following transfusion of bacterially contaminated RBCs.<sup>117</sup>

Sepsis caused by the transfusion of contaminated platelets remains vastly under recognized and underreported. Indeed, Jacobs *et al.* found that during periods at their institution where active culture screening was in place, contaminated platelet components and sepsis were 32.0- and 10.6-fold more likely to be documented than during a period when detection relied solely on clinician recognition and reporting (i.e., passive surveillance).<sup>118</sup> The severity of reactions was greatest with components containing  $\geq 10^5$  CFU/mL and with higher bacterial virulence. At lower concentrations and with less virulent organisms, patients frequently did not display symptoms or presentation of symptoms is delayed. Similarly, patients who are on antibiotic therapy or who are neutropenic may not exhibit classical signs of sepsis (e.g., fever), and even when they do, those signs are often ascribed to other infectious causes or underlying disease.<sup>11</sup>

Patients may not react immediately after transfusion of contaminated platelets: in one well-documented outbreak of *Salmonella choleraesuis*, seven patients were linked to one repeat donor with occult, chronic osteomyelitis. The time to the onset of illness ranged from 5 to 12 days (mean 8.6 days). In all cases, the platelet units had been stored for less than one day.<sup>119</sup> Similarly, in 2006 the CDC reported a multistate outbreak of *Pseudomonas fluorescens* septicemia. All cases could be traced to contaminated heparin flushes.<sup>120</sup> A total of 28 patients had delayed onset of *P. fluorescens* infections, ranging from 84 to 421 days after their last potential exposure. As reported by Hong *et al.*, signs of septic transfusion reactions are not typically identified in the first 4–6 hours following transfusion; by contrast, active surveillance has shown that septic events can be detected up to 24 hours after the transfusion events.<sup>121</sup> A report of the isolation of the Gram-negative strict aerobe *Bordetella holmesii* during platelet culture screening revealed that this organism does not proliferate yet still remains viable during PC storage. It was shown that the contaminating organisms may be neutralized by bacteriostatic factors present in the platelet unit impeding detection.<sup>122</sup>

During transfusion, any change in clinical condition that prompts suspicion of sepsis, even in the absence of fever, should lead to

halting of the transfusion, patient support and investigation for possible transfusion of a contaminated component.<sup>123</sup> Similarly, patients who develop fever  $\geq 38^\circ\text{C}$  ( $<100.4^\circ\text{F}$ ), rigors, hypotension, shock, tachycardia, dyspnea, or nausea/vomiting within 24 hours of a platelet transfusion merit investigation given the potential for transfusion associated sepsis.

### Bacterial contamination of plasma, cryoprecipitate, and derivatives

Cell-free products such as plasma and cryoprecipitate are stored in the frozen state and thus are rarely associated with significant contamination. *Burkholderia cepacia* and *P. aeruginosa* have been cultured from cryoprecipitate and plasma thawed in contaminated waterbaths.<sup>124,125</sup> The increasing use of thawed plasma and liquid, never-frozen plasma<sup>126</sup> warrants greater vigilance for septic reactions with these components, given allowable storage at 1–6 °C for up to 5 days and 26 days, respectively.<sup>127</sup> From 2014 to 2018, the FDA documented one fatality that was attributable to plasma contaminated with coagulase-negative *Staphylococcus*.<sup>6</sup> Thawed plasma contaminated with *Bacillus* spp. was implicated in a transfusion reaction reported to the NHSN Hemovigilance Module.<sup>7</sup> Spiking studies have shown that other bacteria such as *S. liquefaciens* and *P. fluorescens* are also to grow in thawed cryoprecipitate.<sup>128</sup>

Products derived from blood components may also be contaminated with bacteria. Human serum albumin is a good culture medium and preserves the viability of contaminants. A heating step (60 °C for 10 hours) is performed during the manufacture of albumin to inactivate certain viruses rather than to ensure bacterial sterility.<sup>129</sup> The latter would require autoclaving (superheating under pressure), which would cause albumin to denature. On occasion, specific lots of albumin product have been found to be contaminated with bacteria, typically *Pseudomonas* spp.<sup>130</sup> These lots have resulted in endotoxic shock, transient bacteremia, and febrile reactions in recipients. Two patients in different hospitals developed *Enterobacter cloacae* septicemia following infusion of contaminated albumin.<sup>130,131</sup> Cultures of unopened product grew *Stenotrophomonas multophila* and *Enterococcus gallinarum* in addition to *E. cloacae*. This prompted a worldwide recall of selected lots of 5%, and 25% albumin. Cracks in the glass bottles were suspected to be responsible for the contamination. In short, deficiencies in manufacturing processes of blood derivative can pose risk of bacterial contamination with serious ramifications.

### Transfusion-transmitted syphilis

*Treponema pallidum*, the causative agent of syphilis, is a thin-walled, motile, spiral Gram-negative spirochete that cannot be visualized with Gram's stain. Historically, *T. pallidum*, a fastidious organism, was not able to be grown on bacteriologic media or in cell culture, instead relying on inoculation of rabbits and other animals for study.<sup>132</sup> Although *T. pallidum* is a bacterium, it is often regarded as a distinct entity, that is different from other transfusion-transmitted bacteria. Only 25% of patients with primary syphilis have a reactive serologic test for syphilis, and the test does not become routinely positive until the fourth week after the onset of symptoms; therefore, donors infected with *T. pallidum* may be asymptomatic with negative serology during periods of spirochetemia.<sup>133–135</sup> The organism does not survive prolonged storage at 4 °C, remaining viable for 1–5 days at these cold temperatures.<sup>136,137</sup> Nonetheless, infection is conceivable following transfusion of a fresh RBC unit from a donor who is still seronegative at the time of donation. While platelets

provide a more hospitable environment for *T. pallidum* given their storage at 20–24 °C, *T. pallidum* does not thrive in modern platelet storage bags owing to the associated high oxygen tension.

On occasion, the merits of screening for syphilis have been questioned, at least in high-income countries.<sup>138</sup> For one, transfusion-transmitted syphilis is exceedingly rare. Since 1969, only three cases of transfusion-transmitted syphilis have been published in the US.<sup>139–141</sup> Factors that likely contribute to the low incidence include (1) a low prevalence of syphilis among blood donors; (2) donor questioning that targets high-risk behavior for syphilis and other transfusion transmissible infections; (3) universal laboratory screening for syphilis; (4) refrigerated storage, which results in the death of spirochetes; (5) the high proportion of transfusion recipients who are on antibiotics at the time of platelet transfusion (i.e., many of which are bactericidal to *T. pallidum*); and (6) potential exclusion for another positive infectious marker such as HIV, HCV, or HBV.<sup>142,143</sup>

Advocacy for elimination of syphilis testing surrounds the low risk of transfusion-transmitted syphilis, conferring high cost—albeit low yield—to extant screening, coupled with the potential for false-positive test results that require unnecessary counseling and investigation. The counter argument is that donor syphilis testing can uncover individuals at risk of other sexually transmitted diseases (i.e., it serves as a surrogate marker for high-risk behavior) and, therefore, should be retained. There is also an argument for a public health benefit given surveillance of large numbers of individuals (donors). Both counterpoints are debatable: first, coinfections with other transfusion-transmissible infections have been reported but are rare. Second, while donor screening does provide surveillance, this is not the primary intent of blood donor screening and could even incentivize test seeking behavior. However, syphilis, even in high-income settings, is prevalent in selected high-risk groups.<sup>143</sup> Importantly, the argument does not hold true in low-income countries where high prevalence of syphilis, suboptimal donor selection, and transfusion of freshly collected blood, with often absent post-transfusion surveillance, argues for continued testing for syphilis.<sup>144</sup>

### International comparison

There is wide variation in the way different countries approach the problem of bacterial contamination of platelets. An international survey published in 2007 of 12 countries revealed multiple approaches; routine culture screening was performed in a minority.<sup>98</sup> A similar survey in 2014 revealed that all but a few countries had implemented BACT/ALERT™ culture screening in some form. Almost all countries recognize the danger of contaminated platelets and have instituted routine screening of donors for risk factors, standardized skin preparation techniques, and diversion for the initial blood drawn during phlebotomy. With only these interventions, France reported a continued high risk of sepsis (1:40,000 transfusions) and fatality (1:194,000 transfusions). In order to manage this risk, PR was implemented in France. Similarly, universal use of PR was implemented in Switzerland in 2011 and in Belgium in 2015. In contrast, The NHTSB in England adopted universal large volume delayed culture screening in 2011 and reported their five-year experience in 2017 documenting that the protocol was an effective risk reduction measure and increased the safety of the blood supply.<sup>16</sup> From February 2011 to September 2015, a total of 1,239,029 PCs were screened. False-negative cultures, all with *S. aureus*, occurred on four occasions; three were visually detected before transfusion and one confirmed transmission resulted in patient morbidity. The NHTSB screening protocol effectively reduced the number of clinically adverse transfusion transmissions

by 90%. Subsequently, Canada implemented a similar protocol and the US FDA has recognized large volume delayed culture as an effective intervention for use in the US.

In Germany, a pilot study, where 52,243 platelet components were screened with both BACT/ALERT™ and eBDS™ cultures before release, documented a false-negative result for one collection that leads to a fatality and severe reaction in the recipients of split units.<sup>45</sup> Culture screening was not implemented, and subsequently in 2009 the Blood Working Party (Arbeitskreis Blut: National Advisory Board of the Federal Ministry of Health) mandated a shortened shelf life of four days.<sup>66,145</sup> Permission to extend shelf life to five days has been granted based on bacterial screening on Day 3 or 4 after collection. Japan likewise restricts the shelf life of platelets and does not perform bacterial screening. Recently, shelf life was extended from 72 hours to midnight on the third day effectively allowing up to 3.5 days ( $\leq 85$  hours from collection) shelf life, in order to facilitate logistics of supplying hospitals. Seventeen septic reactions were reported from 2008 to 2018 with platelets two and three days old, including one fatality caused by *E. coli*.<sup>146</sup>

To date, attention on bacterial contamination of blood products has largely been confined to the US and other HIC. Blood transfusion safety remains a major challenge in low- and middle-income countries (LMICs). Deficiencies span the complete blood safety continuum from national oversight through donor recruitment, collection to testing, and transfusion and post-transfusion surveillance. Structural barriers that impede blood transfusion safety include competing health-care priorities, funding, education, and infrastructure. Collectively, this has manifested as increased infectious risk, often in locations where the incidence and prevalence of the major transfusion transmissible viruses (e.g., HIV, HBV, and HCV) are high. Where there has been investment in blood safety, initiatives have largely targeted prevention of HIV, HBV, and HCV.<sup>147</sup> By contrast, bacterial contamination has been neglected despite environmental (i.e., heat and humidity in tropical countries) and technical (e.g., inattention to aseptic technique, suboptimal quality systems, and hemovigilance) conditions that favor contamination.<sup>144,148,149</sup> There are comparatively few studies that have evaluated rates of contamination of blood products in LMICs.<sup>76</sup> One review of related studies in Africa suggested much higher rates of contamination (i.e., up to 17.5% for whole blood or packed red cells; up to 17.9% for platelets) than have been reported in HICs.<sup>149</sup> In a survey of members of the African Society of Blood Transfusion, the collated responses suggested low uptake of strategies to contend with contamination that are otherwise routine in HICs, such as bacterial culture and pathogen reduction.<sup>149</sup> While not unique to this topic, it highlights the ever growing divide between high and low resource settings, with little sign of change.<sup>150</sup> Technological advances such as nucleic acid testing and pathogen reduction, which have arguably had modest (i.e., incremental) effect on blood safety in HICs, could prove transformative in low resource settings. Nonetheless, a myriad of challenges (notably related to funding and infrastructure) still preclude their wider adoption.<sup>151</sup>

## Conclusion

Bacterial contamination of blood components is the most common cause of transfusion-transmitted infectious disease. Septic transfusion reactions related to RBC transfusions have declined rapidly in the last decade, possibly related to the more universal application of leukoreduced blood products. Most cases of post-transfusion sepsis

involve platelets that must be stored at room temperature under conditions conducive to bacterial proliferation. With the introduction of improved skin disinfection, diversion techniques, and bacteria detection of platelets using culture techniques, the rate of clinically significant septic reaction has decreased; however, a substantial risk of septic transfusion reactions remains. Many blood centers have moved to universal use of PR, and clinical evidence suggests that this further reduced the risk of sepsis, but recent reports identify a previously under recognized risk of contamination after culture testing or PR treatment through breaches in the integrity of the storage bag. An alternative solution is to use cold stored platelets; however, these products are not yet approved for use and are restricted to the treatment of active bleeding.

In the US, the implementation of the FDA Guidance in October 2021 will further improve patient safety; however, no technology can claim the elimination of all risks. Clinicians must continue to be vigilant for evidence of bacterial contamination and septic reactions, and respond rapidly to support patients when these events occur.

## CHAPTER 47

# Hemolytic transfusion reactions

Sandhya R. Panch<sup>1</sup> & Celina Montemayor<sup>2</sup>

<sup>1</sup>Department of Transfusion Medicine, National Institutes of Health Clinical Center, Bethesda, MD, USA

<sup>2</sup>Medical, Laboratory and Stem Cell Services, Canadian Blood Services, Toronto, ON, Canada

A hemolytic transfusion reaction (HTR) is the accelerated clearance or destruction of red blood cells associated with a transfusion event. HTRs can be due to immunologic incompatibility or to non-immune factors. The majority of HTRs are a result of red blood cell (RBC) transfusion, but they may also derive from the transfusion of plasma-containing blood components or plasma-derived products, or as a result of immune incompatibility in a hematologic or solid organ transplant.

Harmonized definitions for HTRs are available from expert organizations, and their use is encouraged in hemovigilance practice.<sup>1,2</sup> They are classified as acute (AHTR) or delayed (DHTR) hemolytic reactions, based on whether they occur within or after 24 hours of the implicated transfusion. Hyperhemolysis refers to a life-threatening DHTR presentation that is encountered most commonly in sickle cell disease (SCD) patients,<sup>3</sup> but has also been reported in myelofibrosis,<sup>4,5</sup> thalassemia,<sup>6</sup> and other disorders.<sup>7,8</sup> Otherwise known as “bystander hemolysis,” this is an immune phenomenon characterized by accelerated destruction of both autologous erythrocytes and transfused blood cells. It can be accompanied by reticulocytopenia and may not be associated with alloantibody formation.

Transfusion may also stimulate the production of alloantibodies without clinical evidence of hemolysis. This phenomenon has been termed delayed serologic transfusion reaction (DSTR) and is fundamentally distinct from DHTR.<sup>2</sup> DSTR is clinically benign and is often identified during routing blood bank testing. Although there is no evidence of hemolysis, a DSTR is essentially an alloimmunization event and thus predisposes a patient to subsequent HTRs. Earlier reports of hemolytic reactions have not necessarily differentiated clearly between serologic and true hemolytic reactions. One national hemovigilance system stopped collecting DSTR data in 2016.<sup>9</sup>

### Incidence

National hemovigilance programs have become important tools to understand the epidemiology of hemolytic transfusion reactions, identify their root causes, and design and monitor the efficacy of preventive strategies. The extent and scope of hemovigilance surveillance systems varies across the globe. In the

USA, the FDA mandate is limited to reporting fatality events,<sup>10,11</sup> while the Serious Hazards of Transfusion (SHOT) program in the UK encompasses the much more frequent, and highly informative, near-miss incidents.<sup>9</sup> Other programs that provide periodic, public reports, and valuable benchmark data include the Canadian Transfusion Transmitted Injuries Surveillance System (TTIIS)<sup>12</sup> and the Australian Haemovigilance Report.<sup>13</sup> The International Haemovigilance Network (IHN) released a summary of adverse reactions using data submitted by 25 countries throughout 2006–2012.<sup>14</sup> Interpretation of this epidemiologic data must take into account historical changes in imputability and case definitions, as well as variable participation by local health organizations and a pervasive degree of underreporting.

In its 2019 publication, the SHOT group describes 49 reported HTRs within a background of 2,306,983 total transfused blood components that year, yielding a final estimate of one HTR per 47,800 transfusions.<sup>15</sup> Twenty-two (45%) of these reported hemolytic reactions were classified as acute, 23 (45%) as delayed, and 4 as a hyperhemolysis event. No HTR deaths were registered that year, but 11 cases were linked to resulting major morbidity.<sup>15</sup> The number of deaths attributed to hemolytic reactions has oscillated between 0 and 4 per year in the UK since 2010. Statistics from the USA exhibit a similar trend, with a historical reduction of HTR fatalities and a residual low, yet persistent incidence during the last decade (5–9 HTR-related deaths yearly reported FY10 through FY18).<sup>10</sup> Data from IHN indicates that AHTRs accounted for 6.9% of the 349 transfusion-associated deaths reported by the 25 participating nations during 2006–2012.<sup>14</sup> In the same dataset, DHTRs were reported as the fourth most frequent classification (4.3%) within the total 92,850 reported transfusion reactions internationally, but they represented 16% of the reported serious events. DSTRs were reported more frequently (12.1% of all reactions and 20.8% of serious reactions), but DSTR case and severity definitions were inconsistent across participating groups.<sup>14</sup>

Hemolytic reactions secondary to ABO-incompatible transfusions are considered fully preventable sentinel events.<sup>16</sup> A 20-year retrospective review of ABO-incompatible transfusion fatalities reported to the FDA confirmed a significant and sustained decrease in their rate after 2008,<sup>17</sup> indicating a growing focus on

patient safety and improved transfusion procedures, but also a remaining gap for practice improvement. Four ABO-incompatible RBC transfusions, with no associated fatalities, were recorded in the UK in 2019; their historical incidence over the preceding 23 years also shows a marked decreasing trend.<sup>15</sup> The SHOT group, however, also captures ABO-incompatible near-miss events, which totaled 329 during the same year and thus provide powerful insight into the systemic deficiencies that can potentially lead to these serious events.

## Causes of HTRs

Causes of HTRs and differential diagnoses are summarized in Table 47.1. Surveillance data indicate that hemolytic transfusion reactions frequently result from inadvertent administration of incompatible blood components or from failure to detect a potential incompatibility. Incompatible components may also be transfused when clinical urgency dictates emergency release of blood products before completion of pretransfusion testing, although the literature indicates that acute HTRs develop in less than one per 1000 patients in this setting.<sup>18</sup> In 2019, one nonfatal HTR was reported due to emergency transfusion of antigen-positive blood in the UK.<sup>15</sup>

Among 80 ABO-incompatible related fatalities reported to the FDA during 2000–2019, 72.5% of the source errors were traced to clinical service processes, and the remaining fraction was attributed to errors in the transfusion service or laboratory.<sup>17</sup> The latter can be broadly divided into two categories: wrong components issued at the blood bank and laboratory testing errors linked to manual processes (including wrong tube tested, mislabeling, and incorrect typing and clerical errors). The most recent (2019) SHOT document describes 329 incidents related to the transfusion of an incorrect blood component, but their distribution by location exhibits the inverse pattern: 39.8% were attributed to errors in the clinical arena and 60.2% to the blood bank laboratory.<sup>15</sup> Notably, the five ABO-incompatible RBC or FFP transfusion events that provided data for a patient identification method indicated that it was performed manually.<sup>15</sup> Furthermore, SHOT describes an additional 1314 near-miss incidents, which account for 38.7% of the total reports and which could have potentially resulted in erroneous blood group typing or transfusion of an incorrect blood component.<sup>15</sup> Wrong blood in tube (WBIT) incidents accounted for 85.7% of the wrong blood component near-miss events and could be traced back to incorrect patient identification or failure to follow sample labeling protocols.<sup>15</sup>

In the United States, antibodies responsible for HTR fatalities were most commonly of the ABO group during FY14–FY18, followed by two cases attributed to anti-c and two cases attributed to anti-Fy<sup>a</sup> during that period.<sup>10</sup> Other reported specificities include single instances of anti-Jk<sup>a</sup>, anti-Jk<sup>b</sup>, anti-C, anti-U, anti-Fy<sup>a</sup>, anti-e, and anti-Wr<sup>a</sup>.<sup>10</sup> In the UK, three of four AHTRs in 2019 were caused by anti-Wr<sup>a</sup>, and the remaining case was associated with weak anti-E; all four cases were undetected in the initial antibody screen.<sup>15</sup> DHTRs were mostly associated with evanescent antibodies that were not detectable in the pretransfusion sample, including one incident where the patient had informed the clinical service of antibodies formed during a prior pregnancy. Anti-Jk<sup>a</sup> was the most common specificity (36.5%) reported among 104 DHTRs in the UK during 2015–2019, followed by an antibody mixture including anti-Jk<sup>a</sup> or anti-Jk<sup>b</sup> (13.5%), anti-c (10.6%),

anti-Fy<sup>a</sup> (9.6%), and an unspecified mixture of specificities that did not include Jk<sup>a</sup> or Jk<sup>b</sup> (9.6%).

Transfusion of ABO-incompatible platelet products is not infrequent due to inventory constraints,<sup>19–21</sup> and the hemolysis of the recipient's RBCs has been reported due to passive transfer of ABO antibodies in this scenario.<sup>22–26</sup> Such hemolytic reactions have been traditionally attributed to the transfusion of apheresis platelets carrying high titers of anti-A/A,B,<sup>27</sup> but similar titers were documented in pooled products,<sup>28</sup> and although less frequent, a fatality has been reported due to passive transfer of anti-B.<sup>23</sup> Many centers screen group O platelets for high titers; however, the tittering method and the titer threshold vary widely across institutions.<sup>29</sup> Dilution in platelet additive solution (PAS) reduces ABO antibody titers in platelet components,<sup>30</sup> but one fatality has been reported in spite of this mitigation strategy.<sup>23</sup> The use of group A plasma and group O whole blood during emergency resuscitation in trauma patients has been documented as a safe strategy, where the benefits are reported to outweigh the risks of hemolysis.<sup>26,31–33</sup> A growing number of studies suggest that the ABO titer alone is not predictive of the risk of hemolysis,<sup>23,34–37</sup> highlighting the need for further research in this area.

Acute hemolysis can be caused by infusion of an ABO-incompatible hematopoietic progenitor cell (HPC) graft.<sup>38</sup> In addition, delayed engraftment and pure red cell aplasia can result from major ABO-incompatible HPC transplantation (HPCT).<sup>39</sup> An important complication to monitor after minor ABO-incompatible HPCTs is passenger lymphocyte syndrome (PLS), which can be observed as brisk hemolysis 1–3 weeks after infusion of the graft due to viable, immunocompetent donor lymphocytes that produce isoantibodies directed to the recipient's RBC antigens.<sup>40,41</sup> PLS has also been documented after solid organ transplant, including lung and heart, and liver and kidney.<sup>42</sup>

A prospective observational study published in 2021 followed 78 nongroup O patients that received a total of 99 high-dose intravenous immunoglobulin (IVIG) doses.<sup>43</sup> Hemolysis was reported after 32 IVIG infusion events, with 19 (19%) of 99 graded severity 2 or higher.<sup>43</sup> Risk factors included blood group AB, first-time administration of IVIG, and the absence of concomitant immunosuppressive treatment.<sup>43</sup> This reported hemolysis rate following IVIG is higher than the 1.6% frequency previously reported in a 2008 retrospective study of 1000 patients.<sup>44</sup> An analysis of IVIG hemolysis cases published during 2003–2012 identified that hemolysis correlates with high IVIG doses,<sup>45</sup> and a subsequent study documented that heterozygosity, with the presence of the O allele, mitigates this risk.<sup>46</sup> No association was identified between the risk of IVIG hemolysis and recipient secretor (*FUT2*) status, or recipient *FCGR2/3* genomic locus variations.<sup>46</sup> An incidence of 15% was described among 419 pediatric patients with Kawasaki disease that received IVIG, with an increased risk with high-dose (4 g/kg) administration.<sup>47</sup> The rates of IVIG-associated hemolysis in Kawasaki disease patients range from 0.36%<sup>48</sup> to 16%<sup>49</sup> in the literature and may be related to different IVIG preparations.<sup>50</sup> Hemolysis has also been documented after infusion of intravenous anti-D in D+ patients with immune thrombocytopenic purpura.<sup>51–53</sup>

Nonimmune causes of hemolysis associated with transfusion, underlying hemolytic conditions that can be exacerbated post-transfusion, and diagnostic entities that may confound the laboratory and clinical picture should also be considered in the differential diagnosis. These are discussed below (see the Clinical manifestations and diagnosis section) and summarized in Table 47.1.

**Table 47.1** Summary of Hemolytic Transfusion Reactions (HTRs) Causes, Targeted Prevention Strategies, and Differential Diagnoses

Causes of Hemolytic Transfusion Reactions and Differential Diagnosis	
<b>Hemolysis Induced by Alloantibody to Red Cell Antigen</b>	<b>Preventive Strategy</b>
Accidental <ul style="list-style-type: none"> <li>Wrong blood in tube (misidentification and poor labeling practices)</li> <li>Patient or product misidentification at bedside</li> <li>Wrong component issued at blood bank</li> <li>Incomplete or inappropriate pretransfusion testing</li> <li>Errors associated with manual processes</li> <li>Emergency release of un-crossmatched blood</li> </ul>	Robust hemovigilance and safety culture Root-cause analysis encompassing near-miss events Centralized alloimmunization registries Electronic identification systems Prophylactic antigen matching for hemoglobinopathies Patient participation and education
Passive transfer of ABO alloantibodies <ul style="list-style-type: none"> <li>Platelet mismatch due to limited inventory or prioritization of HLA matching</li> </ul>	Titer screening, limiting volume of incompatible plasma, platelet volume reduction, and PAS
Group A plasma in emergency resuscitation of trauma patients Immunoglobulin products: IVIG and RhIg	Report to appropriate agencies and quarantine IVIG lots with high-titer ABO antibodies
ABO-incompatible HSCT <ul style="list-style-type: none"> <li>Acute hemolysis (ABO-incompatible HSCT)</li> </ul>	Red cell or plasma volume reduction and proper selection of peri-transplant blood products
Passenger lymphocyte syndrome (minor incompatibility HSCT or solid organ transplant) Delayed engraftment and pure red cell aplasia (major ABO-incompatible HSCT)	
<b>Coexisting Conditions That May Confound Clinical and Laboratory Presentation</b>	
Autoimmune hemolytic anemia G6PD deficiency Sickle cell disease Drug-induced hemolysis Sepsis Active bleeding Mechanical thrombectomy Hematoma resorption	
<b>Nonimmune Hemolysis Associated with Transfusion</b>	
Incompatible fluids coadministered with the transfusion Thermal damage Mechanical factors Improper deglycerolization G6PD-deficient red blood cell donor	

## Pathophysiology

Early transfusion reactions described in the 1600s developed following the infusion of xenogeneic blood products from sheep or calves into humans. As expected, repeated transfusions uniformly resulted in patient deaths, interdicting the use of transfusions for several years. Almost three centuries later, Karl Landsteiner's discovery of ABO blood groups allowed for the accurate prediction of immunological incompatibility among human-to-human transfusions,<sup>54</sup> paving the way for blood product transfusions in routine clinical practice. However, despite these and several other advances in the field, transfusion reactions continue to occur in clinically significant numbers as highlighted in the previous sections. It is thus critical to understand and further study the pathophysiology of hemolytic transfusion reactions.

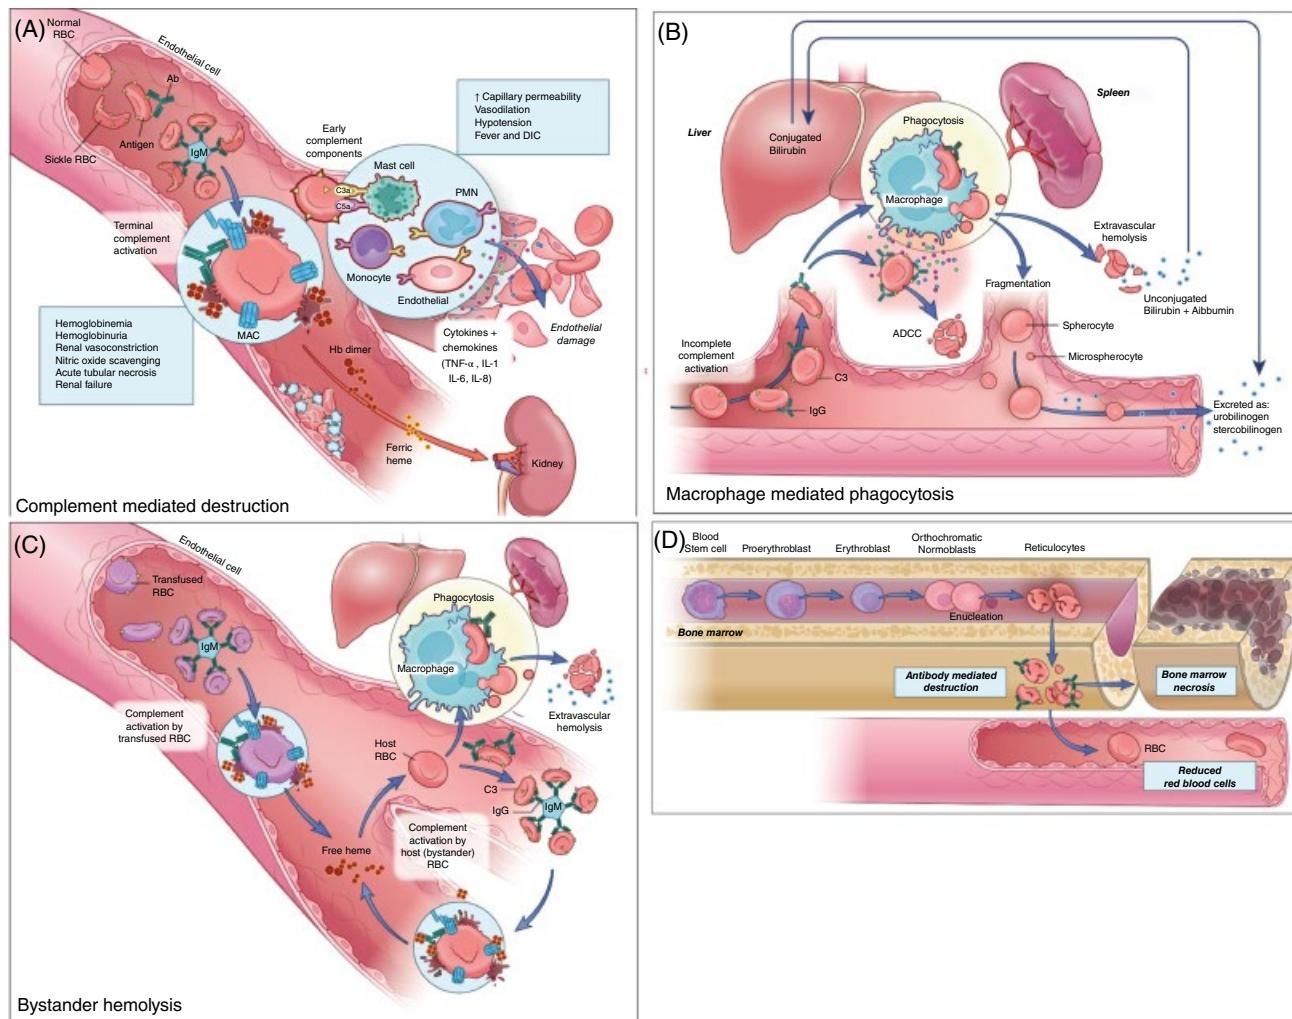

The pathophysiology of hemolytic transfusion reactions is dependent on the type of antigens and antibodies involved, as well as host factors. Broadly, mechanisms of immune hemolysis can be categorized based on the location of hemolysis (intravascular or extravascular) or by timing of onset after transfusion (acute if <24 hours or delayed if 24 hours to 28 days after cessation of transfusion).<sup>2</sup> However, they often present as overlapping phenomena in clinical scenarios. Based on our current knowledge, at least four mechanisms may be important in acute and delayed hemolysis, as well as in hyperhemolytic reactions: the complement system, macrophage mediated mechanisms, bystander hemolysis, and reticulocyte suppression or destruction.

## Role of complement

The complement system is composed of about 50 serum and membrane proteins with tightly regulated proteolytic activation cascades that culminate in the production of effector molecules with multiple biological functions. It represents a major component of the innate immune system, and it provides a powerful and effective mechanism to protect the host from pathogens. It was first described in 1899 by Paul Ehrlich as a heat-labile component of serum that "complemented" the effects of antibodies in bactericidal activity as well as red blood cell lysis.<sup>55</sup>

Activation of the complement system is thought to be the key player in a majority of acute hemolytic transfusion reactions. Acute hemolytic reactions are typically characterized by the interaction of preexisting IgM antibodies in the host with incompatible blood group antigens from the donor (transfusate). Naturally occurring ABO antibodies and reactions following ABO-incompatible transfusions have been implicated in a majority of the fatal cases.<sup>10,56</sup> Circulating IgM, when bound to foreign blood group antigens, activates the complement system, initiating a cascade of events described below and illustrated in Figure 47.1A. More recently, the role of complement mediated cell destruction is also increasingly recognized in the context of delayed hemolysis and hyperhemolytic transfusion reactions.<sup>57</sup>

In the context of transfusion mediated immune hemolysis, the classical and the alternative complement pathways are relevant. The classical pathway is initiated by antibody–antigen immune complexes

**Figure 47.1** Pathophysiologic mechanisms of hemolytic transfusion reactions (HTR). Acute intravascular HTRs are typically characterized by complement-mediated destruction (A). Extravascular macrophage-mediated phagocytosis (B) is the hallmark of delayed HTRs. In addition to mechanisms (A) and (B), bystander hemolysis (C) of host RBCs due to complement activation by transfused RBCs, and reticulocyte suppression (D) and rarely bone marrow necrosis have been described in the context of hyperhemolysis, particularly notable in sickle cell disease.

via C1q recognition of Fc domains in conformationally altered immunoglobulin (Ig) M or clustered IgG. In contrast with the classical pathway, the alternative pathway is constitutively active and provides a primed and rapid response mechanism for the deposition of complement on foreign surfaces. This pathway accounts for about 80% of generated complement activation products (even if the classical pathway is initially activated), and as such it is a major driver of inflammation. Both pathways converge at the cleavage and activation of C3 with the subsequent generation of various biological effector molecules. Specifically, the formation of excessive terminal membrane attack complexes consisting of components C5 through C9 creates multiple functional pores in the transfused red-cell membranes, initiating intravascular osmotic lysis.<sup>55</sup> Consequently, free hemoglobin (Hb) is released into the intravascular space, which results in end-organ damage, including acute tubular necrosis and renal failure (Figure 47.1A).

In addition, complement components are also potent anaphylotoxins. Complement components C5a and C3a have proinflammatory effects, and the activation of less than 1% of C3 or C5 in plasma will cause cellular responses. These anaphylotoxins not only trigger

the inflammatory response but also directly alter the cellular functions of parenchymal cells. Their receptors are present on a wide variety of cells including monocytes, macrophages, neutrophils, platelets, endothelium, and smooth muscle (Figure 47.1A). The engagement of these complement components on this variety of cells can result in distinct immunological outcomes. Effects on myeloid cells results in chemokinesis, degranulation, and stimulation of the respiratory burst. Further, macrophages are stimulated to express proinflammatory cytokines. Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) appears in plasma within two hours and has potent proinflammatory effects, including fever, leukocyte activation, procoagulant activity, and increased expression of a large number of genes related to the inflammatory response. TNF- $\alpha$  in the blood as a result of ABO incompatibility causes endothelial cells to express leukocyte adhesion molecules, chemokines, and procoagulant activity. Chemokines (and the chemokines CXCL8 (interleukin-8 [IL-8]) and CCL2 (monocyte chemoattractant protein-1 [MCP-1])) appear later than TNF- $\alpha$  and may be a secondary phenomenon. These chemokines have effects on granulocytes, lymphocytes, and macrophages expressing CXC and CC receptors.<sup>58</sup>

The resulting endothelial damage and increased capillary permeability contribute to the development of disseminated intravascular coagulation and multiorgan failure.

Incomplete complement activation also destroys incompatible red cells through C3b opsonization and monocyte-and-macrophage-induced erythrophagocytosis in the liver and spleen (extravascular hemolysis). As a potential pathophysiologic process in delayed hemolysis, complement-coated red cells are phagocytosed in stages. This gradual removal of red-cell membrane and surface area results in the formation of spherocytes and microspherocytes. This extravascular destruction process, with minimal release of free hemoglobin in the plasma, may also be mediated by immunoglobulins that are recruited by B-cell growth and differentiation factors (interleukin-1 $\beta$  and interleukin-6). Reactions to Rh antibodies and to other non-ABO antigens may be manifested in this manner.<sup>59,60</sup>

Most clinically significant hemolytic transfusion reactions are due to ABO incompatibility. However, antibodies to other blood group systems, such as Rh, Kell, Duffy, and Kidd, can be implicated in significant HTRs and may be fatal. Antigen density varies significantly for different RBC antigens, and its abundance influences the severity of the reaction. For example, ABO antigens are present at approximately 200,000–800,000 per cell, while Kell antigens are present at approximately 3000–6000 per cell, a 100-fold difference.<sup>61,62</sup> It is postulated that lower antigen density reduces antibody-induced clustering rendering C1q engagement and complement activation less efficient.<sup>63</sup>

Recent studies have elucidated the role of a chronically activated complementemia in the context of sickle cell disease.<sup>57</sup> Chronic hemolysis is a hallmark of sickle cell disease wherein increased free plasma hemoglobin, cell-free heme, and heme-loaded microvesicles directly activate complement. Further an overwhelmed and ineffective haptoglobin and hemopexin scavenging system may aid and abet this process.<sup>64</sup> Furthermore, sickle erythrocytes themselves appear to activate the alternative complement pathway by exposure of phosphatidylethanolamine and phosphatidylserine on these erythrocytes, amplifying hemolysis.<sup>65</sup> As in conditions like atypical hemolytic uremic syndrome, the already inflamed endothelium in patients with SCD, particularly following triggers such as pain crisis, acute chest syndrome, and/or infection, can drive terminal complement activation leading to end-organ damage very rapidly.<sup>57,66</sup>

### Role of macrophages

The role of macrophages in hemolysis (Figure 47.1B) has been studied since the 1950s.<sup>67</sup> Immune incompatible RBCs may become coated with IgG (IgG1, IgG2 or IgG3), IgA, or complement (C3b, iC3b), and these proteins react with receptors specific for these proteins present on macrophages (Fc receptors, CR1, CR3, and CR4) in the spleen and liver (Kupffer cells). Studies using chromium labeled RBCs starting in the 1980s have shown that macrophages may shorten RBC survival by at least three mechanisms. The macrophage surface expresses receptors for the Fc region of the immunoglobulin molecules, which enables engulfment and ingestion of the opsonized RBCs as a whole. Often, however, phagocytosis is incomplete and results in the formation of spherocytes. This has been explained in part by the removal of more membranes than volume. In addition, ectoenzymes on the macrophage surface cause microperforations of the RBC membrane, increasing its permeability and thereby promoting the transition

from a biconcave to a spherical shape of the cell.<sup>68</sup> Spherocytes are prone to further destruction during subsequent passages through the spleen. As a third mechanism, investigators have proposed that part or all the destruction may occur external to the macrophage by antibody-dependent cellular cytotoxicity (ADCC), wherein the macrophage secretes toxic molecules aiding the ADCC process. Some RBCs may escape immediate destruction but have a shortened lifespan because of macrophage-enzyme-induced membrane defects.<sup>60,69</sup> In the laboratory, the monocyte monolayer assay has been used to measure adherence and/or phagocytosis, but not ADCC. Chromium-labeled (<sup>51</sup>Cr) ADCC assays have provided mechanistic insights on the role of macrophages in ADCC.

Interactions between sensitized RBCs and macrophages may be influenced by multiple factors—Characteristics of antibody (class, subclass, specificity, thermal amplitude, complement-activating efficiency, and affinity and amount of galactose on the Fc carbohydrate), quantity of RBC bound, type of complement on RBCs, activity of the macrophage system, and/or CD47/inhibitor balance.<sup>70,71</sup> Although macrophages are undoubtedly the most important cell line involved, it is still unclear how important the role of other cells (e.g., lymphocytes [cytotoxic T-cells; natural killer, NK, cells]; dendritic cells; and granulocytes) can be in individual patients. All these cells can be shown to interact with sensitized RBCs (e.g., direct lysis) in vitro, when conditions are optimal, but are thought by most investigators to generally play a minor role.<sup>60,69</sup>

### Bystander hemolysis

Bystander hemolysis has been defined as the destruction of antigen-negative red cells during immune hemolysis; it plays an important role in DHTRs in SCD and is a hallmark of hyperhemolysis.<sup>72,73</sup> In their retrospective analysis, King *et al.* evaluated five patients with sickle cell disease (SCD) who underwent exchange transfusion and subsequently experienced a DHTR.<sup>72</sup> Serial samples were examined for complete blood counts, the percentage of hemoglobin A and S, and the percentage of reticulocytes. Some of these patients had a decrease in HbS red cells in addition to the transfused HbA cells suggesting the destruction of autologous red cells. This was evident in one patient despite a high/normal reticulocyte index providing additional evidence for bystander hemolysis. While the mechanism for bystander hemolysis is unclear, it may likely arise from autoimmunization following transfusion and red cell destruction.<sup>72</sup> Young and colleagues described two patients with autoimmune hemolytic anemia (AIHA) that was suspected to have been associated with previous blood transfusions. In a retrospective study, they found that 5% of 2618 patients with a positive DAT had demonstrable RBC autoantibodies, and 34% of these had a history of the positive DAT developing after transfusions and subsequently developed alloantibodies.<sup>72,74–76</sup> Several inciting events have been proposed. T lymphocytes from multiple transfused patients develop cytotoxicity against autologous cells; this was not necessarily associated with tissue damage. Other studies have demonstrated increases in preexisting endogenous antibody levels following transfusions, as well as alterations in self-reactive IgM and IgG antibody repertoires in plasma that are independent of a specific immune response to RBC antigens.<sup>70</sup>

### Reticulocyte suppression/destruction

Paradoxically, in severe delayed hemolytic transfusion reactions as well as with hyperhemolysis seen hemoglobinopathies, severe retic-

ulocytopenia has been reported following transfusions.<sup>77,78</sup> Studies have hypothesized that suppression or erythropoiesis and rarely bone marrow necrosis may contribute to this phenomenon.<sup>79,80</sup> Yet others have identified that both mature sickle cells and sickle reticulocytes adhere more readily to macrophages, and that hyperactive macrophages perpetrate a peripheral consumption rather than suppression of erythropoiesis, as evidenced by bone marrow erythroid hyperplasia in some of these cases.<sup>81</sup>

### Clinical manifestations and diagnosis

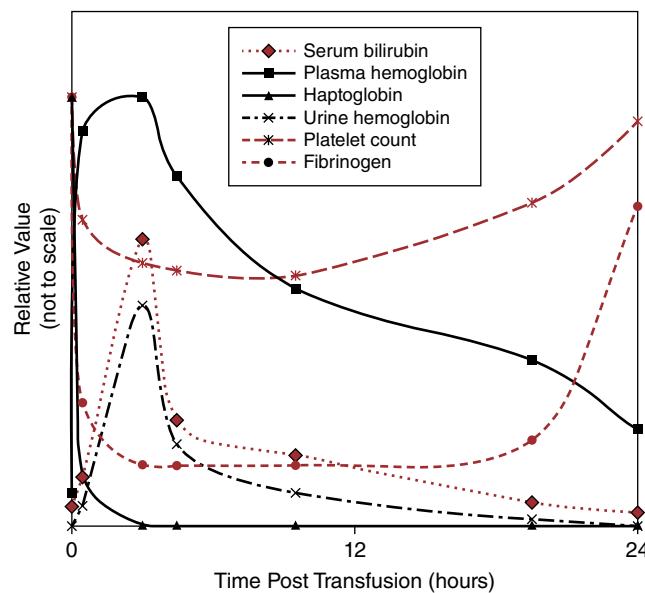

In an acute, immune-mediated hemolytic reaction, signs and symptoms present within 24 hours of the implicated transfusion event and may include fever and/or chills, flushing, nausea, vomiting, tachycardia, dyspnea, pain at the infusion site, abdomen/chest/flank/back pain, a subjective sensation classically described as “impending doom,” and red or dark urine signaling hemoglobinuria. These are not only broad and highly variable in their presentation, but also overlap with other etiologies, although fever is most commonly reported presentation. A high index of suspicion is warranted for prompt cessation of the transfusion and active investigation. The cause of pain is unclear, but may be related to spasm of coronary vessels, vascular occlusion of agglutinated cells, or direct bradykinin stimulation of nociceptive nerves in perivascular tissue.<sup>82,83</sup> In the anesthetized patient, hypotension refractory to fluid replacement, oliguria, red urine, and abnormal bleeding may be the only warning signs.

It has been traditionally believed that the severity of an AHTR is related to the total volume and infusion rate of incompatible blood, but even small volumes (10 mL) can produce rapid hemolysis and symptoms.<sup>37</sup> An analysis of 80 fatal ABO-incompatible transfusions reported to the FDA during 2000–2019 failed to detect a correlation between the number of transfused incompatible units and the time interval to death.<sup>17</sup> When an AHTR is suspected, the transfusion must be immediately stopped, and a bedside clerical check should be performed to verify the blood product label and patient identification band. Intravenous access should be maintained for supportive therapy. This should be followed by prompt reporting; a patient post-transfusion blood sample, along with the blood bag and remaining product if available, should be sent to the blood bank for evaluation. Initial laboratory testing typically includes a clerical check, visual inspection of the post-transfusion sample for hemolysis, a direct antiglobulin test (DAT), and verification of ABO and Rh typing. Ancillary tests that may be ordered by the physician include a post-transfusion CBC, LDH, urinalysis, serum haptoglobin, bilirubin, coagulation studies, blood smear, and hemoglobin electrophoresis. Table 47.2 summarizes the investigation of suspected transfusion reaction events, and Figure 47.2 illustrates a timeline of laboratory values in intravascular HTR.

Visual inspection of the postreaction plasma in an adult can detect as little as 10 mL of hemolyzed red cells, equivalent to free hemoglobin in the range of 20–50 mg/dL.<sup>86</sup> It should be remembered that free serum hemoglobin may also be present in nonimmune causes of hemolysis, hemoglobinopathies, severe burns, infusion of hemoglobin-based oxygen-carrying solutions, and after percutaneous intravascular thrombectomy.<sup>87</sup> If visual inspection is positive, a second sample is frequently requested to exclude mechanical factors due to an inappropriate blood draw. False-negative test results can be due to an excessive delay in the collection of the specimen, by which time the free hemoglobin has already been cleared

**Table 47.2** Investigation of Hemolytic Transfusion Reactions

Bedside	Blood Bank Laboratory
Stop transfusion Verify patient/product identifier Report incident	Visual check for hemolysis DAT ABO/Rh verification
Maintain IV access Draw post-transfusion sample and send to blood bank along with blood bag	Antibody screen in pre- and post-transfusion sample Eluate (include testing with A1 and B cells for non-group O recipients)
Additional baseline laboratory tests as indicated by physician (CBC, LDH, urinalysis, haptoglobin, bilirubin, BUN, creatinine, coagulation studies, blood smear, and Hb electrophoresis)	Antigen typing of units
Interconsultation with renal and intensive care specialist and management of complications as necessary	Repeat crossmatch with pre- and post-transfusion samples
	Investigation of nonimmune causes (Gram stain and culture, investigation of transfusion technique and blood storage conditions, check blood bag, and tubing and segments for hemolysis)

**Figure 47.2** Time course of hemolytic and coagulation parameters in intravascular HTR. Source: Based on Duvall *et al.* (1974).<sup>85</sup>

from the circulation. A low level of hemolysis may be challenging to detect visually in an icteric specimen.

A newly positive or stronger DAT supports an immune hemolytic etiology, but the strength of the testing does not correlate with the severity of the reaction. A false-negative DAT may occur if antibody-coated red cells have been already cleared from the circulation, or if the number of bound IgG molecules is below the sensitivity of the assay. Manual DAT using the spin antiglobulin tube method requires a minimum level of 100–150 bound anti-D IgG molecules for detection.<sup>88,89</sup> In a study that compared the relative sensitivity of DAT performed with monospecific IgG antiglobulin technique, flow cytometry, and antibody elution, the DAT could

detect 10% antibody-coated cells.<sup>90</sup> Antibody could be detected in the eluate of the samples with as little as 1% antibody-coated red cells present; flow cytometry, however, was consistently the most sensitive method with a detection limit of approximately 1%.<sup>90</sup> This underscores the need to perform an eluate when the clinical suspicion of hemolysis is high, a sensitive tool that can identify antibodies that are not detectable in plasma. In addition to the conventional reagent screening cells, the eluate should be tested with A and B cells in nongroup O patients that have received plasma containing products or immunoglobulin concentrates. Additional laboratory tests include repeating the antibody screen and confirming antigen typing and crossmatch of the implicated unit using pre- and post-transfusion samples.

Manifestations of DHTR appear more than 24 hours after the implicated transfusion, typically within the next two weeks but up to four weeks later, due to a delayed, anamnestic antibody response. Previous alloimmunization occurs from transfusion, pregnancy, or HSCT, with subsequent evanescence of the corresponding alloantibody titers to levels that are undetectable by common laboratory techniques. The most common signs of a DHTR are fever and/or chills, in addition to an unexpected hemoglobin drop (or failure to sustain a post-transfusion hemoglobin increment) due to the extravascular lysis of transfused cells. Hemoglobin degradation leads to an increase in plasma bilirubin levels and may manifest as jaundice 5–10 days after the triggering transfusion.<sup>83</sup> Figure 47.3 illustrates a time course of laboratory parameters in delayed, extravascular hemolysis. The degree of hyperbilirubinemia depends upon the patient's liver function and rate of red cell destruction. Spherocytosis may be observed in the blood smear. Laboratory testing will characteristically reveal a newly positive DAT. Eluate testing is important since it may be the only mean to identify the responsible alloantibody, which is often undetectable in plasma.<sup>15</sup> Once identified, segments from units previously transfused to the patient should be antigen-typed; this will provide an estimate of the burden of incompatible transfused erythrocytes with shortened survival.

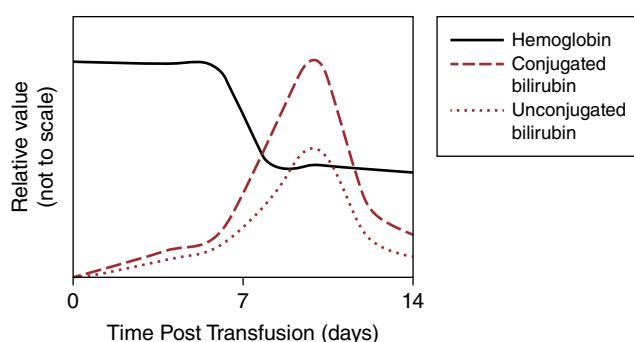

In patients with SCD, the clinical presentation of a DHTR may mimic a vaso-occlusive crisis, posing a risk of misdiagnosis.<sup>92–94</sup> In a retrospective five-year review of 637 adult SCD patients treated at a tertiary care center, at least one DHTR was documented in 7.7% of the 220 patients that received transfusions under an Rh and Kell-matched protocol.<sup>93</sup> Overall, a DHTR was implicated in 1.1% of the total 2158 documented transfusions in this study.<sup>93</sup> Most importantly, 47.8% of DHTR events were not diagnosed as such at the

time of presentation, most frequently mistaken for an SCD pain crisis.<sup>93</sup> The most common reported presenting symptom in this dataset was pain, followed by fever and hemoglobinuria.<sup>93</sup> A larger, 12-year retrospective analysis described 99 DHTRs in 69 adult SCD patients and reported hemoglobinuria as the most common presenting sign in 94% of cases, followed by pain in 89% and fever in 64%.<sup>95</sup> Only 7% DHTRs in this study were diagnosed at initial presentation in the emergency room.<sup>95</sup> Clinical signs of DHTR were reported to appear  $10.1 \pm 5.4$  days<sup>93</sup> and  $9.5 \pm 5$  days<sup>95</sup> post-transfusion in each of these studies. A significant fraction of these DTHR cases—56%<sup>93</sup> and 38%<sup>95</sup>—did not document the formation of new antibodies; in the remaining cases, new alloantibodies, autoantibodies, or nonspecific new reactivity were identified. No association was reported between the presence and specificity of the detected antibodies and the DHTR clinical severity.<sup>95</sup>

DHTRs are not only more frequent in the SCD population, but also more concerning due to the propensity to evolve into hyperhemolysis.<sup>3</sup> Awareness of the risk and variable manifestations of DHTR in these patients is critical to establish an early diagnosis and initiate appropriate interventions. A thorough transfusion history should always be obtained in SCD patients presenting with vaso-occlusive crisis, followed by the appropriate laboratory investigation. This includes the traditional hemolysis markers (CBC, LDH, serum bilirubin, urinalysis), hemoglobin electrophoresis, repeat DAT, antibody screen, and eluate. Comparison with a pretransfusion sample, and if available, a sample obtained shortly after transfusion, can provide valuable diagnostic information. The hallmark of hyperhemolysis is a hemoglobin nadir that is below the pretransfusion value. A predictive scoring system, based on a patient's previous DHTR episodes and their alloimmunization and transfusion burden history, is available for clinicians to estimate the risk of DHTR.<sup>96</sup> A second strategy employs a nomogram of expected HbA decay after transfusion, using the relative HbA change in relation to the post-transfusion elapsed time to calculate the risk of selective hemolysis.<sup>97</sup> The latter method requires two separate HbA percentage values, one taken as a baseline shortly (within one week) after transfusion, in addition to the value at the time that DHTR is suspected.

Drug-mediated immune hemolysis may present with a positive DAT and should also be considered in the differential diagnosis.<sup>98</sup> Suspicion of drug-induced immune hemolytic anemia (DIIHA) necessitates a detailed clinical history that establishes a temporal association between drug administration and the start of hemolysis. The list of drugs that have been implicated in DIIHA is vast and growing; the most frequent culprit reported by a research lab in California during the period of 2008–2013 was piperacillin, followed by ceftriaxone and cefotetan.<sup>99</sup> Other drugs frequently reported in the literature, in association with drug-dependent antibodies, include catechin, cephalothin, diclofenac, oxaliplatin, penicillin G, phenacetin, quinidine, rifampin, and tolmetin, among others.<sup>99</sup> In these cases, DIIHA classically presents in the laboratory as a positive DAT (IgG and/or C3), with a positive autocontrol and a negative eluate. Confirmatory testing in a reference laboratory involves the use of the soluble causative drug and/or manufacture of drug-treated reagent RBCs. Other medications, such as methyldopa, fludarabine, interferon, and mefenamic acid, have been associated with drug-independent antibodies and are therefore indistinguishable from warm autoantibodies by serologic methods.

Nonimmune hemolysis can have a similar clinical presentation to HTR (Table 47.1). Lysis of red cells can be caused by physical factors, such as overheating in a blood warmer or accidental freezing.<sup>100</sup>

**Figure 47.3** Time course of hemolytic parameters in extravascular hemolysis. Source: Cummins *et al.* (1997).<sup>91</sup> Reproduced with permission of Sage.

Excessive heat damages the RBC membrane, and this can cause spontaneous lysis of RBCs and result in intravascular hemolysis. The cells that have not already been lysed are cleared from the circulation by the spleen (extravascular hemolysis). Freezing injury occurs when red blood cells are exposed to below-freezing temperatures in the absence of a cryoprotective agent such as glycerol or dimethyl sulfoxide (DMSO). This can lead to a dehydration injury if the freezing is slow, or ice crystal formation if the freezing is rapid, both resulting in intravascular destruction. Hemolysis can also be caused by inadequate removal of glycerol from frozen red cells,<sup>101</sup> by attempting to force blood through a filter or small-bore needle,<sup>102</sup> or from defective pumps or blood administration sets. Infusion of blood in the same tubing with hypotonic solutions can lead to entry of free water into the RBCs, with subsequent cellular swelling and intravascular lysis. Intravenous DMSO infusion has been reported to mimic HTR.<sup>103</sup> Resorption of a hematoma can have manifestations very similar to extravascular HTR as well, including hyperbilirubinemia, elevated LDH, and depressed haptoglobin levels.<sup>83</sup> In addition, the presence in the serum of fibrin degradation products from the hematoma may be mistaken with DIC, one of the known complications of HTRs.<sup>86</sup> Transfusion of blood from donors with glucose-6-phosphate dehydrogenase (G6PD) deficiency can lead to hemoglobinemia and hyperbilirubinemia in the recipient<sup>104</sup> and may be particularly marked in the setting of concomitant oxidative medications.

Establishing the diagnosis of HTR may be particularly difficult in patients with liver disease, autoimmune hemolytic anemia (AIHA), sepsis, or active bleeding, due to overlapping features and laboratory abnormalities. Characteristically, in both bleeding and AIHA there is proportionate loss of both autologous and transfused red cells. One indication of HTR in these settings is the persistence of transfused red cells that lack the implicated antigen, but the absence of transfused cells bearing the antigen.

## Complications

Although the half-life of IgG is approximately 3–4 weeks, a positive direct antiglobulin test (DAT) by IgG may persist for longer periods than the transfused cells, and there may be evidence of complement deposition on autologous red cells, with a positive DAT with C3 persisting for weeks to months.<sup>105</sup> Autoantibodies are frequently found concomitantly with alloantibodies, with a reported range of 15–53%.<sup>106–108</sup> A retrospective review of cases with coexistent auto and alloantibodies reported that 75% were associated with a red cell transfusion.<sup>106</sup> Autoantibodies are also a common specificity developed by SCD patients with DHTR and/or hyperhemolysis.<sup>93,95</sup>

Hypotension occurs in some cases of intravascular HTR but is rare in extravascular reactions. Complement activation, with subsequent release of vasoactive peptides, is likely to be the most important determining factor (Figure 47.1A). As discussed previously, the anaphylatoxins C3a and C5a are released during immune hemolysis. Additionally, consumption of C1-esterase inhibitor contributes to activation of the kinin pathway, leading to generation of bradykinin.<sup>109</sup> The proinflammatory tumor necrosis factor (TNF) produced by phagocytes during HTR may also contribute to hypotension and shock.

Intravascular hemolysis also modulates blood pressure and local blood flow through alterations in the metabolism of the potent physiologic vasodilator nitric oxide (NO). NO can combine with heme and thiol groups of hemoglobin.<sup>110</sup> In oxyhemoglobin, NO

causes reduction of ferrous iron ( $\text{Fe}^{2+}$ ) to form ferric methemoglobin [ $\text{Hb}(\text{Fe}^{3+})$ ]. NO combines with deoxyhemoglobin to form  $\text{Hb}(\text{Fe}^{2+})\text{NO}$  but does not cause reduction. Scavenging of NO by free hemoglobin through these pathways results in vasoconstriction and hypertension. NO can also combine with cysteine on the beta-globin chain to form S-nitrosohemoglobin (SNO-Hb). This process is reversible, so SNO-Hb can act as a NO donor with resultant vasodilation. Free hemoglobin reacts with NO much more rapidly than does intraerythrocytic hemoglobin.<sup>111</sup> The effects of intravascular hemolysis may be very similar to the infusion of stroma-free hemoglobin (i.e., hemoglobin-based oxygen carriers [HBOCs]). Indeed, prominent hypertensive effects limited early trials of hemoglobin solutions as a blood substitute.<sup>112</sup>

Disseminated intravascular coagulation (DIC) is a rare complication of intravascular HTRs and is reported even less frequently in extravascular hemolysis. The production of proinflammatory cytokines, triggered by potent complement activation, is likely to be a major factor in this complication (Figure 47.1A). It can be challenging to distinguish DIC from other causes of coagulopathy, particularly in massive transfusion or liver disease. Uncontrolled bleeding caused by DIC may be the initial manifestation of an acute HTR in the intraoperative setting. Unfortunately, if HTR is not recognized early in this situation, more incompatible blood may be transfused in an attempt to keep up with blood loss. In one report, 9 of 35 patients experiencing HTR while under anesthesia received 4–6 additional units because of excessive bleeding.<sup>113</sup>

Impairment of renal function is seen in both intravascular and extravascular HTR, although it is more common in the former. The degree of renal function abnormality varies from an asymptomatic elevation of serum blood urea nitrogen (BUN) and creatinine to complete anuria. Both hypotension and intravascular coagulation contribute to renal impairment. Thrombus formation in renal arterioles caused by disseminated intravascular coagulation (DIC) may cause cortical infarcts. Free hemoglobin contributes to renal injury, causing so-called pigment nephropathy. Experimental evidence indicates that hemoglobin is toxic to renal tubular epithelium cells.<sup>114</sup>

Recent epidemiologic data on the mortality of HTRs were discussed previously. Mortality due to AHTRs is historically believed to depend on the volume of incompatible red cells transfused.<sup>83</sup> A review of 41 HTRs causing acute renal failure indicated that no deaths occurred among patients receiving less than 500 mL of incompatible blood; there was 25% mortality in the group receiving 500–1000 mL and 44% mortality among those receiving greater than 1000 mL of incompatible blood. However, the transfusion of even small amounts of incompatible blood is not necessarily safe. A 20-year retrospective review of ABO-incompatible transfusion fatalities reported to the FDA failed to identify a significant correlation between the number of RBC units transfused (dichotomized at  $\leq 1$  unit or  $> 1$  unit) and the reported time interval of days until death.<sup>17</sup>

A rapid hemoglobin drop due to HTR could itself exacerbate any preexisting SCD complications in this patient group.<sup>115</sup> Development of acute chest syndrome as a complication of DHTR was documented in 50% of cases, hepatic dysfunction in 25.3%, followed by pulmonary hypertension (16.2%) and renal failure (10.1%). ICU admissions were required in 41.4% of cases, with a mean ICU stay of  $6.2 \pm 4$  days. Mortality as a complication of DHTR in SCD patients was reported as 6%, with a mean interval of  $10 \pm 2$  days between the implicated transfusion and the patient's demise.<sup>95</sup>

**Table 47.3** Therapeutic Options in HTR

Therapeutic Intervention	Indication	Typical Dose or Goal
Hydration	Prevention of renal impairment	Maintain urine output to 0.5–1 mL/kg
Supplemental diurects	Prevention of renal impairment	Furosemide 40 mg IV bolus and then 10–40/mg. Monitor for hypotension
Alkalization of urine	Prevention of renal impairment	$\text{NaH}_2\text{CO}_3$ 130 mmol/L in 5% dextrose at 200 mL/hour; maintain urinary pH > 6.5, discontinue if it exceeds 7.5
Blood product transfusion	Treatment of DIC complications	Maintain platelet > 20,000/mcL, INR > 2.0, fibrinogen > 100 mg/dL
Glucocorticoids	Prevention of hemolysis in incompatible transfusion	Hydrocortisone 100 mg before transfusion and 24 hours later
IVIG	Prevention of hemolysis in incompatible transfusion	1.2–2.0 g/kg over 2–3 days

## Management

An AHTR is considered a medical emergency. The first important intervention is interrupting any ongoing transfusion and avoiding further infusion of incompatible blood, followed by initiation of the establishment's transfusion reaction response and investigation procedure. Clear protocols must be in place at each institution describing the interdisciplinary steps in this process. Intravenous access should be maintained, and baseline laboratory samples should be collected as instructed by the physician. Therapy is primarily supportive, following current practices for the management of shock, DIC, and renal failure, as required by the patient's clinical evolution.<sup>83</sup> Renal consultation is advised to assess the need for dialysis, and admission to the intensive care unit may be required. Vigorous hydration is recommended to maintain a minimum urine output; supplemental diuretics and forced alkaline diuresis may also be helpful (Table 47.3). Renal-sparing pressor support with dopamine may be required if hypotension develops, and any electrolyte abnormalities should be corrected. DIC should be addressed with blood product support to maintain minimal platelet, INR, and fibrinogen values.

Pretreatment with glucocorticoids and IVIG has been employed with some success when transfusion is clinically warranted and compatible RBC units are unavailable.<sup>116</sup> The monocyte monolayer assay has been useful in predicting the clinical significance of an alloantibody, and thus the probability of a hemolytic transfusion reaction, upon infusion of incompatible blood; but this assay requires specialized laboratory resources and skills.<sup>117</sup> A regimen of rituximab and methylprednisolone has been employed in heavily alloimmunized patients undergoing transplantation with incompatible grafts. Appropriate selection of blood components, which should be donor and recipient compatible, is essential in the peritransplant period of an ABO-incompatible HSCT. For minor incompatible grafts, awareness of the risk of PLS by the clinical team, watchful monitoring of hemoglobin levels 5–14 days post-transplantation, and prompt transfusion support with donor and recipient-compatible blood products are recommended.

DHTRs are often asymptomatic or clinically mild, with the exception of SCD patients who can present as a vaso-occlusive crisis or develop hyperhemolysis. Early diagnosis of hyperhemolysis is critical for prompt initiation of the appropriate management strategy. This typically includes avoiding further transfusions, except for severe cases with signs of end-organ hypoperfusion. Documented management strategies for DHTR in SCD include watchful and supportive, use of erythropoietin stimulating agents, and immunomodulatory drugs (IVIG, corticosteroids, rituximab, bortezomib, eculizumab, and tocilizumab).<sup>118–122</sup> Literature is often limited to case reports and case series; further studies are needed to better understand the underlying pathophysiology and to prospectively evaluate different treatment strategies and their clinical benefit. In

DHTRs that present without detectable antibodies, testing should be repeated three months after the event to capture any new, developing antibodies and establish the appropriate future transfusion strategy for each patient.

## Prevention

Many core blood bank procedures are ultimately directed toward the prevention of HTRs. Proper typing of donor units, pretransfusion testing, antibody identification, and crossmatching are critical elements that are discussed in Chapter 28.

A robust hemovigilance system is essential to document HTRs, dissect their underlying causes, and implement the appropriate corrective and preventive actions at a system-wide level. National hemovigilance surveillance systems, often coupled with open, periodic data sharing, have proven invaluable for the global transfusion community in its quest for continuous quality improvement and maximum patient safety.<sup>123</sup> The World Health Organization encourages the implementation of such a surveillance system at a national scale and provides a detailed guide document for this purpose.<sup>124</sup> Participation in the International Haemovigilance Network (IHN) has progressively increased, with 41 countries listed as members at the time of this writing.<sup>125</sup>

Lessons extracted from recent hemovigilance reports include the need for simple and clear standard operating procedures in the laboratory, rigorous competency assessment practices, addressing staff shortages, investigating incidents and near-misses systematically with a learning approach, and establishing a just patient safety culture.<sup>15</sup> The 2019 SHOT report recommends that all staff receive holistic training, including a focus on human factors. This refers to the study of human elements such as teamwork, workspaces, tasks, equipment, and culture within the functions of a clinical setting. Adequate staffing is critical to ensure safe patient care; four of the six ABO-incompatible transfusions reported in 2019 in the UK occurred after 8:00 pm or before 8:00 am,<sup>15</sup> when there is likely to be minimal or only one laboratory staff member. Elements of a strong safety culture include a climate where staff feels motivated and safe to report incidents and where this behavior is encouraged and even rewarded, a willingness to adapt to changing circumstances and demands, a growth mindset with a desire to learn from incidents and near-misses, and an open environment where practices and protocols are regularly questioned.<sup>9</sup> The concept of Safety-II was set forth to describe a proactive approach that recognizes existing health-care resilience and successful events, capitalizing on the lessons therein.<sup>126</sup>

A health system that views patients as active participants in their care, rather than only as passive recipients, supports safe health-care practices. In transfusion medicine, this includes asking patients for a history of alloimmunization or transfusion reactions, and ensuring that this information is documented and acted upon.<sup>15</sup> Establishment

of universally available alloimmunization registries has been advocated to ensure appropriate blood product selection for patients that are transfused at multiple sites or that have a history of evanescent alloantibodies, which pose risk factors for HTRs.<sup>127–129</sup> A review of fatalities due to ABO-incompatible RBC transfusions, reported to the FDA over a 20-year period, confirms the importance of verification practices for the ABO blood group and the value of electronic identification systems.<sup>17,130,131</sup> Rigorous labeling and patient identification protocols, including a final bedside check, remain critical elements for transfusion safety and prevention of HTRs.<sup>17,132</sup>

Full crossmatch procedures and selection of donor units lacking antigens corresponding to a patient's known clinically significant alloantibodies are essential for the prevention of HTRs. The concept of prophylactic red cell antigen matching has been advocated for hemoglobinopathy patients as a strategy to prevent alloimmunization in this frequently transfused group that is also known to have higher alloimmunization risk.<sup>127,133,134</sup> The rationale for prophylactic antigen matching is to provide these patients with units that are matched for RBC antigens beyond ABO and RhD, in order to prevent future alloimmunization and therefore reduce the risk of ensuing difficulty in finding compatible units, transfusion delays, and HTRs.

Guidelines from the American Society of Hematology and the International Collaboration for Transfusion Medicine (ICTM) recommend prophylactic matching for Rh (C/c and E/e) and K antigens in patients with SCD;<sup>127,134</sup> ICTM extends these recommendations to β-thalassemia patients as well. Extended matching to include Jk<sup>a</sup>/Jk<sup>b</sup>, Fy<sup>a</sup>/Fy<sup>b</sup>, and S/s is mentioned in these two guideline documents as a strategy to further reduce the possibility of alloimmunization in these patients. Provision of extended-matched units may be hindered by a limited inventory of compatible donor units,<sup>135,136</sup> and care should be taken to avoid transfusion delays that would have an adverse clinical impact.<sup>134</sup> Although extended matching has been shown to result in a lower incidence of red cell antigen alloimmunization compared to ABO/RhD matching alone,<sup>137</sup> no studies are yet available to address the impact of prophylactic antigen matching in clinical outcomes. Thus, the optimal degree of antigen matching in this patient population is still uncertain, and further trials are needed to clarify the best strategy and evaluate its clinical value.

Guidelines suggest obtaining an extended red cell antigen profile for hemoglobinopathy patients at the earliest opportunity.<sup>127,134</sup> Genotyping assays are advantageous over serologic phenotyping for recently transfused patients, and they can provide information for antigens for which no commercial antisera is available.<sup>138</sup> In addition, molecular platforms can precisely identify genomic variations associated with weak or partial antigen expression, and they can interrogate the silencing promoter variant that is frequently encountered upstream of the Fy<sup>b</sup>-encoding gene in individuals of African descent.<sup>138,139</sup> A comparison of hemagglutination and molecular RBC antigen typing in 494 SCD patients at a pediatric hospital reported higher accuracy and a larger information yield from genotyping assays.<sup>140</sup> Although genotyping cost and availability are important considerations, declining sequencing price and development of new technologies augur a feasible solution in the future.<sup>141–143</sup> RH genotype matching for provision of blood products in SCD patients has been explored and would likely require concerted efforts to increase the ethnic diversity of the donor pool.<sup>135,144</sup>

Transfusion services should have a policy addressing passive transfer of ABO-alloantibodies in plasma-containing products. Strategies currently employed to mitigate this risk include screening for platelet units that exceed a titer threshold that has been deemed

acceptable by the transfusion service,<sup>145,146</sup> limiting the quantity of incompatible plasma products transfused per patient,<sup>21</sup> volume reduction of ABO-incompatible platelet products,<sup>21,147</sup> and dilution with platelet additive solution.<sup>30</sup> The optimal ABO-titer threshold and its clinical significance remain undefined;<sup>29,34</sup> thus, these strategies might evolve as future research resolves with more detail the patient and immune determinants of hemolysis in this scenario.

Hemolysis in the setting of major and/or minor ABO-incompatible HSCT can be tempered by graft red cell or plasma volume reduction, respectively.<sup>148,149</sup> Reduction of graft-directed ABO antibodies has also been documented through therapeutic plasma exchange or through deliberate transfusion of incompatible, donor-type RBCs prior to transplant.<sup>150,151</sup> Establishment of transfusion policies for blood product selection in the peri-transplant period, considering ABO and donor/recipient alloimmunization to other red cell antigens, is also important.<sup>38</sup>

## Summary

Although the incidence of HTRs has significantly reduced during the last decade, the prevention of these adverse transfusion reactions continues to be a major focus in transfusion medicine. Establishment of robust hemovigilance programs and systematic protocols to identify and investigate all suspected HTRs remain as central practices. Advances in the understanding of the pathophysiology of HTRs and hyperhemolysis continue to provide insights to help guide the management of patients undergoing these reactions.

## CHAPTER 48

# Nonhemolytic transfusion reactions

Emmanuel A. Fadeyi & Gregory J. Pomper

Department of Pathology, Wake Forest University School of Medicine, Winston-Salem, NC, USA

This chapter reviews a variety of acute, nonhemolytic, and noninfectious transfusion reactions, the most common of which are febrile, nonhemolytic transfusion reactions (FNHTRs) and allergic reactions. Other acute, nonhemolytic reactions are reported less frequently and include transfusion-related acute lung injury (TRALI) and anaphylactic or anaphylactoid reactions. Additional acute adverse effects can occur in massive transfusion because of the large volume of blood components transfused over a short period. The complications of massive transfusion include dilutional coagulopathy, hypothermia, citrate toxicity, and electrolyte disturbances, among others. Some patients cannot tolerate the acute increase in intravascular blood volume caused by transfusion and experience the complications of transfusion-associated circulatory overload (TACO). Acute reactions can be caused by the toxicity of chemicals that leach into blood components from blood storage containers or filters or by chemicals added to improve storage conditions, such as dimethyl sulfoxide (DMSO). Other reactions are caused by endogenous mediators generated in the blood during filtration, processing, or storage, such as bradykinin-mediated hypotensive reactions. It is important that these complications of transfusion be recognized by patient care teams and blood bank personnel, and that appropriate treatments and preventive measures be instituted for patient safety and well-being.

## Febrile nonhemolytic transfusion reactions

### Description

An FNHTR is commonly defined as an increase in body temperature of 1 °C or more that occurs during or within several hours of transfusion and is unrelated to hemolysis, sepsis, or other known causes of fever. The use of a 1 °C increase in body temperature as a threshold for defining an FNHTR avoids undue concern over small fluctuations in body temperature unrelated to transfusion which do not justify discontinuation of transfusion and follow-up investigation. Many FNHTRs begin with the patient feeling uneasy and experiencing chills. In mild reactions, the signs and symptoms do not progress. Chills with or without an increase in body temperature can be classified as an FNHTR if other possible causes of chills

are unlikely and the time course of the reaction correlates with the transfusion. In the most severe reactions, patients may experience rigors (severe shaking chills) or a fever elevation of 2 °C or more over baseline. Although signs and symptoms usually are limited to chills and fever, some patients may also rarely experience more severe symptoms such as headache, nausea, and/or vomiting.

The fever of FNHTR usually persists no more than 8–12 hours after the start of transfusion. If fever persists 18–24 hours or longer, it is unlikely to be transfusion related. Generally, FNHTRs are self-limited and have no sequelae. However, elderly patients, patients with compromised cardiovascular status, or critically ill patients are at risk of cardiorespiratory complications associated with FNHTR. Because fever increases oxygen demand and consumption by an estimated 13% for every 1 °C over 37 °C and shivering increases oxygen demand approximately 300%, FNHTRs can aggravate pre-existing cardiac, pulmonary, and cerebrovascular insufficiency. Therefore, prompt recognition and antipyretic management of FNHTRs can be very beneficial.

An FNHTR almost always is associated with the transfusion of cellular blood components, such as red cells, platelets, and granulocyte preparations, and less commonly with noncellular components, such as plasma and cryoprecipitate. The incidence of FNHTR varies widely, and median rates have been reported as higher for platelets (4.6%) than for red cells (0.33%).<sup>1</sup>

The reaction risk of blood components, however, varies according to numerous factors, such as the method of preparation of the blood component (e.g., leukocyte reduction, storage time, medications, patient and donor characteristics, monitoring practices, and many others). These factors vary among different geographic regions and medical centers. In addition, rates based on reactions reported to blood banks are lower than those based on systematic surveillance of responses to all transfusions. One study demonstrated that the rate of reported FNHTR was low for prestorage-leukocyte reduced pooled platelets compared to poststorage-leukocyte reduced pooled platelets.<sup>2</sup> Longer platelet storage times are also associated with higher rates of FNHTR.<sup>3–5</sup> Reactions are also more frequent among certain recipients, such as multitransfused patients or multiparous women who have developed leukocyte or platelet alloantibodies.

## Etiology

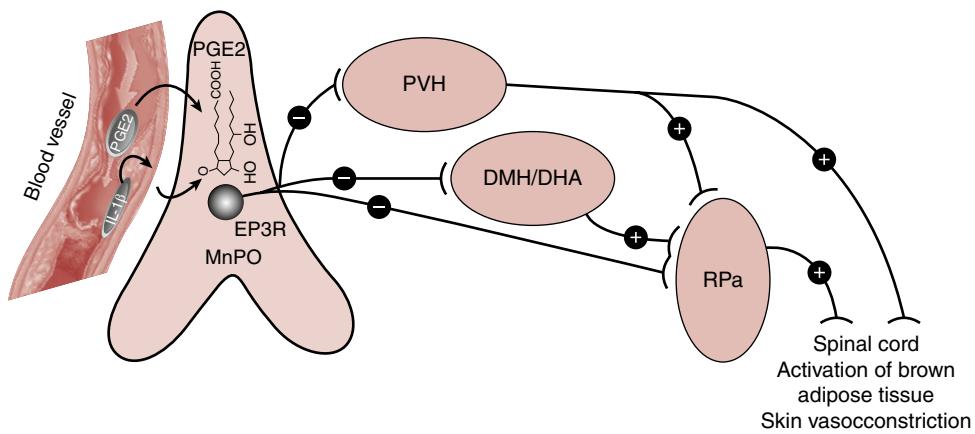

An FNHTR appears to be part of the systemic inflammatory response syndrome (SIRS) provoked in transfusion recipients by the immune challenge of transfusing foreign cells or infusing soluble inflammatory mediators present in stored blood components. The term *systemic inflammatory response syndrome* was coined to describe the constellation of observed body responses to various insults, such as infection, trauma, burns, and ischemia. It is defined as the presence of two or more of the following: body temperature more than 38 °C or less than 36 °C; heart rate more than 90 beats/minute; tachypnea (respiratory rate >20 breaths/minute or  $\text{PaCO}_2$  less than 32 mmHg); and white cell count more than 12,000/ $\mu\text{L}$  or less than  $4 \times 10^9/\text{L}$ , or more than 10% immature neutrophils (band forms). Although a mild FNHTR may not completely fulfill these criteria, FNHTR is nevertheless an inflammatory response.

Exogenous pyrogens such as lipopolysaccharide (LPS) and pyrogenic cytokines initiate a series of responses leading to hyperthermia. These responses include rapid muscle contractions that cause shivering, rigors, and an increase in heat generation. Heat conservation is achieved through cutaneous vasoconstriction, which also contributes to the sensation of a chill. Perceived chills lead to behavioral changes that can further increase body temperature. For example, the patient may cover up, and the result is inhibition of heat dissipation.

An FNHTR appears to have two possible underlying causes: (1) the more “classical” pathway of infused antigens, such as leukocytes, that stimulate the *in vivo* generation of cytokines in the recipient; and (2) the infusion of pyrogenic cytokines or other inflammatory response mediators (e.g., activated complement proteins, LPS, or neutrophil-priming lipids) that accumulate in the plasma portion of cellular blood components during storage.<sup>5–6</sup>

Other causes include immune recognition of donor leukocytes by recipient antileukocyte antibodies, passive transfer of donor inflammatory cytokines, and immune destruction of incompatible donor platelets by recipient antibodies.<sup>7</sup> Another cause of fever is the infusion of blood components contaminated with bacteria or bacterial products, will produce a febrile

response, but it is not usually categorized as an FNHTR but rather as a bacterial septic reaction, if recognized. The common pathway by which these different stimuli induce post-transfusion fever has been attributed to an increase in circulating pyrogenic cytokines in the recipient, such as interleukin-1 $\beta$  (IL1 $\beta$ ), IL6, and tumor necrosis factor  $\alpha$  (TNF $\alpha$ ). Pyrogenic cytokines induce fever by mediating upregulation of the thermostatic set point for body temperature in the thermoregulatory center of the hypothalamus. This mechanism is supported by the association of febrile reactions with a specific cytokine polymorphism *IL1RN*\*2.2 genotype.<sup>8</sup> Severe nonhemolytic transfusion reaction have also being linked to inflammatory cytokines and chemokines generated by mononuclear cells in donor blood by HLA Class II antibody containing plasma unit.<sup>9</sup> Recently, research has led investigators to a more complex model of fever generation, building on a model where cytokines principally induce fever to one where central nervous system stimulation by prostaglandin E2 (PGE2) is pivotal. Alternative hypotheses have resulted from the finding that a febrile response to LPS occurs even with blockade of either IL1 or TNF $\alpha$  and that the presence of circulating cytokines lags behind the development of fever.<sup>10</sup> Research has found that LPS-induced C5a production via complement activation results in rapid peripheral PGE2 production.<sup>11</sup> In addition, LPS binds to toll-like receptor 4 and induces cytokine production, leading to a two-phase rapid and delayed febrile response. Hyperthermic stimuli compete with hypothermic stimuli to achieve a central thermal balance point that may elevate or decrease based upon physiologic stimuli.<sup>12</sup> Central to the febrile response is the presence of EP3 prostaglandin receptors that bind PGE2 in the hypothalamus (Figure 48.1).<sup>13</sup> These newer models of the fever response provide possible explanations for why FNHTRs continue to occur despite prestorage leukocyte reduction that minimizes cytokine accumulation in storage. Clinical evidence also supports the hypothesis that febrile reactions can be caused by noncytokine hyperthermic stimuli present in cellular transfusion products.<sup>14</sup> More research is needed for the development of more targeted antipyretic medications that may eventually lead to the extinction of FNHTRs.

**Figure 48.1** A model for neuronal action of the EP3 receptors (EP3Rs) in the fever response after systemic immune challenge. In response to lipopolysaccharides or cytokines, prostaglandin E2 (PGE2) is generated by macrophages of the liver and lung and endothelial cells lining venules in the brain. PGE2 is transported or diffuses across the blood-brain barrier and acts on EP3Rs in the median preoptic area (MnPO). These are hypothesized to be GABAergic neurons that inhibit thermogenic systems in the hypothalamic paraventricular nucleus (PVH), the dorsomedial nucleus/dorsal area (DMH/DHA), and the raphe pallidus nucleus in the medulla (RPa). These thermogenic nuclei activate sympathetic preganglionic neurons in the spinal cord, resulting in cutaneous vasoconstriction and activation of brown adipose tissue that ultimately raise body temperature.

### **Alloimmunization to leukocytes or platelets**

Transfusion recipients at greatest risk of an FNHTR are those with leukocyte or platelet antibodies who receive transfusions with blood components containing large numbers of passenger leukocytes or platelets.<sup>15–16</sup> Less frequently, donor antibodies to leukocytes, present in the plasma portion of blood components, are associated with FNHTRs. The implicated antibodies most often have HLA specificity, although they also may be platelet- or granulocyte-specific. A minimum of approximately  $1 \times 10^7$  leukocytes per unit of red blood cells (RBCs) appears necessary to cause an FNHTR, although this number varies among individuals.<sup>17–18</sup> The role of donor leukocytes in FNHTR is supported by the finding that decreasing the leukocyte content of blood components below this threshold reduces the incidence of FNHTRs.

A variety of mechanisms are possible by which antibody-leukocyte or antibody-platelet interactions cause fever. For example, donor monocytes may be activated and secrete pyrogenic cytokines when recipient antibodies bind to them. An alternative explanation is that immune complex formation between recipient antibodies and donor leukocytes or platelets leads to the generation of activated complement components, such as C5a, which stimulate the production of PGE2.

### **Storage-generated cytokines**

Antibodies to leukocytes or platelets do not appear to account for all FNHTRs, particularly those caused by platelet transfusions. For example, some patients with no history of transfusion or pregnancy experience an FNHTR to their first transfusion of platelets.<sup>19</sup> It is unlikely that these reactions are mediated by recipient leukocyte or platelet antibodies because these recipients have no previous exposure to foreign cells. In addition, the rate of FNHTRs to platelet transfusion increases with increasing blood bank storage time of the transfused platelet concentrate.<sup>3–5</sup> This indicates that time-dependent change occurs in the platelet concentrate during storage that has a role in stimulating an FNHTR in some patients. Furthermore, febrile reactions still occur with the use of prestorage leukocyte reduction. In some cases, this is the result of inappropriate filter use or filter failure. However, this observation also supports the possibility that a substance or substances in the plasma portion of blood components not removed by filtration may be responsible for mediating at least some FNHTRs. The discovery that proinflammatory cytokines accumulate in the plasma portion of platelet concentrates may account for many of these findings.

A variety of leukocyte-derived, proinflammatory cytokines, including IL1 $\beta$ , IL6, IL8, tumor necrosis factor- $\alpha$  (TNF $\alpha$ ), macrophage inflammatory protein-1 $\alpha$  (MIP1 $\alpha$ ), and growth-related oncogene- $\alpha$  (GRO $\alpha$ ), are generated and accumulate in the plasma portion of platelet concentrates during storage.<sup>20–22</sup> Extracellular levels of these cytokines generally increase with increasing component storage time and are roughly proportional to the passenger leukocyte content of the blood component bag. Prestorage or early storage leukocyte reduction (within 1–2 days of collection) prevents or greatly reduces the generation of these cytokines. Because they have pyrogenic activity, many of these cytokines (if present in high enough concentration) can induce febrile responses in transfusion recipients. Elevated levels of IL1 $\beta$ , IL6, and TNF $\alpha$  in the plasma portion of platelet concentrates correlate positively with the occurrence of an FNHTR. Some studies have shown that IL6 levels in the plasma portion of platelet concentrates correlate best with the occurrence of FNHTR. In one study, chills, fever, or both occurred more frequently after infusion of the plasma portion of the platelet

concentrates than after infusion of the cellular portion containing platelets and leukocytes.<sup>20</sup> The plasma portions that caused an FNHTR contained higher levels of IL1 $\beta$  and IL6 than did those that did not cause chills or fever. These data support the role of the plasma portion of platelet concentrates as a source of inflammatory mediators and as a possible stimulus of FNHTR in some transfusion recipients. Although levels of a variety of proinflammatory cytokines in the plasma portion of platelet concentrates correlate with the occurrence of FNHTRs, it is unknown which, if any, of these actually mediate FNHTRs.

Soluble CD40L (sCD40L) in the supernatant of stored platelets can induce cytokines, chemokines, and lipid mediators by activating CD40 bearing cells. Increased levels of sCD40L in transfused blood are associated with milder transfusion reactions such as fever and rigors.<sup>23</sup>

Platelet-derived cytokines, such as CD40L (CD154), CCL5 (RANTES), transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1), CXCL4 (platelet factor 4; PF4), CXCL8 (IL8), and MIP1 $\alpha$ , are present in the plasma portion of platelet concentrates and apheresis platelets. All platelet-derived cytokines accumulate during platelet storage, and CD40L has been associated with clinical FNHTRs.<sup>24</sup> These cytokines are not known to be directly pyrogenic, but they stimulate the synthesis of proinflammatory mediator, IL1 $\beta$ , IL6, IL8, and TNF $\alpha$ . Because RANTES can activate basophils and mast cells and stimulate histamine release, it may play a role in mediating some allergic reactions (see the “Allergic reactions” section).<sup>25</sup>

Some proinflammatory cytokines, such as IL1 $\beta$  and IL8, have been detected in the supernatant portion of stored RBCs, although at much lower levels than in platelet concentrates.<sup>26</sup> Because the cold storage temperature of RBC units, 1–6 °C, has an inhibitory effect on cellular metabolism, the capacity of passenger leukocytes in RBC units to synthesize and secrete cytokines is less than those in platelet concentrates. As a result, the levels of cytokines in RBC units appear to be too low to mediate significant physiologic reactions.

The stimulus for cytokine generation during storage of blood components remains unknown. Measurements of cytokine messenger RNA levels and total cytokine levels (intracellular plus extracellular) in platelet concentrates indicate that accumulation of leukocyte-derived cytokines is caused in part by new synthesis and secretion. The stimulus for synthesis and secretion of leukocyte-derived cytokines may be, for example, contact activation of monocytes after these cells interact with the plastic of the storage containers or tubing.<sup>27</sup> Other possibilities include the direct stimulatory effects of C5a on PGE2 or the stimulatory effects of activated complement components on monocytes or other leukocytes in the blood component bag. The presence of platelet derived cytokines (e.g., CD40L, RANTES, and TGF- $\beta$ 1) in the plasma portion of platelet concentrates likely results from their release from preexisting stores because the biosynthetic activity of platelets is limited.

### **Bacterial contamination of blood components**

An FNHTR may result from infusion of a blood component contaminated with bacteria or bacterial products such as LPS. Unless a Gram's stain and bacterial cultures are performed, mild septic transfusion reactions characterized by only fever and chills are likely to be classified clinically as FNHTR, especially if the patient is concurrently receiving antibiotic therapy for their clinical condition.<sup>28–29</sup>

Transfusion reactions caused by contaminating bacteria, whether mild or severe, are manifestations of the SIRS, described earlier.

Proinflammatory cytokines (such as IL1 $\beta$ , IL6, IL8, and TNF $\alpha$ ) are implicated in the pathogenesis of SIRS associated with sepsis.<sup>30</sup> If bacterial contamination of blood components has occurred, the greatest source of cytokines is likely the transfusion recipient's cells stimulated by the infused bacteria or bacterial products. However, cytokine production by leukocytes in the component bag during storage stimulated by bacteria or bacterial products may also contribute to the reaction.

### Diagnosis

As a routine part of the transfusion procedure, the vital signs of transfusion recipients (pulse, temperature, and respiratory rate and oxygen percent saturation) should be measured immediately before transfusion and at intervals during and soon after transfusion. The patient should be watched closely, particularly in the first 30–60 minutes of transfusion, for the onset of chills, shivering, or rigors, which often precede a fever.

A transfusion reaction is a possibility if chills, fever (1 °C or more over pretransfusion temperature), or both develop any time during transfusion or up to several hours after the transfusion has ended. A febrile response to transfusion, however, is not specific for an FNHTR. For example, a fever may be the early manifestation of a more serious acute hemolytic, septic, or TRALI transfusion reaction. When a patient has a febrile reaction to transfusion, an evaluation to rule out hemolysis and possibly bacterial contamination should be undertaken promptly. Nursing staff should stop the transfusion immediately and notify the physician caring for the patient. They should verify that the identity of the transfusion recipient, based on the patient's identification bracelet and verbal confirmation with the recipient, if possible, matches that of the intended recipient, as indicated on the blood component tag. All containers and transfusion sets should be sent to the blood bank laboratory along with a post-transfusion blood specimen and a report that summarizes the clinical reaction. The clinical team should also have verbal communication with the blood bank staff to ensure that the postreaction blood specimen, component bag, and infusion set are received by the blood bank as soon as possible.

Investigation of a febrile reaction in the blood bank generally begins with a recheck of the records for clerical errors. The post-transfusion serum/plasma must be visually evaluated for hemolysis and should be compared with the pretransfusion specimen. A direct antiglobulin test must be performed on the post-transfusion blood specimen and ideally on a pretransfusion specimen for comparison. The ABO grouping of the patient sample and the donor unit should be repeated. When suggested by the preliminary serologic results, the crossmatch may be repeated for RBC transfusions to confirm patient–donor compatibility. The results of these tests confirm or exclude a hemolytic transfusion reaction as the basis for the fever. When a septic reaction is highly suspected, for example if the patient arrives with a high fever (2 °C or more) or accompanying hypotension, the bag contents should be examined by means of a Gram's stain and culture for bacterial contamination. Blood cultures should also be obtained from the transfusion recipient's post-transfusion blood specimen to correlate bacteremia with the same organism that may be detected in the blood component bag. Most blood banks do not test for HLA-specific, platelet-specific, or granulocyte-specific antibodies in the recipient's serum as possible causes of an FNHTR. Identification of these antibodies and pyrogenic cytokines is reserved for specialized laboratories and does not play a role in the immediate evaluation of most reactions.

The patient is examined by the primary team and the blood bank physician to determine whether associated symptoms or circumstances can explain the fever, such as drug reactions, sepsis, or other inflammatory conditions unrelated to transfusion. The time course of the development and resolution of fever should be examined in relation to the transfusion. In cases in which the transfusion recipient has a fever at the start of transfusion or is experiencing intermittent spiking fevers, a post-transfusion increase in body temperature can be difficult to interpret. In such cases, *possible* FNHTR may be the most definitive diagnosis that can be made. An FNHTR is a diagnosis of exclusion, arrived at by means of eliminating the possibility of immune hemolysis, bacterial contamination of the blood component, TRALI, or other causes of fever unrelated to transfusion.

### Treatment

The transfusion should be stopped immediately. The intravenous line should be kept open with normal saline solution to provide ready access for the possible infusion of crystalloid and intravenous medication in case the fever is a sign of a more serious hemolytic or septic reaction. Most patients, however, should be reassured that febrile transfusion reactions are usually harmless and that the fever typically responds to antipyretic therapy. The antipyretic agent of choice is acetaminophen (adults, 325–650 mg orally; children, 10–15 mg/kg orally or rectally). Aspirin and nonsteroidal anti-inflammatory drugs are contraindicated in the treatment of many transfusion recipients, such as those receiving platelets. Unless the patient has signs of an allergic reaction, such as urticaria, erythema, or pruritus, antihistamines are not indicated in the management of FNHTR. However, it is not recommended for physicians to prescribe both an antipyretic and an antihistamine in combination for mild reactions.

Patients occasionally develop rigors (severe shaking chills) after a transfusion and meperidine had been a mainstay therapy for many years. Because shivering can increase oxygen demand significantly, it is important to control the shaking chills, particularly for patients with cardiac or respiratory insufficiency. When administered to adults at doses of 25–50 mg intravenously, meperidine remains a very effective treatment for rigors. Meperidine is effective in rapidly arresting rigors through mechanisms not clearly understood. Unfortunately, meperidine has fallen out of favor with some hospitals because of unacceptable central nervous system toxicities and other downsides. Use of meperidine is generally contraindicated in the care of patients with renal failure because of accumulation of the proconvulsant metabolite normeperidine. Use of meperidine is also contraindicated in the care of patients who have taken monoamine oxidase inhibitors within the previous 14 days because of the risk of serotonin syndrome (excess serotonin activity). Toxicities secondary to metabolite accumulation, short half-life, and higher equianalgesic dose compared to morphine have decreased interest but were used in 36% of cases.<sup>31</sup> The advantages of meperidine include rapid and effective results, sedation and analgesia, and the avoidance of long-acting muscle relaxants or the acute hypotensive effect of chlorpromazine.<sup>32–33</sup>

On the basis of anecdotal evidence, morphine may be slightly less efficacious for the treatment of rigors, but its safety profile is more acceptable when given as a onetime dose of 2–4 mg intravenously.

After symptoms of an acute febrile reaction have been treated and the patient has been stabilized, any unused portion of the blood component should be returned to the blood bank and not transfused, even if blood bank testing rapidly rules out hemolysis. A new

device that has been FDA approved for the detection of bacteria in both whole-blood-derived platelets and apheresis PLT products is the Pan Genera Detection (PGD) test, which can detect  $10^3$ – $10^5$  colony-forming units per mL and may be more sensitive than the Gram stain.<sup>34</sup> The use of Gram's stain helps detect heavily contaminated units (with detection limits not less than  $10^6$  organisms per mL), and lower levels of contamination may be missed. If the febrile reaction is caused by bacterial contamination of the component bag, restarting transfusion of the same component can cause a severe and even fatal septic transfusion reaction as more bacteria or bacterial products are infused. For this reason, a new blood component unit should be used if transfusion is still needed after the patient's condition has been stabilized. Hemolysis of either donor or recipient red cells is usually not significant because of the small amount of red cells and plasma in platelet preparations. The transfusion should generally not be restarted at all as a precaution to allow other possible signs or symptoms of a serious reaction to develop. High transfusion-related fevers, such as a  $2\text{ }^\circ\text{C}$  increment or more, are more likely to be associated with septic reactions and should preclude restarting the transfusion. However, lesser fevers do not rule out bacterial contamination of the blood component. If the transfusion is restarted, the patient should be made as comfortable as possible with appropriate antipyretic therapy, as described earlier. The transfusion should proceed slowly and the patient should be observed closely for further signs of a reaction or further temperature elevation throughout the transfusion, which should be stopped if symptoms recur. Restarting transfusion of a blood component that has caused an FNHTR should not be routine.

## **Prevention**

### **Premedication**

Premedication with acetaminophen but not diphenhydramine should be considered for patients with a history of FNHTR. Patients who have no history of FNHTR do not need premedication. Despite a number of studies showing no benefit to premedication in preventing transfusion reactions, the practice remains common in many institutions.<sup>35</sup> A prospective, randomized, double-blind controlled trial of acetaminophen and diphenhydramine pretransfusion medication versus placebo showed that pretransfusion medication may decrease the risk of FNHTR to leukoreduced blood products.<sup>36</sup> Premedication with the glucocorticoid hydrocortisone sodium succinate (adults, 100 mg intravenously) may be useful in the care of reaction prone patients when an antipyretic agent alone is ineffective. Glucocorticoids have anti-inflammatory effects that may help prevent or reduce the severity of FNHTRs. For example, they inhibit the enzyme phospholipase A<sub>2</sub>, thereby blocking production of arachidonic acid and its metabolites such as PGE2, a key mediator of fever. Glucocorticoids also inhibit synthesis of pyrogenic cytokines, such as IL1 and IL6. A variety of glucocorticoids other than hydrocortisone are available. However, hydrocortisone has the advantage of being a short-acting glucocorticoid (biologic half-life, 8–12 hours), and it induces a shorter period of immunosuppression than do many other glucocorticoid preparations. Because glucocorticoids generally act through changes in gene expression, hydrocortisone should be administered at least 4–6 hours before transfusion so that its anti-inflammatory action has time to take effect.

### **Rate of infusion**

Slowing the speed of infusion of a blood component can possibly prevent or decrease the severity of FNHTR. The rate of increase in body temperature in FNHTR caused by leukocyte alloimmunization

appears to be directly related to the rate of infusion of leukocytes in the blood components.<sup>18</sup> A slower rate of infusion is of theoretic advantage in decreasing the severity of reactions caused by bacterial contamination or storage-generated cytokines. Slower infusion avoids a sudden bolus of bacterial toxins or cytokines that may provoke an immediate and possibly massive inflammatory response.

### **Leukocyte reduction**

The prophylactic transfusion of leukocyte-reduced components in the treatment of patients receiving repeated transfusions is effective in avoiding alloimmunization to leukocytes, which is one of the major causes of FNHTR. Leukocyte-reduced blood components should ideally be transfused to such patients beginning with the first transfusion. Leukocyte reduction is effective in the care of patients already alloimmunized to leukocytes because FNHTRs in these patients are directly related to the number and rate of infusion of passenger leukocytes. The threshold number of white cells associated with the development of an FNHTR generally ranges from  $0.25 \times 10^9$  to  $2.5 \times 10^9$ .<sup>18</sup> The removal of approximately 90% of leukocytes ( $1 \times 10^{10}$ ), which usually leaves less than  $5 \times 10^8$  white cells per RBC unit, is sufficient to prevent most FNHTRs.<sup>17,37</sup> For that reason, leukocyte reduction for the purpose of preventing FNHTRs often is defined as decreasing the passenger leukocytes to less than  $5 \times 10^6$  per transfusion. Leukocyte reduction of blood components can be performed either at the time of component preparation (prestorage leukocyte reduction) or immediately before transfusion (poststorage leukocyte reduction). Poststorage leukocyte reduction by means of filtration can be performed in the blood bank before distribution of the component for transfusion or during administration of blood components. The latter is often called *bedside leukocyte reduction*.

Leukocyte-reduced RBC units have in the past been prepared by various poststorage techniques, including simple centrifugation with buffy coat removal, saline washing, and deglycerolization of frozen RBCs.<sup>38–39</sup> Saline-washed and frozen deglycerolized RBCs are rendered leukocyte reduced because approximately 1–2 log<sub>10</sub> leukocytes are removed by repeated centrifugation and washing steps on automated cell washers. Filtration of RBCs units through microaggregate filters designed to remove microaggregate debris more than 40  $\mu\text{m}$  in diameter after an extra centrifugation step or after centrifugation and cooling (spin, cool, and filter) has also been shown to reduce leukocytes in RBC units sufficiently to reduce the incidence of FNHTRs.<sup>40–43</sup>

High-efficiency leukocyte reduction filters for red cells and platelets have been developed that are capable of removing both microaggregate debris and nonaggregated leukocytes.<sup>44</sup> These leukocyte reduction filters can remove three or more log (99.9% or more) leukocytes, thereby decreasing the leukocyte content to approximately  $1 \times 10^6/\text{unit}$  or less. Despite their efficacy in leukocyte reduction, the use of bedside leukocyte reduction filters has had variable and sometimes disappointing results in reducing the incidence of FNHTRs to platelet concentrates.<sup>45</sup> This may be the result of causes of FNHTR other than leukocyte antibodies in the transfusion recipient. For example, storage-generated, extracellular cytokines in the component bag that either are not removed or are inadequately removed by means of poststorage filtration are now believed to mediate some reactions. As a result, the practice of prestorage leukocyte reduction is increasingly replacing poststorage leukocyte reduction. Prestorage leukocyte reduction not only removes leukocytes but also removes leukocytes before they have a chance to release cytokines that can accumulate extracellularly in blood

component bags during storage. Prestorage leukocyte reduction has also yielded conflicting results on the efficacy of leukocyte reduction to mitigate FNHTRs.<sup>46</sup>

Prestorage leukocyte reduction of platelet concentrates or RBC units is achieved by the use of blood component containers with in-line leukocyte reduction filters in a closed system between the primary collection bag and satellite containers. Prestorage leukocyte-reduced platelets can also be prepared with some automated apheresis instruments equipped with centrifugation chambers designed to minimize leukocyte collection (so-called *process leukocyte reduction*). Because some data indicate that only approximately 15% of patients who experience an FNHTR will have a similar reaction to the next transfusion, some blood banks provide a leukocyte-reduced component (either prestorage or bedside leukocyte reduced) only when a patient has had two or more documented febrile reactions.<sup>47</sup> This practice is cost-effective but has the disadvantage of subjecting some patients to two uncomfortable reactions before a preventive measure is taken. Prestorage leukocyte reduction by means of filtration is a more efficient and cost-effective way to eliminate extracellular leukocyte-derived cytokines while reducing passenger leukocytes. Moreover, in evaluations of plasma removal from platelet concentrates to reduce the risk of FNHTR, this technique is still associated with FNHTR in a relatively large percentage of recipients. Neither leukocyte reduction nor poststorage plasma removal has been effective in eliminating all FNHTRs to platelet transfusions.

## Allergic reactions

### Description

An allergic reaction can be classified as an immediate hypersensitivity response consisting of transient localized or generalized urticaria, erythema, and pruritus. More serious allergic reactions can be complicated by hypotension and angioedema of the face and larynx. Allergic reactions can be categorized as those that have only cutaneous manifestations and usually are mild, resolving soon after administration of antihistamines. If other organ systems—cardiovascular, respiratory, or gastrointestinal—are involved beyond mild hypotension, particularly if the reaction is serious enough to necessitate treatment beyond antihistamines, the reaction would be considered *anaphylactic* or *anaphylactoid* (see the “Anaphylactic and anaphylactoid reactions” section). Allergic and anaphylactic reactions, however, are part of a continuum. Allergic reactions occur during or soon after transfusion of plasma-containing blood components. Atopic individuals—those with other known allergies—appear at greater risk of allergic reactions. A large retrospective review of reported transfusion reactions noted that 17% of all reactions in a nine-year period were allergic and 1% of reactions were very severe.<sup>48</sup> Other papers report allergic reaction rates of approximately 0.19% for red cells and 0.53% for platelet transfusions.<sup>49,50</sup> Hemovigilance studies have demonstrated a lower rate of allergic transfusion reaction associated with red cells in the US 0.05%.<sup>46</sup> Studies have also shown that ABO-compatible platelet transfusions have the lowest rate of transfusion reactions. Transfusion of ABO-antigen-incompatible platelets had the highest rate of allergic transfusion reactions and resulted in a transfusion reaction rate 1.5–2 times that of ABO-compatible transfusions.<sup>51</sup>

### Etiology

Allergic reactions are mediated by recipient immunoglobulin E (IgE) or non-IgE antibodies to proteins or other allergenic soluble substances in the donor plasma. The result of the hypersensitivity reaction is secretion of histamine from mast cells and basophils, which mediates cutaneous reactions by increasing vascular permeability.

Although the source of histamine in allergic reactions is believed in many cases to be the transfusion recipient's mast cells and basophils, it has been hypothesized that histamine generated by leukocytes in stored cellular blood components may play a role. Several studies have shown that histamine accumulates in the plasma portion of platelet concentrates and RBC units with increasing storage time. However, histamine is not synthesized during storage but rather it leaks into the extracellular plasma or may be due to calcium ion ( $\text{Ca}^{2+}$ ) influx-inducing activity toward mast cell in patients prior to transfusion.<sup>52–54</sup> These data are consistent with the observation that allergic transfusion reactions are also more common with increasing storage time of blood components.<sup>55</sup> Several of the chemokines that accumulate in the plasma portion of platelet concentrates during blood bank storage, such as IL8, RANTES, and MIP1 $\alpha$ , can recruit and activate basophils and stimulate histamine release. Therefore, it is theoretically possible that the infusion of storage generated donor cytokines during transfusion may contribute to the onset of allergic reactions among transfusion recipients. Consistent with this hypothesis, the biologic activity of RANTES is present at higher levels in apheresis platelets that cause allergic reactions.<sup>54</sup> One study measured the concentration of allergic agonists such as C5a, brain-derived neurotrophic factor (BDNF), and CCL5 (RANTES) in apheresis platelets showed that high levels of these agonists were associated with allergic transfusion reactions. Therefore, levels of acute inflammatory mediators and growth or chemotactic factors of basophils and mast cells do not appear to be associated with allergic transfusions reactions according to the study. However, the study only evaluated 20 platelet transfusions with associated allergic transfusion reactions.<sup>55</sup>

Allergic (and anaphylactic) reactions have been reported after infusion of antibodies in donor plasma, such as penicillin antibody infused into recipients receiving penicillin or related antibiotics, and after infusion of drugs in donor plasma, such as penicillin infused into recipients already sensitized to penicillin.

### Diagnosis

Urticaria is readily diagnosed clinically by the presence of the cutaneous wheal-and-flare reaction. Because allergic symptoms are usually mild and are not characteristic of hemolytic transfusion reactions, serologic blood bank investigations to rule out hemolysis usually are unrevealing. Isolated, mild urticarial reactions not accompanied by other signs and symptoms necessitate minimal diagnostic evaluation. If the reaction is severe, has atypical manifestations, or is accompanied by fever (uncharacteristic of allergic reactions), a more elaborate laboratory evaluation to rule out a hemolytic or septic transfusion reaction is indicated. In the diagnosis of an allergic reaction as transfusion related, it is important to rule out, if possible, urticarial drug reactions that may be circumstantially attributed to transfusions. Careful attention to the timing of onset of urticaria relative to the transfusion may help avoid this confusion. Administration of medications should generally be discouraged in the peritransfusion period to avoid such confusion.

Even mild allergic reactions should be reported to the blood bank. Monitoring allergic reactions and correlating reactions with any newly implemented changes in blood component collection, processing, storage, or filtration are important in detecting new and unexpected causes of reactions. In the care of patients with repeated allergic reactions, notification of the blood bank allows the blood bank medical director to consult on measures to manage or prevent such reactions in the future.

### Treatment

The patient can be treated with a first-generation, H<sub>1</sub>-blocking antihistamine (adults, 25–50 mg diphenhydramine intravenously or orally). If the sedating side effects of first-generation antihistamines must be avoided, newer, less sedating antihistamines are available for oral administration (adults, cetirizine 10 mg orally, loratadine 10 mg orally, or fexofenadine 60 mg orally); however, parenteral antihistamines are preferred in the management of acute reactions because of their more rapid bioavailability. An H<sub>2</sub> blocker, such as cimetidine (adults, 300 mg intravenously) or ranitidine (adults, 50 mg intravenously), may be added to the H<sub>1</sub> blocker to speed resolution of the reaction. However, as of 1 April 2020, the FDA has requested the immediate market withdrawal of all prescription and OTC ranitidine products due to the presence of a contaminant, *N*-nitrosodimethylamine (NDMA), found in some ranitidine products. NDMA is considered a probable human carcinogen, and sustained higher levels of exposure may increase the risk of cancer.<sup>50</sup>

Combining H<sub>1</sub> and H<sub>2</sub> antagonists has given better results in treating patients with allergic reactions in nontransfusion settings than has use of an H<sub>1</sub> antagonist alone.<sup>56–57</sup> For reactions characterized by only localized urticaria, such as a few hives, the transfusion can be temporarily discontinued while an antihistamine is administered. The transfusion can be resumed in approximately 30 minutes if the urticaria has cleared and if no further symptoms occur. For patients with generalized urticaria or a more serious allergic reaction accompanied by facial or laryngeal edema or hypotension, the transfusion should be discontinued and the infusion set with any untransfused blood returned to the blood bank. If laryngeal edema causes breathing difficulties or if hypotension is severe, epinephrine (adult dose, 0.2–0.5 mL of 1:1000 solution [0.2–0.5 mg] subcutaneously) can be administered.

### Prevention

Transfusion recipients are often given routine premedication with an antihistamine such as diphenhydramine in an effort to prevent or reduce the severity of allergic transfusion reactions, even when they have had no previous reactions. The value of this approach is uncertain because few patients have allergic reactions. At least two randomized double-blind placebo-controlled studies of premedication using diphenhydramine and acetaminophen have failed to show a benefit of premedication to reduce reactions.<sup>58–59</sup> When premedication is restricted to patients who have had two or more previous allergic reactions, overall reaction rates do not increase. Accordingly, premedication with an antihistamine should probably be reserved for recipients who have had a previous allergic reaction. For patients with repeated reactions not eliminated by premedication with an H<sub>1</sub> blocker alone, a combination of H<sub>1</sub> and H<sub>2</sub> blockers has been shown more effective.<sup>56–57</sup>

Should premedication not prevent repeated allergic transfusion reactions, another option is to reduce the plasma content of transfused blood components. This can be achieved in RBC and plate-

let preparations with automated saline “washing.”<sup>60–61</sup> However, washing or plasma removal steps generally should be reserved for patients with two or more serious allergic reactions (e.g., those that include angioedema or hypotension) that are not prevented with premedication with both H<sub>1</sub> and H<sub>2</sub> blockers because cell washing is time-consuming and can delay transfusion. Patients with two or more severe allergic reactions can undergo testing for IgA deficiency to rule out a relative deficiency of IgA because this has been reported to cause both a severe allergic and anaphylactic reactions.<sup>62</sup>

## Anaphylactic and anaphylactoid reactions

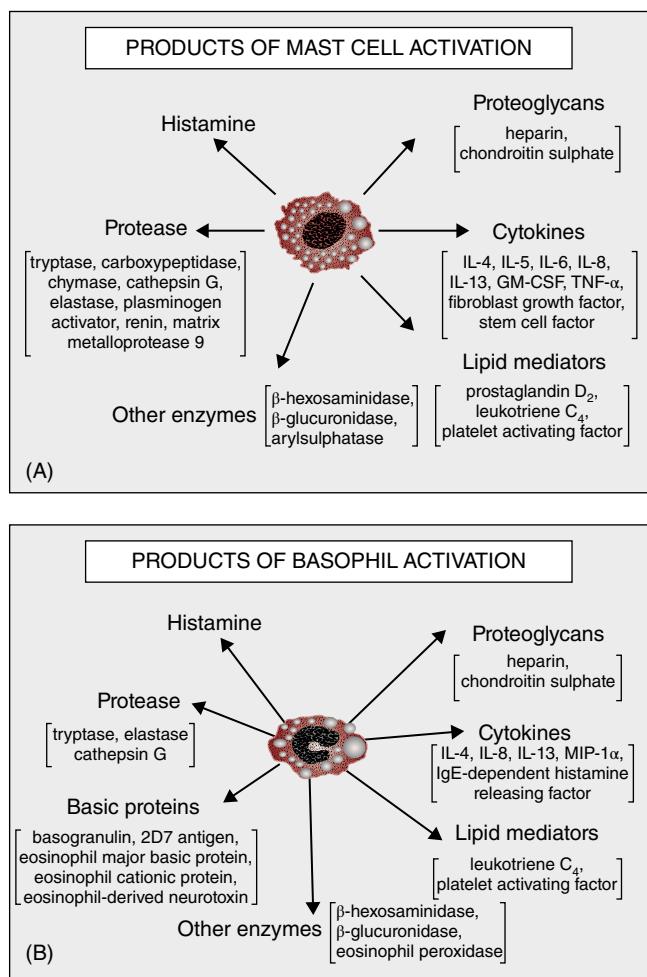

### Description

Anaphylactic reactions are serious and potentially life-threatening immediate hypersensitivity reactions to allergens in the plasma of transfused blood components.<sup>63</sup> These reactions can have a rapid onset beginning as early as seconds to minutes after the start of the transfusion and can occur with small transfused volumes. Anaphylactic reactions are differentiated from other allergic (urticarial) transfusion reactions by their systemic nature and severity. These reactions generally affect multiple organ systems as evidenced by cutaneous, respiratory, cardiovascular, and gastrointestinal effects. The symptom complex often includes the rapid onset of laryngeal edema and bronchospasm with stridor, wheezing, coughing, and respiratory distress. Other symptoms include generalized urticaria, erythema, tachycardia, hypotension, nausea, vomiting, diarrhea, and cramping abdominal or pelvic pain. Severe reactions can proceed rapidly to shock, syncope, respiratory failure, and death. Fatal anaphylactic reactions are less common than are fatal hemolytic or septic reactions.

### Etiology

Anaphylactic reactions occur when an allergen present in plasma is transfused to a patient who through previous sensitization has an IgE directed against that allergen.<sup>64</sup> Immunoglobulin E is bound by means of Fc receptors to mast cells and basophils. The binding of allergen to cell-bound IgE results in crosslinking of IgE and Fc receptors. This crosslinking activates the mast cells and basophils to secrete preformed mediators, such as histamine, as well as newly synthesized mediators, such as leukotrienes, prostaglandins, cytokines, and platelet-activating factor (PAF) (Figure 48.2).<sup>65</sup> PAF induces downstream production of nitric oxide (NO) through inducible and possibly constitutively expressed NO synthase.<sup>66</sup> As a potent vasodilator, NO is believed to be the principal compound causing hypotensive and cardiovascular collapse during anaphylaxis, although the exact mechanism remains under debate.

Anaphylactoid reactions are acute hypersensitivity reactions that are clinically identical to anaphylaxis but are not mediated by IgE antibodies or IgE involvement cannot be established. For example, immune complexes involving antibodies other than IgE may result in complement fixation and generation of the anaphylatoxins C3a, C4a, and C5a, which activate basophils and mast cells. Some cytokines secreted by monocytes as part of the inflammatory cascade initiated by non-IgE immune complex formation can also directly activate basophils and mast cells and initiate anaphylactoid reactions. Moreover, IgG4 subclass antibodies can bind to Fc receptors of mast cells and basophils and, in a manner analogous to that of IgE, mediate cellular activation and degranulation after binding

**Figure 48.2** (A) Mast cell with its activation products. (B) Basophil with its activation products. Note that currently only two products of mast cell activation (histamine and total tryptase) and one product of basophil activation (histamine) can be measured in clinical laboratories as markers of acute anaphylaxis events. Used with permission from Simons *et al.* (2007).<sup>66</sup> IL: interleukin; GM-CSF: granulocyte macrophage colony-stimulating factor; TNF $\alpha$ : tumor necrosis factor alpha; MIP: macrophage inflammatory protein.

of allergen. The term *anaphylactoid* is sometimes used to describe mild or clinically atypical anaphylactic reactions. However, *anaphylactoid* is better used to differentiate the mechanism of the reaction, not its clinical severity or presentation.

The best documented anaphylactoid reactions have resulted from the transfusion of donor plasma containing IgA- to IgA-deficient recipients who have produced a class-specific IgG anti-IgA antibody that reacts with all IgA subclasses. A recent case report of neutropenia and monocytopenia in a recurrent anaphylactoid reaction after red blood cell transfusions showed an atypical signs and symptoms of anaphylactoid reaction with the patient only experiencing rigors, fever, and hypertension in addition to neutropenia and monocytopenia. The patient was later found to be IgA deficient (<0.05 mg/dL) with IgG anti-IgA in serum.<sup>67</sup>

Less commonly, patients with normal total IgA levels have a subclass-specific IgA deficiency and may make an anti-IgA of restricted specificity. Although IgA deficiency is relatively common (approximately 1 case among 700 persons), anaphylactoid reactions

occur only among some IgA-deficient transfusion recipients because not all make anti-IgA. Anaphylactic or anaphylactoid reactions have been documented among patients with deficiencies of other plasma proteins, such as complement, von Willebrand factor, and haptoglobin.<sup>68–69</sup> In an analogous manner, these patients produce an antibody to the missing factor that reacts with transfused, plasma-containing blood components. Angiotensin-converting enzyme (ACE) inhibitors are drugs commonly prescribed to treat hypertension. Patients taken ACE inhibitors have been reported to have anaphylactoid reactions during online extracorporeal apheresis such as plasma exchange.<sup>70</sup> In most anaphylactic or anaphylactoid reactions, however, the allergen is never identified, nor is evidence obtained to differentiate anaphylactic from anaphylactoid mechanisms.

### Diagnosis

Anaphylactic and anaphylactoid reactions are diagnosed from clinical signs and symptoms.<sup>71</sup> The cutaneous signs and symptoms and the often rapid onset of the reaction help differentiate anaphylactic reactions from acute hemolytic and septic transfusion reactions. Serum  $\beta$ -tryptase levels may be measured to confirm an anaphylactic reaction because it is a marker for mast cell degranulation. However, no laboratory measurement is available in time to meaningfully affect recognition and management of an anaphylactic reaction.

Recipient IgA levels should be measured in a pretransfusion blood specimen to determine if the recipient is IgA deficient. Although the results of tests for IgA deficiency do not affect diagnosis or management of the reaction at hand, it is important for avoiding future reactions.<sup>63</sup> Testing should be performed on a specimen drawn before transfusion because IgA deficiency can be masked by any IgA provided by the transfusion. Recipient anti-IgA can also be measured, especially for rare cases in which the anti-IgA is subtype-specific and total IgA levels are within the reference range. Although IgA is the most commonly known allergen in anaphylactoid reactions, in many anaphylactic and anaphylactoid reactions, the offending allergen is not IgA and is never identified.

### Treatment

Anaphylactic and anaphylactoid reactions are managed identically.<sup>71</sup> Severe reactions are true medical emergencies and should be managed by experienced critical care staff, if possible. The patient should be placed in an intensive care unit as soon as it is practical without jeopardizing emergency care. Once anaphylaxis is evident clinically, 1:1000 epinephrine solution (1 mg/mL) should be administered subcutaneously in a dose of 0.2–0.5 mL for adults (0.01 mL/kg of body weight for children). The dose may be repeated every 15–30 minutes as needed. Intravenous crystalloid or colloid solution should be administered as needed to support the patient's blood pressure. For example, 500 mL to 1 L of normal saline solution can be administered in the first 15–30 minutes. Further infusion should be titrated to blood pressure. If the systolic blood pressure is less than 60 mmHg, intravenous epinephrine in a dose of 1–5 mL of a 1:10,000 solution (0.1 mg/mL) for adults and 0.1 mL/kg for children is administered over 2–5 minutes by means of intravenous push. An epinephrine drip (1–4  $\mu$ g/minute) may be started, and administration of other pressors, such as dopamine, can be considered. Blood pressure, pulse, and urine output should be monitored. It may be necessary to monitor the effectiveness of fluid replacement and pressor infusion through measurement of central venous pressure.

Respiratory distress is managed with supplemental oxygen. The patient's upper airway may have to be secured with endotracheal intubation if obstruction from laryngeal edema is imminent. Stridor is a sign of laryngeal edema. Endotracheal intubation and mechanical assistance with ventilation are indicated if the PaCO<sub>2</sub> increases to more than 65 mmHg. When intubation is difficult or impossible because of laryngeal obstruction, cricothyrotomy or tracheostomy is an option. Wheezing caused by obstruction of small bronchi and bronchioles by increased mucus production and smooth muscle contraction can be managed with nebulized albuterol or metaproterenol and intravenous aminophylline.

Urticaria, angioedema, or gastrointestinal distress is managed with an antihistamine (adults, 50 mg diphenhydramine intravenously; children, 1–2 mg/kg intravenously). H<sub>2</sub>-blocking antihistamines may be added as an adjunct to H<sub>1</sub> blockers. Glucocorticoids, such as hydrocortisone, 200 mg given intravenously every six hours, are also administered because they reduce late-phase inflammatory responses. Glucocorticoids, however, are not expected to be of benefit in the initial management of anaphylaxis because of their delayed onset of action.

### **Prevention**

Patients with IgA deficiency who have already had an anaphylactic reaction or who are known to have anti-IgA should receive transfusion of RBC and platelet preparations that have been saline-washed with an automated cell washer.<sup>59,62</sup> If plasma transfusion is necessary, only IgA-deficient donors should be used. Patients who have anaphylactic reactions to any other known plasma allergen should also be treated with transfusion of saline-washed RBCs or platelet preparations. Because anaphylactic reactions can be induced by very small amounts of allergen, washing must be extensive. Washing and saline replacement by means of automated cell washers have been shown generally successful in removing IgA sufficiently to prevent recurrences of anaphylactoid reactions.

If a patient has had one anaphylactic reaction of unknown causation, the next transfusion need not necessarily be performed with washed RBCs or platelets because the reaction might have been donor specific. The next transfusion may be administered slowly with vigilance after premedication with both H<sub>1</sub> and H<sub>2</sub> blockers and a glucocorticoid. The patient care team should be prepared to respond to an anaphylactic reaction. The patient should ideally be in a critical care unit with monitoring at the time of transfusion and with a critical care physician and nurses in attendance. Some blood banks with the capability of automated cell washing, nevertheless, may choose to provide saline-washed RBCs and platelet concentrates for future transfusions after a single anaphylactic reaction as a precautionary measure, particularly if the patient is not expected to receive many more transfusions.

### **Complications of massive and rapid transfusion**

Massive transfusion is defined as the replacement of one blood volume within a 24-hour period. For practical purposes for adults of average size, this is roughly equivalent to 10 units of RBCs with any accompanying crystalloid, colloid, platelet, or plasma infusions. An infusion of greater than four units of RBCs in an hour and ongoing use anticipated could also be regarded as a massive transfusion. The possible complications include citrate toxicity, electrolyte imbalance (hyperkalemia from transfusion of older RBCs and hypocalcemia from citrate toxicity), circulatory overload, and hypothermia.

Recipients of massive transfusions are at increased risk of hemolytic transfusion reactions (including ABO incompatibility), FNHTR, and allergic reactions because of the number of units they receive. Reactions can be more severe with massive transfusion because rapid infusion means the implicated unit often has been completely administered before the onset of symptoms. The large number of units transfused in a short time complicates the investigation of transfusion reactions because each transfused component must be investigated. Due to the resurgent interest in transfusing whole blood for hemorrhagic shock, low-titer group O whole blood (LTOWB) is being used at many trauma centers, and there is increasing evidence both in the military and civilian populations that the early intervention with blood products in patients with traumatic bleeding saves lives.<sup>72–74</sup> The AABB Standard 5.15.1 in the 31st edition states “recipient shall receive ABO group-compatible Red Blood Cell (RBC) components, ABO group-specific Whole Blood, or low-titer group O Whole Blood (for non-group -O recipients or for recipients whose ABO group is unknown).” This new standard permits the use of LTOWB in a manner that is similar to how group O un-crossmatched RBCs are provided to a recipient of unknown ABO group in an emergency.<sup>75</sup> Transfusion of LTOWB to nongroup O recipients has the potential for hemolysis because of the presence of anti-A and anti-B in the plasma of the whole blood. The safety of using group A plasma and LTOWB in trauma resuscitation had been previously demonstrated in the STAT study and other studies.<sup>76–78</sup>

The nonhemolytic lethal triad of severe trauma consists of hypothermia, acidosis, and coagulopathy. “Damage control” resuscitation methods have been developed to directly address the coagulopathy of trauma. The coagulopathy of trauma develops because of severe injury and is already present when a patient presents for emergency medical care. Trauma coagulopathy is not caused by the resuscitation efforts of emergency medical interventions as traditionally understood.<sup>79</sup> Advances in trauma research have shown that early application of damage control resuscitation can greatly improve survival through an application of a 1:1:1 plasma-red-cell-platelet ratio from patient presentation.<sup>80</sup> In well-coordinated trauma centers, massive transfusion protocols now provide six units of plasma, six units of RBCs, six whole-blood-derived platelet concentrates (or one apheresis platelet) or four units of plasma, four units of RBCs, and one unit of apheresis platelets. Aggressive damage control transfusion has been associated with a number of risks including hyperkalemia. Despite these risks, retrospective studies have shown that the application of early, aggressive transfusion support improves overall survival in this severely injured population that would otherwise have very poor prognosis.

Rapid transfusion can also occur during therapeutic apheresis and red cell exchange apheresis (erythrocytapheresis). During apheresis procedures, as many as 10–20 units of fresh frozen plasma or 4–8 units of RBCs can be transfused over 1.5–2 hours. Although any acute transfusion reaction can occur during apheresis-associated transfusion, citrate toxicity in particular is a common but usually mild complication.

### **Citrate toxicity**

Rapid blood transfusion can cause a transient decrease in the level of ionized calcium because of the calcium-chelating properties of the citrate anticoagulant in stored blood components.<sup>81</sup> The clinical presentation of citrate-induced symptoms is also termed *citrate toxicity*. Citrate toxicity can occur whenever large volumes of plasma

that contain citrate are transfused, such as during massive transfusion, plasma exchange, or other apheresis procedures.<sup>82–84</sup> Citrate infusion can induce hypocalcemia, hypomagnesemia, and other electrolyte imbalances, and these imbalances are associated with clinical symptoms. Apheresis procedures can produce a unique clinical paradox of urinary calcium excretion in the setting of hypocalcemia.<sup>83,85</sup> Hypocalcemia is a recognized complication of liver transplantation, in which large amounts of plasma are transfused. However, the precise mechanism of hypocalcemia is not well understood and may not be caused entirely by citrated plasma.<sup>86–87</sup>

Citrate ordinarily is rapidly metabolized to bicarbonate in mitochondria-rich tissue, such as liver, skeletal muscle, and kidney.<sup>81</sup> In the routine transfusion of blood components, patients with normal liver function usually tolerate the citrate infusion without significant complications. However, patients with liver or renal failure or parathyroid dysfunction are at greater risk of citrate toxicity when they receive rapid transfusions of plasma or plasma-containing blood components. Citrate anticoagulates blood by binding divalent cations such as calcium, thus hypocalcemia is a primary symptom. Other divalent cations such as magnesium and zinc can also be bound by citrate, but the contribution of hypomagnesemia to clinical symptoms is less pronounced.<sup>88</sup> During apheresis, citrate is administered as acid–citrate–dextrose formula A (ACD-A) in constant proportion to the whole blood flow rate. Healthy plateletpheresis donors receive relatively large doses of citrate, and many experience mild symptoms of the citrate effect, but the symptoms usually do not progress because of the short duration of the procedure. Donors of peripheral blood stem cells (PBSCs), however, receive smaller doses of citrate per unit of time but usually experience more severe citrate toxicity because of the longer duration of the procedure. Paresthesia caused by transient hypocalcemia is common in apheresis. It typically occurs after the initial infusion of the priming solution (if citrate is used) or later as apheresis progresses. Apheresis practitioners should be aware that peripheral paresthesia caused by hypocalcemia can be masked in patients with a preexisting neuropathy as a result of chemotherapy (vincristine) or as part of a neurologic condition.

Citrate toxicity is recognized clinically because of the signs and symptoms of hypocalcemia. It can be confirmed by measuring the plasma-ionized calcium level in the patient. Symptoms of hypocalcemia include peripheral and perioral paresthesia (Chvostek and Trousseau signs can occasionally be elucidated), muscle spasm, cramping, nausea, vomiting, cardiac arrhythmia, bradycardia, hypotension, and, if severe, tetany. An electrocardiogram (ECG) can show prolongation of the QT interval with hypocalcemia, but the relation is not linear with the ionized calcium level, and ECG findings are an unreliable guide to calcium therapy.

Mild citrate toxicity during transfusion or apheresis is managed or prevented in part by means of slowing the rate of transfusion or reinfusion. When slowing the infusion rate is impossible or ineffective and the patient has signs and symptoms of hypocalcemia, calcium supplementation is indicated. The best guide to determining a need for calcium supplementation is the measurement of the patient's ionized calcium levels, if results can be obtained rapidly. Calcium replacement during apheresis should generally be given when a patient has symptoms, when the patient's clinical condition may exacerbate citrate effects, or when prolonged large-volume leukapheresis is expected to cause citrate toxicity. Infusion of calcium itself, however, is associated with the development of ventricular arrhythmia and even cardiac arrest. Therefore, intravenous calcium replacement for the management or prophylaxis

of apheresis-induced citrate toxicity should be administered only by experienced apheresis staff. Under no circumstances should calcium be added directly to a unit of blood because it causes clots to form in the bag.

Citrate toxicity during apheresis is related to the citrate concentration of the reinfused blood or colloid solution, the infusion rate, the blood volume of the patient, and the total time over which the citrate is infused.<sup>89</sup> It is difficult to establish a definitive safe rate of citrate infusion because of the large number of variables involved. However, citrate dosages of up to 1 mg/kg/minute given during plateletpheresis are usually well tolerated during a 60–90 minute collection. A safe rate of calcium replacement for controlling citrate toxicity during more prolonged (several hours) PBSC apheresis is 0.5–0.6 mg of calcium ion for every 1.0 mL of infused ACD-A.<sup>90–91</sup> These dosages have been successful for prophylaxis against citrate toxicity during large-volume leukapheresis. To avoid excessive volume during PBSC apheresis, the administration of a concentrated calcium solution (calcium chloride or calcium gluconate) is appropriate. Care must be taken to coordinate the calcium infusion with whole blood flow during the apheresis procedure to avoid the potential for catheter thrombosis. Calcium administration should be halted soon after interruptions in whole blood flow.

### **Electrolyte disorders**

Because of inhibition of sodium–potassium–adenosine triphosphatase in red cell membranes by the cold storage temperature of RBC units, extracellular potassium accumulates with increasing blood bank storage times. Extracellular potassium increases at the rate of approximately 1 mEq/day during the first three weeks of RBC storage in citrate–phosphate–dextrose–adenine-1 (CPDA-1).<sup>92</sup> Potassium levels in additive solution-1 (Adsol) units are markedly higher on Day 7 of storage (17 mmol/L) than on Day 0 (1.6 mmol/L). The increase is even greater by Day 42 (46 mmol/L).<sup>93</sup> Total extracellular volume in additive solution is less than half of that in CPDA-1 blood; this must be taken into account when the amount of transfused extracellular potassium is considered.

Hyperkalemia resulting from massive transfusion of older RBC units with an elevated amount of extracellular potassium can cause significant cardiac complications and possibly death in some patients.<sup>94</sup> Acidosis can contribute to hyperkalemia, and severely injured patients presenting with a potassium level greater than 4 mmol/L are at increased risk. Other patients at risk of hyperkalemic complications are neonates and those with renal failure. The diagnosis of hyperkalemia is made by means of measurement of potassium in the serum and observation of ECG changes, which include peaked T waves, prolongation of the PR interval, and ventricular arrhythmia.<sup>95</sup> In neonatal transfusions, hyperkalemia can be avoided by use of fresh RBC units (less than seven days old) or older units that have been saline-washed to remove the extracellular fraction containing the potassium.<sup>96–97</sup> However, the transfusion of older RBC units does not place neonates at risk of hyperkalemia if small-volume transfusions (10–15 mL/kg) are given slowly.<sup>98</sup> Hypokalemia can also develop during massive transfusion or large-volume apheresis.<sup>83,99</sup>

As the anticoagulant citrate in blood components is metabolized to bicarbonate, the blood can become alkalotic, producing hypokalemia. The degree of hypokalemia may be sufficient to necessitate infusion of potassium if symptoms develop. However, the use of newer RBC additive solutions such as Adsol has helped to decrease the effect of hypokalemia. RBC units are plasma-reduced before the addition of additive solution, which itself

contains no additional citrate. Therefore, most of the citrated plasma is removed from additive solution RBC units during production. Animal studies have shown fewer physiologic aberrations during massive transfusion with Adsol RBCs than with CPDA-1 units.<sup>100</sup> The complications of hypokalemia, therefore, are more likely when large numbers of units of plasma rather than RBC units are transfused. Post-transfusion hypokalemia can also be due to potassium uptake by transfused old RBCs.

### Hypothermia

Hypothermia, defined as a core body temperature of less than 35 °C, may be caused by rapid infusion of large quantities of cold (1–10 °C) blood or RBC units. Hypothermia during massive transfusion has been shown to induce cardiac arrhythmia and arrest.<sup>101</sup> Hypothermia is a known independent risk factor for early coagulopathy, multiple organ failure (MOF) development, and mortality.<sup>102</sup> Even smaller quantities of cold blood can be cardiotoxic if transfused into central venous lines because the newly infused cold blood can reach the heart before sufficient warming has occurred. Data published in the early 1960s showed that massive transfusion at a rate of approximately one unit every 5–10 minutes was sufficient to lower the temperature of an esophageal probe behind the right atrium to nearly 30 °C.<sup>101</sup> The resulting decrease in sinoatrial node temperature was associated with the development of ventricular fibrillation.

For most routine transfusions given at a standard rate of administration, blood does not have to be warmed.<sup>103</sup> The patient may experience minor chills, but this is easily remedied by warming the patient, as with extra blankets. Transfusion of cold RBC units through central venous lines, however, should be avoided. Indications for warming blood include rapid transfusion, which are generally considered to be more than 50 mL/kg/hour for an adult and more than 15 mL/kg/hour for a child, and exchange transfusion for infants. Because blood warming during certain massive transfusions sometimes delays infusion and impedes resuscitation, it is not always practical. Warming blood for transfusion in the treatment of patients with cold agglutinin disease has a theoretic basis but is debatable because supportive outcome data are lacking.

If blood has to be warmed, an approved warming device should be used and the temperature must be kept below a point where hemolysis occurs.<sup>103</sup> Care must be taken when warming up blood because warming to a temperature above 42 °C may cause hemolysis.<sup>104</sup> Infusion of thermally injured cells can induce disseminated intravascular coagulation and shock. Heating blood with a device other than an approved blood warming device, such as a commercial microwave oven, is unacceptable. Blood that has been warmed but not used should not be reissued for another patient because of the increased risk of bacterial proliferation at warmer temperatures.

The maximum flow rate that can be achieved with commercially available blood warmers is 850 mL/minute; however, most can provide a rate of only 150 mL/minute. Most recent research has focused on comparisons between commercial warming devices, and the comparison studies usually evaluate warming capability in the rapid transfusion setting.<sup>105</sup> Most of the available federally approved blood warming devices safely warm blood and other intravenous fluids across a range of flow rates. However, although little recent data exist correlating the clinical benefits of warming blood, many emergency centers and trauma services use such devices routinely without incident.

An alternative to using mechanical blood warmers that circumvents such flow limitations is rapid admixture with warm or hot

saline solution immediately before transfusion.<sup>103,106</sup> This technique immediately warms a unit of RBCs, yet does not cause significant hemolysis. However, it necessitates that warmed saline solution be available at all times in trauma care and requires attention to technique to avoid the direct infusion of hot saline solution into the patient.

### Reactions attributed to microaggregate debris

Microaggregate debris ranges in diameter from 20 to 120 µm and consists of nonviable platelets, white cells, and strands of fibrin that form in blood during storage.<sup>107–108</sup> Because of their size, microaggregates are not removed from transfused blood with the standard 170–260-µm screen filters. A variety of adverse events have been attributed to the presence of microaggregate debris after large-volume and massive transfusion.

Studies in the 1960s showed that patients undergoing open heart surgery with cardiopulmonary bypass experienced post-perfusion syndrome during the postoperative period. This symptom complex consisted of cerebral and renal dysfunction attributed in part to occlusion of end-organ capillaries with microaggregate debris. Cotton wool (Swank) microaggregate blood filters capable of retaining particles or debris with a size of 40 µm or more appeared to eliminate many of these reactions. Microaggregate blood filters (MBFs) with 10–40 µm pore size are able to eliminate larger-diameter, retained, blood component microaggregate materials and nonblood, particulate matter that is potentially harmful to the recipients. In other words, MBFs ensure the patient protection from microaggregate materials, clots, and particulate debris that can cause pulmonary embolization.<sup>109</sup>

During the Vietnam War, some soldiers who underwent massive transfusion experienced respiratory distress syndrome (shock lung). At autopsy, the cause was presumed to be the material found in soldiers' lungs that was positive on a periodic acid-Schiff (PAS) test. Because microaggregate debris stains PAS-positive, this was taken at the time as evidence of the pathologic nature of microaggregate debris.

During the 1970s and 1980s, studies were undertaken to determine whether removal of microaggregate debris from blood was clinically significant.<sup>107</sup> Several studies showed that microaggregate filtration of up to six units of blood during either hip or cardiac surgery provided no benefit. Collins *et al.*<sup>110</sup> concluded that the underlying clinical condition rather than the infusion of the microaggregate debris in blood led to the development of the respiratory distress syndrome reported earlier among patients undergoing massive transfusions. Microaggregate blood filters today are used mostly in conjunction with cardiopulmonary bypass pumps and reinfusion of shed autologous blood collected during or after surgery. With the widespread adoption of leukocyte reduction filtration, routine leukocyte-reduced red cell transfusions are no longer complicated by microaggregate debris because these filters can remove not only leukocytes but also the larger microaggregate particles. As an alternative to microaggregate filters, cell washing can be used to remove intraoperative microparticulates.<sup>111</sup>

### Circulatory overload

*Hypervolemia*, termed Transfusion Associated Circulatory Overload (TACO), is a possible consequence of transfusion in the care of patients with cardiac insufficiency, renal impairment, or already expanded blood volumes, such as patients with chronic anemia.

Moreover, patients with restricted blood volumes (e.g., infants and small children) are at risk of TACO if transfused blood is not reduced to an amount proportional to body mass and intravascular blood volume. The reported incidence of TACO varies widely depending on the method of data collection used. The risk of TACO increases with rapid infusion. The 2011 US Food and Drug Administration report on transfusion-related mortality indicated that TACO was the second most commonly reported cause of death next to TRALI, accounting for an average of 15% of reported deaths between 2007 and 2011.<sup>112</sup> According to the annual summary for fiscal year (FY) 2018 from the US Food and Drug Administration report, TACO is now the leading cause of reported transfusion-associated deaths for FY16 through FY18 and is currently the leading cause of transfusion-associated fatalities over the five-year reporting period (FY2014 - FY2018) accounting for 32% of all reportable deaths. Prior to FY2016, TRALI was the consistent leading cause of transfusion-associated fatalities.<sup>113</sup>

Circulatory overload increases central venous pressure, causes congestion of the pulmonary vasculature, and decreases lung compliance, manifesting as dyspnea, tachycardia, acute hypertension, and in the extreme, pulmonary edema and left- or right-sided heart failure. Other signs and symptoms of circulatory overload include tachypnea, dry cough, chest or throat tightness, jugular venous distention, and pulmonary rales.

Recent studies have shown that the proinflammatory cytokine IL-6 was increased in post-transfusion TACO patients, and fever was described to occur in one-third of the patients developing TACO.<sup>114-116</sup>

Laboratory measurements of circulatory overload include PaO<sub>2</sub>, atrial natriuretic peptide, and B-type natriuretic peptide (BNP).<sup>117-118</sup> B-type natriuretic peptide (BNP), and N-terminal pro-BNP (NT-pro-BNP) are cardiac neurohormones specifically secreted from the ventricles in response to volume expansion and pressure overload.<sup>119</sup> BNP has a reported 81% sensitivity for detecting circulatory overload in the appropriate clinical setting. However, BNP and NT-pro-BNP testing did not reliably distinguish TACO from TRALI and possible TRALI in a cohort of transfused critically ill patients.<sup>120</sup> Diagnosing TACO can be difficult and confounded by other concomitant pathology. There is no accepted clinical definition of TACO, and the symptoms of

TACO can overlap significantly with other transfusion reactions such as TRALI (Table 48.1).<sup>121-122</sup> Some rapid methods of differentiating the overlapping symptoms include blood pressure, response to diuretic therapy, white cell count, and heart auscultation for an S3 (third heart sound).

If symptoms of overload appear, the transfusion should be stopped, and intravascular volume reduction through diuresis should be instituted as needed (e.g., administration of 40 mg furosemide intravenously). The patient should be placed in an upright (reverse Trendelenburg) position, if possible, with supplemental oxygen as necessary.

Rapid transfusion of any blood component into a patient who is not actively hemorrhaging produces no benefit and can cause harm. As a general guide, infusion should be at a rate not to exceed 2–4 mL/kg/hour, and the rate should be lower (~1 mL/kg/hour) for patients at high risk of circulatory overload.<sup>123</sup> In neonates, a slower blood infusion rate increases the hematocrit and decreases cardiac demand without affecting pulmonary artery pressure. More rapid infusion rates are associated with decreased lung compliance and increased pulmonary airflow resistance.<sup>124-125</sup>

For patients with volume overload caused by medical reasons existing before transfusion, furosemide can be given prophylactically, and transfusion should proceed slowly. The rate of transfusion can be even further slowed, if necessary, by dividing a unit of RBCs or another component into smaller aliquots and transfusing a portion at a time over as much as four hours, the maximum allowable time a blood component should be kept outside blood-bank-monitored storage. For RBCs and thawed plasma, the unused portion can be stored in the blood bank at 1–6 °C for up to 24 hours while the initial aliquot is administered. Platelet aliquots can be sampled from a single apheresis platelet unit, and with this practice, donor exposures can be minimized. It is important that the transfusion of all or part of a blood component be completed within four hours and that any unused portion be stored under regulated blood bank conditions because of concerns about increased risk of bacterial contamination during improper storage. RBC units, apheresis platelets, and whole-blood-derived platelet pools can be further concentrated by means of centrifugation and plasma removal, if other measures to prevent volume overload are inadequate.

**Table 48.1** Features in TRALI and TACO

Feature	TRALI	TACO
Body temperature	Fever can be present	Fever may be present (one-third of patients) <sup>102</sup>
Blood pressure	Hypotension	Hypertension
Respiratory symptoms	Acute dyspnea	Acute dyspnea
Neck veins	Unchanged	Can be distended
Auscultation	Rales	Rales, S3 may be present
Chest radiograph	Diffuse, bilateral infiltrates	Diffuse, bilateral infiltrates
Ejection fraction	Normal, decreased	Decreased
PA occlusion pressure	18 mmHg or less	Greater than 18 mmHg
Pulmonary edema fluid	Exudate	Transudate
Fluid balance	Positive, even, negative	Positive
Response to diuretic	Minimal	Significant
White count	Transient leukopenia	Unchanged
BNP	<200 pg/mL	>1200 pg/mL
Leukocyte antibodies	Donor leukocyte antibodies present, and crossmatch incompatibility between donor and recipient	Donor leukocyte antibodies may or may not be present, and positive results can suggest TRALI even with true TACO cases

The typical patterns that would be expected for cases of transfusion-related acute lung injury (TRALI) or transfusion-associated circulatory overload (TACO) are represented. A given case of TRALI or TACO may lack some of the typical features. Also, a case of TRALI may have some features suggesting TACO or vice versa, and TRALI and TACO can be present together. The best strategy is to develop a full clinical profile of the case using the feature list above and determine which diagnosis is most supported. BNP: brain natriuretic peptide; PA: pulmonary artery.

## Toxic reactions resulting from blood manufacture or processing

### Hypotensive reactions

Hypotension may accompany various transfusion reactions including hemolytic and allergic reactions, septicemia, and TRALI, but isolated hypotension as a primary manifestation has not been considered a unique type of transfusion reaction. In the past several years, there have been several reports of transfusion reactions characterized primarily by hypotension, and it now appears that such reactions do require a separate category of transfusion reactions.<sup>126</sup> Hypotension has been reported among patients receiving bedside, leukocyte-reduced platelets who are also medicated with ACE inhibitors.<sup>127</sup> These reactions appear to be caused by generation of bradykinin in transfused blood just as it is being passed through negatively charged leukocyte reduction filters. The mechanism is believed to involve the formation of activated factor XIIa when factor XII, a contact factor, is exposed to the negatively charged filter surface. The filter surface can mimic exposed, negatively charged subendothelium, which is the natural activating stimulus for the contact factors of the intrinsic coagulation pathway after blood vessel damage *in vivo*. Factor XIIa converts prekallikrein to kallikrein, which cleaves high-molecular-weight kininogen to form bradykinin. The biologic activity of the infused bradykinin is prolonged in transfusion recipients who are also receiving ACE inhibitors (e.g., captopril and enalapril), which inhibit kininase II, the enzyme that breaks down bradykinin. The combination of bradykinin generation just as the blood is being infused with inhibition of the transfusion recipient's ability to break down bradykinin produces prolonged bradykinin activity conducive to hypotensive reactions.

These reactions are less likely with use of prestorage leukocyte-reduced blood components because the bradykinin is broken down rapidly in the component bag during storage before transfusion. Although hypotensive reactions have been reported more frequently with negatively charged bedside leukocyte reduction filters, they also have been rarely reported with positively charged filters. This can be explained in part by the possibility that patients taking ACE inhibitors may be more prone to hypotensive reactions in general because of their relative inability to rapidly break down bradykinin generated *in vivo* by any allergic mechanism. Hypotensive reactions to bedside leukocyte reduction among patients taking ACE inhibitors can be prevented by the use of prestorage leukocyte-reduced blood components or by means of temporary discontinuation of ACE inhibitor treatment.

Apheresis procedures are also associated with hypotensive reactions, and the literature has described hypotensive reactions in both adult and pediatric apheresis patients.<sup>128–129</sup> Apheresis may contribute to hypotensive reactions through several mechanisms including the potentiation of bradykinin-mediated effects by albumin and secondary to hypocalcemia.<sup>129</sup> Data suggest that calcium infusions can mitigate some atypical apheresis reactions, while withholding ACE inhibitor medications 24–48 hours before apheresis may also contribute to lessening reactions.

### Plasticizer toxicity

Plasticizers are chemicals used to make rigid polyvinyl chloride plastics more malleable. The traditional plasticizer for blood storage bags is di(2-ethylhexyl)phthalate (DEHP), which leaches over time from the plastic into the blood and blood components with increasing exposure. The DEHP metabolite, mono(2-ethylhexyl) phthalate (MEHP), also accumulates during storage.<sup>130</sup> Infusion of

blood that contains DEHP results in deposition of DEHP in various tissues; the greatest accumulation is in body fat. Results of some studies with animals have suggested that DEHP is toxic and may even be carcinogenic in large quantities.<sup>131</sup> Other studies with animals have shown that MEHP is associated with the formation of peroxisomes, indicating tissue alteration and toxicity. Although there have been no reports of transfusion-related plasticizer toxicity among humans, results of some *in vitro* experiments suggest that high concentrations of MEHP have a negative inotropic effect and can cause irregular contractions in isolated human myocardial cells. Some clinical data have described the production of antiplasticizer IgE in transfusion recipients and the incorporation of plasticizer into red cells during storage.<sup>132</sup> Despite the possible adverse effects of DEHP plasticizers, other data indicate that these substances stabilize red cell membranes and improve the morphologic features of platelets during storage.<sup>133–134</sup> No good evidence exists, however, of actual improvement in post-transfusion outcomes as the result of these effects.

Formulations for plastic blood bags were developed with plasticizers other than DEHP that have a decreased capacity to leach into plasma. For example, one polyvinyl chloride-based material is made with plasticizer butyryl tri-*n*-hexyl citrate (BTHC). Although BTHC also leaches into blood components, it does so at a significantly slower rate than does DEHP. It also provides an antihemolytic effect similar to that of DEHP.<sup>135</sup> Studies have shown this citrate-based plasticizer is suitable for the storage of both RBCs and platelets.<sup>136</sup>

### Dimethyl sulfoxide toxicity during infusion of cryopreserved progenitor cells

DMSO is a versatile solvent that has been used as the principal cryopreservative for mononuclear cells since the 1950s. It is widely used as a cryopreservative for marrow and PBSCs used in human hematopoietic progenitor cell transplantation. Despite this, DMSO is not approved by the FDA as a pharmacologic agent for intravenous administration, and guidelines for intravenous administration are obscure. Toxicologic studies, however, have established the general safety of intravenous DMSO infusion.<sup>137–138</sup> The metabolism of DMSO yields a characteristic harmless odor, described as a malodorous garlic or sulfur-like smell. Because of the exceptional solvent properties of the compound, DMSO is distributed throughout all tissues after administration. The two metabolites of DMSO are dimethyl sulf dioxide and dimethyl sulfide (DMS). Dimethyl sulf dioxide is an odorless compound excreted by the kidney, and DMS is excreted through the lungs and through other tissues and contributes to the characteristic odor.

The clinical toxicity of DMSO in marrow transplantation has been studied. Anaphylactoid symptoms attributable to the release of histamine and other mediators are common. Other toxic clinical signs and symptoms include hemolysis with hemoglobinuria, hyperosmolality, increased serum transaminase values, nausea, vomiting, abdominal cramping, fever, chills, tachypnea, cough, diarrhea, flushing, and headache.<sup>139–140</sup> Patients who have been conditioned with chemotherapy or who have smaller body mass (<70 kg), seem more likely to experience nausea and vomiting after infusion of DMSO-preserved cells. Cardiovascular toxicities include decreased heart rate and bradycardia, occasionally increased heart rate and tachycardia, ectopic heartbeat, heart block, hypertension, and other lesser blood pressure changes.<sup>139,141</sup> Some studies, however, raise the question whether there is any significant cardiovascular toxicity of DMSO.<sup>142</sup> It is possible that some

adverse effects attributed to DMSO may be caused by the cellular infusion itself.

The mechanism of the clinical toxicities associated with DMSO infusion has not been well established. Histamine receptor binding of DMSO, histamine release, direct vagal tonic effects, cold thermal vagal responses, and renal failure secondary to hemolysis explain many of the symptoms observed during cryopreserved cellular infusion.<sup>139,143</sup> Increases in thrombin-antithrombin complex,  $\beta$ -thromboglobulin, platelet factor 4, and von Willebrand factor caused by DMSO have been described.

Several measures can be taken to prevent or reduce DMSO toxicity. Antihistamine prophylaxis is recommended routinely before any administration of DMSO. Additional premedications to consider before infusion of hematopoietic stem cells cryopreserved with DMSO include a sedative such as lorazepam and/or hydrocortisone. Intravenous DMSO should be given as a 10–40% solution to avoid local irritation. The recommended maximum daily dose of DMSO is 1 g/kg/day. Slowing an infusion containing DMSO or increasing the time between infusions of multiple aliquots greatly diminishes DMSO-related toxicity, which appears to be a dose-dependent but short-lived response. However, because DMSO is toxic to thawed mononuclear cells, hematopoietic progenitor cells can tolerate exposure to 10% DMSO for only as long as one hour.<sup>144</sup> This limits how much the infusion rate can be slowed. Antiemetics and sedatives can help to ameliorate symptoms, and cellular products can be carefully washed before infusion to remove DMSO and other substances.

## Reactions in special transfusion settings

### Granulocyte transfusion reactions

Granulocyte transfusions remain in use as a treatment option for neutropenic patients because of improved granulocyte collection yields after donor treatment with steroids and granulocyte colony-stimulating factor (G-CSF). Febrile nonhemolytic transfusion reactions after granulocyte transfusion are common and to some degree expected. Severe reactions can be accompanied by pulmonary complications (e.g., TRALI, dyspnea, pulmonary infiltrates, and hypoxia), hypotension, and even cardiovascular collapse.<sup>145</sup> In a recent study of dexamethasone and G-CSF-stimulated granulocyte transfusions, 37% of patients (7% of transfusions) experienced chills, 32% of patients (7% of transfusions) experienced a fever, and 11% of patients (2% of transfusions) experienced hives or itching during a course of therapy.<sup>146</sup> Oxygen desaturation of greater than 3% occurred in 7% of transfusions, and severe desaturation of greater than 6% occurred in 3 of 11 patients experiencing oxygen desaturation. In addition, granulocyte transfusions carry further risk of leukocyte alloimmunization and cytomegalovirus infection.<sup>147</sup>

Concurrent administration of amphotericin B and granulocytes has been linked to severe pulmonary reactions, although the association has not been confirmed and remains in doubt. In a study that examines 195 granulocyte transfusions in 144 patients demonstrated no severe pulmonary toxicity from concomitant administration of granulocytes and amphotericin B.<sup>148</sup> Dyspnea as a side effect of granulocyte transfusion was equally common among patients receiving amphotericin B and those in a matched control group not receiving amphotericin B. It is safe to administer granulocyte transfusion and amphotericin B simultaneously without pulmonary toxicity.

Nevertheless, it is prudent to separate amphotericin B administration and granulocyte therapy by at least six hours to avoid confusion about the cause of a severe reaction, which can occur with either of these reaction-prone treatments. Because of the relatively high rate and severity of febrile, pulmonary, and allergic reactions, it is prudent to give premedication with acetaminophen and diphenhydramine to recipients of granulocyte transfusions. Hydrocortisone may be added as premedication in the treatment of patients with severe reactions who otherwise cannot tolerate granulocyte transfusion, although the immunosuppressive effects of this agent are unwelcome among patients who need granulocyte transfusions to fight serious and life-threatening infections. Granulocyte concentrates should be transfused slowly.

### Autologous transfusion reactions

A variety of reactions to autologous blood occur despite the complete compatibility. In a study involving 596 hospitals, the rate of reported FNHTRs to autologous blood was 0.12% and the rate of allergic reactions was 0.01% per transfused unit.<sup>149</sup> Such rates are approximately 5–10-fold lower than those reported for allogeneic units. The cause of autologous transfusion reactions has not been clearly established. Mechanisms in many cases presumably are the same as for allogeneic transfusions. For example, autologous units can be contaminated with bacteria as can allogeneic units, and contamination leads to febrile reactions or septic complications.<sup>150</sup> Because autologous donors are patients, not healthy volunteers, they may have various medical problems that put them at increased risk of bacteremia.

RBCs: red blood cells; TRALI: transfusion-related acute lung injury; TACO: transfusion-associated circulatory overload.

Accumulation of inflammatory mediators in blood component bags during storage, released from passenger leukocytes or platelets, may result in the infusion of pyrogenic substances. Autologous leukocytes, rather than allogeneic leukocytes, can also generate endogenous pyrogens. Allergic reactions may be provoked by histamine generation during storage of blood components or by chemicals leached from blood storage containers or filters. Moreover, autologous transfusions may contribute to volume overload and hypervolemic reactions through mechanisms identical to allogeneic transfusions.

### Summary

A variety of acute, nonhemolytic, and noninfectious reactions are reported after transfusion (Table 48.2). Many of these reactions have an immune basis and represent inflammatory or allergic responses to infused cells (e.g., many FNHTRs) or plasma (e.g., some FNHTRs, allergic, and anaphylactic reactions). Although urgent transfusion can be lifesaving, it is important to recognize that a large volume of blood components given too quickly can itself have adverse chemical or physical effects, such as hypothermia, hyperkalemia, hypokalemia, hypocalcemia, and circulatory overload. Some reactions are also caused by unintended consequences of blood storage conditions or processing, such as generation of bradykinin by the contact of blood with some filter surfaces, leaching of toxic chemicals from filters or containers, and use of the chemical DMSO during hematopoietic progenitor cell preservation. It is important that these reactions and toxicities be recognized rapidly by the patient care team and blood bank personnel so that appropriate treatment and preventive measures can be instituted quickly.

**Table 48.2** Transfusion Reaction Summary

Type	Cause	Signs and Symptoms	Treatment	Prevention
<b>Febrile, nonhemolytic frequency of FNHTRs</b> before leukocyte reduction 0.33–0.37% (red cells) and 0.45–2.18% (platelets), and after leukocyte reduction 0.15–0.19% (red cells) and 0.11–0.15% (platelets) <b>Allergic</b> overall frequency of 0.11%	Recipient antibodies against leukocytes or platelets antigens in donor blood components; cytokines in plasma or supernatant portion of stored components; undetected bacteria contamination of blood component Allergen is a soluble substance in donor plasma	Chills, fever (>1 °C increase in body temperature); rigors in severe reactions Localized or generalized urticaria, erythema and pruritus; if severe, may have laryngeal or facial angioedema, and hypotension Urticaria, flushing, angioedema, stridor, wheezing, tachycardia, hypotension, shock, abdominal pain, diarrhea, pelvic pain	Stop transfusion, notify physician and blood bank, maintain IV line, monitor vital signs; physician may order acetaminophen Hold transfusion, notify physician, monitor vital signs; physician may order antihistamines or restart of transfusion if mild urticaria clears and no other symptoms in 30 minutes Stop transfusion; maintain IV line; notify physician and blood bank, monitor vital signs; physician may order antihistamines, epinephrine, oxygen, IV crystalloid, or glucocorticoids	Premedicate with acetaminophen (or glucocorticoid for refractory cases); give leukocyte-reduced RBCs Premedicate with H <sub>1</sub> blocking antihistamine; add H <sub>2</sub> blocker or glucocorticoid for refractory cases; consider washed RBCs and platelets for repeated or severe reactions Premedicate with antihistamines and glucocorticoid; transfuse washed RBCs and platelets for recurrent reactions; use IgA deficient donors or washed RBCs and platelets for sensitized patients with IgA deficiency
<b>Anaphylactic or anaphylactoid</b>	Recipient antibodies to a soluble substance in donor plasma; infusion of plasma with IgA into IgA-deficient recipient with IgG anti-IgA antibodies	Dyspnea, orthopnea, systolic hypertension, headache, peripheral edema, coughing, cyanosis, fever may be present	Slow or stop transfusion; keep IV line open; notify physician; monitor vital signs and input and output; physician may order diuretics and oxygen	Transfuse slowly; use split units; consider premedication with diuretics; carefully monitor aged, debilitated, cardiac or pediatric patients
<b>Transfusion-associated circulatory overload (TACO)</b>	Blood volume too large or infusion too fast for compromised cardiovascular system	Decreased body temperature, chills, cardiac arrhythmia (ventricular fibrillation)	Slow or stop transfusion; use an approved blood warmer, blankets, and other patient warming techniques (warm lavages, lamps)	Transfuse slowly, use an approved blood warmer
<b>Hypothermia</b>	Core body temperature <35 °C caused by rapid infusion of cold blood products, such as RBCs, FFP, cryoprecipitate	Perioral or peripheral paresthesia, tingling, buzzing, teeth chattering, bed or chair moving, cramps, nausea, vomiting, arrhythmia, bradycardia, hypotension, prolongation of QT interval, tetany	Slow or stop transfusion; slow or stop apheresis procedure; give IV calcium chloride or gluconate (for PBSC apheresis: 0.5 mg Ca <sup>2+</sup> /1.0 mL ACD-A), or check ionized Ca <sup>2+</sup> and dose per results; monitor relief of symptoms; consider hypomagnesemia	More likely in pediatric and lightweight patients (<70 kg) and patients with liver dysfunction, renal failure, or less skeletal muscle; observe patients closely for any symptoms; give IV calcium (for PBSC apheresis: 0.5 mg Ca <sup>2+</sup> /1.0 mL ACD-A).
<b>Citrate toxicity</b>	Excessive infusion of citrate during apheresis procedure or massive or rapid transfusion; patients with liver failure are at increased risk	Hyperkalemia: cardiac arrhythmia, ECG changes—peaked T waves, prolongation of PR interval (if severe, flat or lost P wave), widened QRS, ventricular arrhythmia Hypokalemia: massive or rapid transfusion of citrate and metabolic alkalosis	Hyperkalemia: give calcium to protect against cardiac effect, alkalinize blood, D50 plus insulin, sodium polystyrene sulfonate; dialysis Hypokalemia: give potassium	Hyperkalemia: give fresh products (<7 days old), or washed products
<b>Electrolyte disorder</b>	Hyperkalemia: transfusion of older blood components or massive transfusion of RBCs	Hypokalemia: massive or rapid transfusion of citrate and metabolic alkalosis	Hypokalemia: give potassium	Hypokalemia: give Adsolpreserved RBCs (not Nutrice)
<b>Hypotensive</b>	Bradykinin generation with use of negatively charged bedside leukocyte reduction filters in patients taking angiotensin-converting enzyme (ACE) inhibitors; apheresis procedures using albumin, especially in patient's taking ACE inhibitors; see also citrate toxicity	Hypotension; sometimes also flushing, respiratory distress, nausea, abdominal pain, and loss of consciousness	Stop transfusion, notify physician and blood bank; support blood pressure	Avoid use of bedside leukocyte reduction filters in patients taking ACE inhibitors; use prestorage leukocyte-reduced components or discontinue ACE inhibitor before transfusion or apheresis procedure; if during apheresis, correct electrolyte disorder such as hypocalcemia
<b>DMSO toxicity</b>	Cryopreservative for bone marrow, PBSCs, Cord blood, donor lymphocyte infusions, or any frozen cellular component; toxicity with DMSO >1.0 g/kg/day	Flushing, nausea, vomiting, abdominal cramping, throat tightness and cough, hypotension, hypertension, arrhythmia, fever, chills, headache, hemoglobinuria, hyperosmolality, increased liver enzymes	Antihistamines; antiemetics; slow or stop the infusion; supportive care; wait between infusions for symptoms to clear	Antihistamines; sedative (lorazepam) and hydrocortisone, washed or plasma or volume depleted cellular infusions; antiemetics

IV: intravenous; RBCs: red blood cells; FFP: fresh-frozen plasma; PBSC: peripheral blood stem cell; ACD-A: acid-citrate-dextrose-adrenaline; D50: dextrose 50% in water; ECG: electrocardiogram; DMSO: dimethyl sulfoxide.

**Table 48.3** Overlapping Signs and Symptoms of Transfusion Reactions

Sign or Symptom	Possible Reaction	Most Likely > Less Likely Blood Component*
Fever, chills, and rigors	Febrile nonhemolytic	Platelets (especially septic)
	Septic	> RBCs > plasma
	Acute hemolytic	
Urticaria and pruritus	TRALI or TACO	
	Allergic	Plasma > platelets > RBCs
Dyspnea	Anaphylactic	
	TACO	Any
	TRALI	
Hypotension	Anaphylactic	
	Septic	Platelets > plasma > RBCs
	Hypotensive	
	Acute hemolytic	
	Anaphylactic	

\* Granulocytes would very likely cause febrile reactions and dyspnea. However, granulocytes are not listed in the table because they are infrequently transfused compared to other blood components.

Care providers who administer transfusions must recognize that some symptoms of transfusion reactions, such as fever, are non-specific and may be early manifestations of potentially life-threatening reactions, such as hemolysis or sepsis (Table 48.3). For that reason, the guiding rule regarding most transfusion reactions is to err on the side of conservatism and stop the transfusion immediately. Transfusion of a blood component that causes a reaction before complete infusion should not be restarted, with the possible exception of mild urticarial reactions. Several strategies are available to prevent repeated reactions among patients who are reaction-prone. These include

leukocyte reduction for the prevention of FNHTR, cell washing for the prevention of allergic and anaphylactic reactions and possibly some FNHTRs, and various premedication regimens.

## CHAPTER 49

# Transfusion-related acute lung injury and other respiratory-related transfusion reactions

E. Alexander Dent & H. Clifford Sullivan

Department of Pathology and Laboratory Medicine, Emory University Hospital, Atlanta, Georgia, USA

Respiratory compromise related to transfusion may be divided broadly into cardiogenic and noncardiogenic causes. Acute noncardiogenic pulmonary edema occurring immediately after transfusion of donor plasma known to contain leukoagglutinins was first described by Brittingham in 1957.<sup>1</sup> Scattered case reports of *allergic pulmonary edema* or *anaphylactic pulmonary edema* followed. In 1985, Popovsky and Moore published the first prospective study of this complication that they termed *transfusion-related acute lung injury* (TRALI).<sup>2</sup> They reported a much higher incidence of the complication than had previously been considered, and following their report, increasing numbers of individual cases and small case series were published. With the development of hemovigilance schemes in the late 1990s, it became apparent that TRALI was not only an important cause of transfusion-related morbidity but also, with the reduction in infectious complications of transfusion, a leading cause of transfusion-related mortality. Better understanding of the pathophysiology has led to more efficacious prevention strategies. The increased understanding and interest in TRALI also led, via active hemovigilance schemes, to improved recognition of cardiogenic dyspnea due to volume overload, now generally termed *transfusion-associated circulatory overload* (TACO).

### TRALI: clinical features

Clinical reports of TRALI describe sudden deterioration of lung function temporally related to blood transfusion. Acute lung injury with noncardiogenic pulmonary edema is common among critically ill patients and is generally considered to have a multifactorial pathogenesis. Many sick patients receive transfusion, especially after trauma. There is evidence that TRALI is a significant contributor to acute lung injury (ALI) and that plasma-rich components are particularly implicated. Many case reports describe severe clinical manifestations, including most of the early published reports. Thanks to a better understanding of the pathophysiology, consensus definitions, and hemovigilance schemes, milder cases are being recognized more often, including those with more subtle presentation.

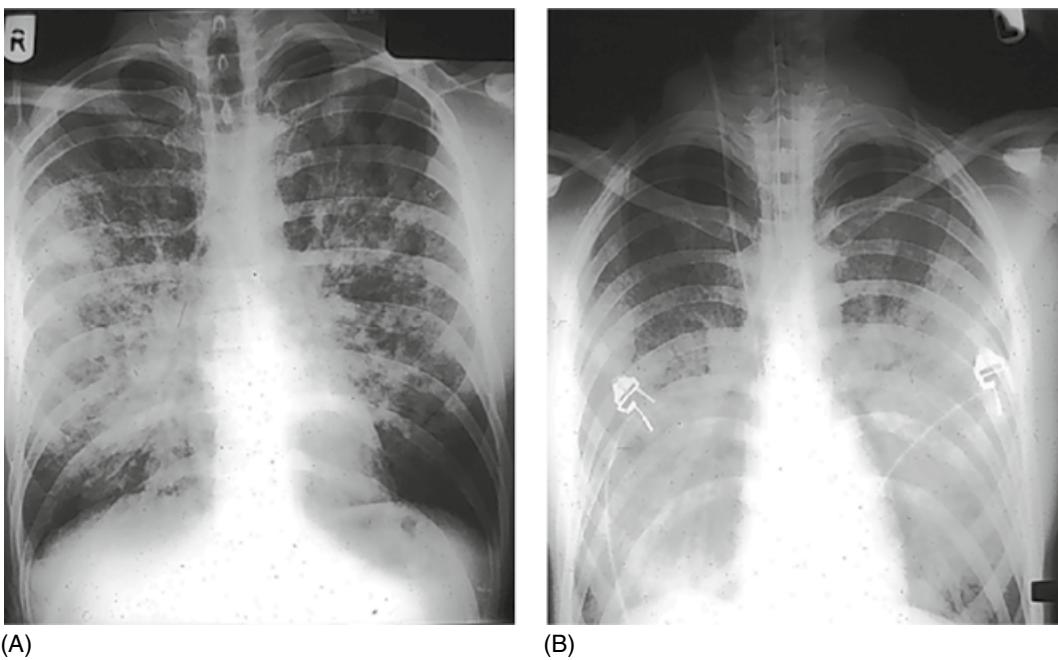

The 2019 consensus definition of TRALI eliminates “probable” and “possible” terminology in lieu of Type I and Type II.<sup>3</sup> In TRALI

type I, patients have no evidence of ALI prior to transfusion, while TRALI type II occurs in patients with preexisting, mild acute respiratory distress syndrome (ARDS) or risk factors for developing ARDS. TRALI symptoms quickly occur after cessation of transfusion: usually within two hours and almost always within six hours. A small number of reports suggest that the onset may rarely be delayed until 12 hours or more after transfusion.<sup>4</sup> Patients describe chest tightness, shortness of breath, and dry cough but may also experience nausea, dizziness, or rigors. On examination, the patient is hypoxic, often hypotensive, tachypneic, and tachycardic. On chest auscultation, widespread crepitations are heard. Rigors and fever are commonly reported but are not always present, and fever may develop hours later.

If the patient is mechanically ventilated, a typical finding is copious and frothy tracheal exudate, resembling whipped egg whites. Although nondiagnostic, anesthesiologists often remark on the quantity of this exudate, and it may be a hallmark of some severe cases of TRALI. Arterial blood gasses show hypoxia ( $\text{PaO}_2/\text{FiO}_2 \leq 300$  mmHg or oxygen saturation less than 90% on room air) and hypercapnia that are often severe.

Chest radiographs show bilateral infiltrates, typically in the “bat’s wing” pattern of acute respiratory distress syndrome (ARDS) (Figure 49.1). The edema from increased pulmonary capillary permeability is characterized as patchy or nodular shadowing mainly in the peripheral lung. The apices and costophrenic angles are spared and have the appearance of air bronchograms. In later stages or in severe TRALI, the chest radiograph may progress to a complete whiteout of the lung fields. Recovery of respiratory function starts as early as six hours after symptom onset in milder cases, but in some patients deterioration may continue for 24 hours or beyond.

Some authors have reported a slightly different clinical picture in which the chief signs are rigors and fever with transient respiratory dysfunction, hypertension rather than hypotension, and occurrence usually within 30 minutes of transfusion. Pulmonary edema is not always demonstrated radiologically, and recovery is within one or two hours. These reactions have typically been associated with cellular blood components. It has been suggested that these cases may represent a different, nonantibody-related etiology from the “classic” severe cases.<sup>5</sup> However, a similar spectrum of mild-to-moderate

**Figure 49.1** Chest X-rays from a 33-year-old man with severe TRALI, taken 2 hours (A) and 24 hours (B) following transfusion of FFP containing HLA class II antibodies. Note the "bat's wing" pattern of edema with sparing of the lung bases, the air bronchograms clearly visible on the first radiograph, and the more confluent airspace shadowing but continued basal sparing in the second X-ray.

reactions of this nature has also been documented with transfusion of plasma-containing antibodies to a neutrophil antigen, anti-HNA-2.<sup>6</sup>

### Pathophysiology

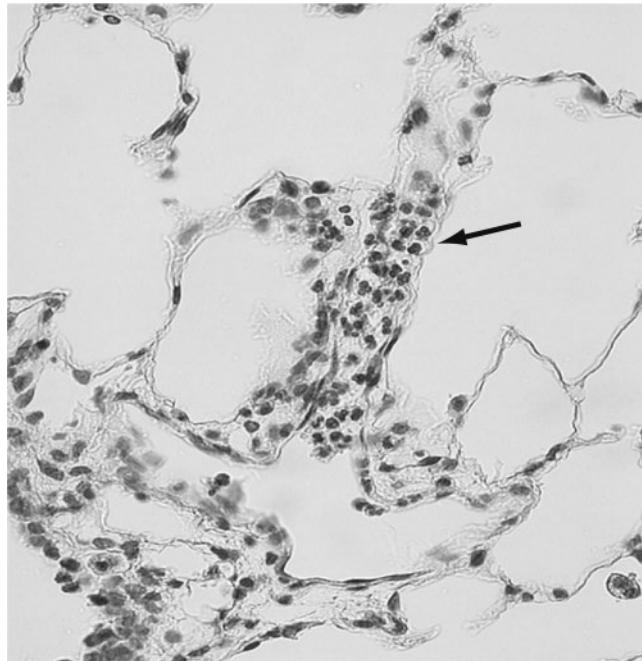

It is now understood that many cases of TRALI, including the most severe cases, are due to an antibody–antigen interaction between donor and recipient. Other mechanisms have been postulated and may be contributory to antibody-related cases or to other causes of lung damage. It is helpful to divide TRALI into antibody-related and nonantibody-related lung damage.

### Acute lung injury

ALI is the result of capillary endothelial leakage, allowing fluid to pass from the pulmonary vessels, through the interstitial space, and into the alveolar air space. Because this edema is distinct from hydrostatic edema caused by cardiac failure or volume overload, it is sometimes known as *nonhydrostatic edema*. Numerous stimuli have been suggested to contribute to the likelihood of developing nonhydrostatic pulmonary edema, including sepsis, trauma, aspiration of gastric contents, disseminated intravascular coagulation, and high tidal volume ventilation. In some cases of TRALI, the transfusion appears to be the only probable cause of the lung injury, whereas in other cases it may be only one of several possible factors present. Histopathology, clinical findings and experimental work have helped elucidate the stimulus present within the transfused blood and the mechanism of subsequent lung damage.

### Histopathology

Histopathologic findings from fatal TRALI cases are consistent with those for early ARDS: interstitial and intra-alveolar edema<sup>2,4,7–11</sup> with extravasation of neutrophils into the interstitial and air spaces (Figure 49.2).<sup>4,7,8,11</sup> Hyaline membrane formation and

**Figure 49.2** Sections of lung from a fatal case of TRALI. Note the presence of granulocytes in the capillaries (arrow indicates neutrophils).

destruction of the pulmonary architecture have also been reported.<sup>7,8</sup> A consistent finding in TRALI is the presence of increased numbers of neutrophils within the pulmonary capillary vasculature and other small pulmonary vessels.<sup>10,11</sup> On electron photomicrographs, neutrophils were degranulated and (focally) in direct contact with denuded stretches of the capillary wall. A positive correlation has been reported both between capillary

leukostasis and desquamated epithelial cells, as well as between the degree of capillary leukostasis and the amount of proteinaceous fluid within the alveolar air spaces.<sup>11</sup> From these observations, it appears that the neutrophil is a central culprit of lung damage. Following neutrophil sequestration in the early stages of TRALI, neutrophils and endothelial cells establish close contact within the pulmonary microvasculature. Activation of the neutrophils leads to endothelial damage and capillary leakage. The transit of proteinaceous fluid from the vessels into the air spaces results in acute pulmonary edema. In the later stage, especially of severe TRALI, neutrophils extravasate from the capillary into the alveoli where they induce further pulmonary injury.

### Evidence for an antibody-related etiology

The relationship between TRALI and leukocyte antibodies in donor plasma was first noted by Brittingham, who reported that leukoagglutinins present in the plasma of a multitransfused patient induced an acute pulmonary reaction when transfused to a volunteer.<sup>1</sup> Similarly, severe pulmonary edema occurred in a healthy volunteer who received an experimental gamma globulin concentrate, deliberately prepared from plasma that contained leukocyte- and monocyte-reactive antibodies.<sup>12</sup> It is likely that this preparation contained high levels of human leukocyte antigen (HLA) class II antibodies. In addition to these cases of TRALI resulting from experimental transfusion of plasma containing leukocyte antibodies, there are numerous case reports of TRALI in which a transfused unit has been found to contain antibodies reactive with recipient leukocytes. In two large series of TRALI, where pulmonary infiltrates were apparent in chest X-rays, leukocyte antibodies in the

donor of a transfused blood component were detected in 61–89% of cases.<sup>2,13</sup> Animal models have provided confirmation of this antibody-mediated mechanism of TRALI.<sup>14</sup>

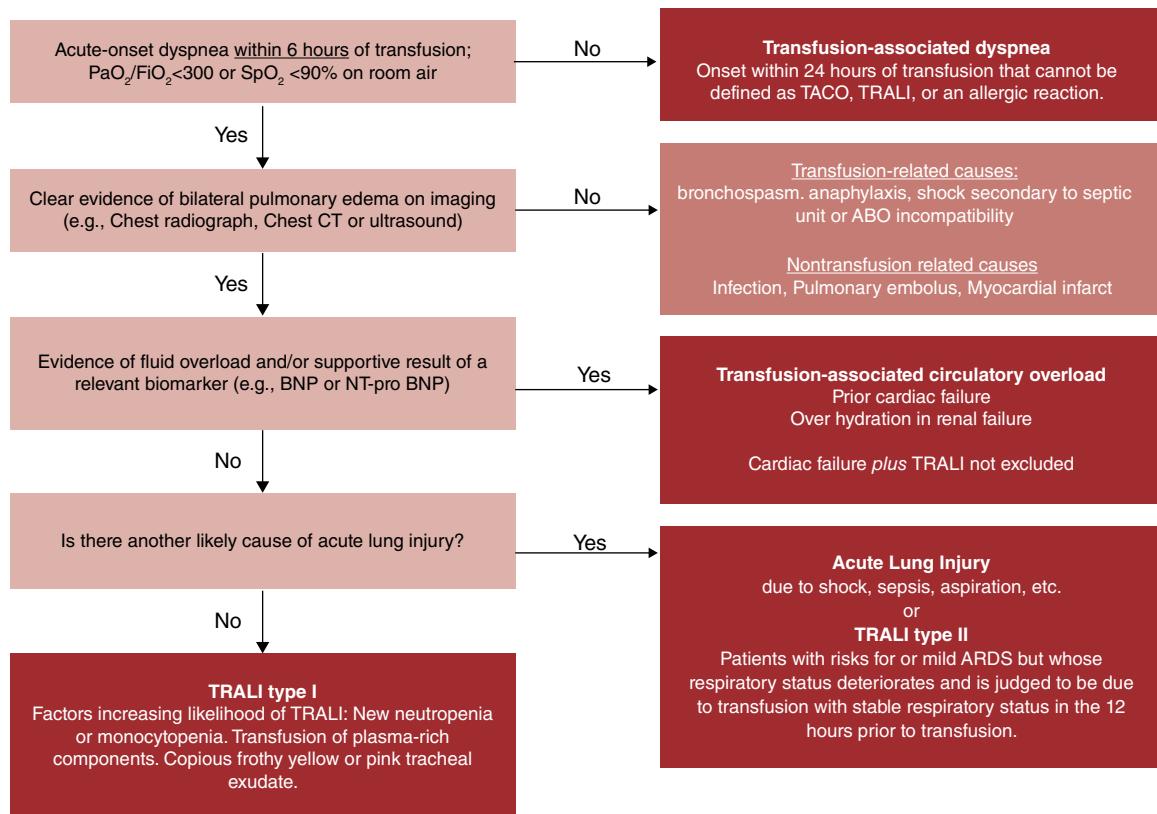

Alternative mechanisms leading to TRALI have been proposed and are discussed in this chapter, but the available evidence demonstrates that the predominant mechanism is donor leukocyte antibodies reacting with recipient antigens. Large clinical studies have corroborated these experimental findings, as have hemovigilance data obtained in countries where plasma from female donors (or female donors with a history of pregnancy) is no longer used for clinical transfusion.<sup>15–20</sup>

### Diagnosis

#### Respiratory dysfunction

New-onset respiratory dysfunction caused by pulmonary edema in a patient with recent transfusion should prompt consideration of TRALI. Significant respiratory dysfunction consistent with ALI can be defined as a decrease in transcutaneous oxygen saturation to less than 90% or an arterial  $\text{pO}_2$  of less than 60 mmHg while breathing room air or a  $\text{PaO}_2\text{--FiO}_2$  ratio of less than 300 mmHg.

Pulmonary edema can be demonstrated by clinical examination or chest X-ray. Alternative causes of sudden respiratory dysfunction, without edema, include transfusion-related problems (such as allergic reactions with bronchospasm, shock associated with a bacterially infected unit, or ABO incompatibility) and causes unrelated to the transfusion such as cardiac arrhythmias, infection, or pulmonary embolus (Figure 49.3).

**Figure 49.3** Flowchart for differential diagnosis of respiratory-related transfusion reactions.

## Physiologic measurements

Left atrial pressure or volume may be measured by pulmonary artery wedge pressure through a Swan–Ganz catheter, via esophageal Doppler ultrasound, or by transthoracic echocardiography. The goal of such measurements is to assess cardiac status in patients with suspected TRALI. High left atrial filling pressure or volume suggests cardiogenic pulmonary edema or fluid overload. Normal or low pressure or volume is consistent with noncardiogenic pulmonary edema. Low left atrial pressure indicates hypovolemia, a common finding in TRALI. Electrocardiography may also be helpful in detecting cardiac strain patterns or evidence of infarction.

Prior or new cardiac failure does not exclude the possibility of TRALI because both may be present in the same patient. However, cardiac failure does indicate that the use of diuretics, which are otherwise contraindicated in TRALI, may be beneficial.

## Consensus definition of TRALI

A consensus definition of TRALI was agreed upon in 2004 and revised in 2019.<sup>3,21</sup> These criteria do not include laboratory tests. A clinical diagnosis of TRALI is considered where a new episode of ALI has occurred within six hours of a blood component or derivative transfusion. Where no other cause of ARDS is found, the diagnosis of TRALI is designated Type I. Where another possible cause of ARDS is present, the diagnosis of TRALI is designated Type II (Table 49.1). Many cases of TRALI occur in patients with competing etiologies for ALI. Further recipient and donor investigation can help determine, often in retrospect, the probability of lung injury being entirely or partly due to transfusion.

## Laboratory tests

### Changes in circulating leukocytes

When leukopenia—in particular neutropenia and monocytopenia—occurs within the first hour after transfusion or is present before clinical signs of lung injury, transfusion is favored over other causes of ALI. The neutropenia is often followed by neutrophilia 5–6 hours later.<sup>1,22</sup> Monocytopenia is common, may be absolute, and may be more persistent than neutropenia.<sup>22,23</sup> Neither change is completely specific nor sensitive. The degree of neutropenia is likely to be greater with neutrophil-specific antibodies, such as anti-HNA-2, and with neutrophil-agglutinating antibodies, such as anti-HNA-3a and anti-HLA-A2, whereas monocytopenia alone is most likely to be seen with HLA class II antibodies.<sup>23</sup> Neutropenia is seen without evidence of lung damage with some neutrophil-specific antibodies.<sup>6,24</sup>

**Table 49.1** 2019 Consensus TRALI Definition

TRALI type I—patients who have no risk factors for ARDS and meet the following criteria:

- A   i   Acute onset
- ii   Hypoxemia:  $\text{PaO}_2/\text{FiO}_2 \leq 300$  or  $\text{SpO}_2 < 90\%$  on room air
- iii   Clear evidence of bilateral pulmonary edema on imaging (e.g., chest radiograph, chest CT, or ultrasound)
- iv   No evidence of left atrial hypertension or, if LAH is present, it is judged to not be the main contributor to the hypoxemia
- B   Onset during or within 6 hours of transfusion
- C   No temporal relationship to an alternative risk factor for ARDS

TRALI type II—patients who have risk factors for ARDS (but who have not been diagnosed with ARDS) or who have preexisting mild ARDS ( $\text{PaO}_2/\text{FiO}_2$  of 200–300), but whose respiratory status deteriorates and is judged to be due to transfusion based on:

- A   Findings as described in categories A and B of TRALI type I
- B   Stable respiratory status in the 12 hours prior to transfusion

## B-type natriuretic peptide and edema-to-serum protein concentration

A serum level of B-type natriuretic peptide (BNP) of  $<250$  pg/mL is consistent with ALI rather than cardiac failure, whereas a level of  $>250$  pg/mL or a twofold increase from a prior level is consistent with cardiac failure.<sup>25</sup> A low level is neither specific for ALI nor sensitive: many patients with ALI also have cardiac dysfunction. A high level may also be seen in renal failure.

A protein concentration in the pulmonary edema greater than 70% of the serum protein concentration is strong evidence in favor of a capillary-to-alveolus leak as seen in ALI from any cause.

## Incidence and epidemiology

### Variables affecting the incidence of TRALI

The frequency of reported TRALI depends upon variables affecting donors, recipients, and treating clinicians. Antibody-associated TRALI is the most common form and historically associated with blood from female donors with a history of pregnancy. Antibody-associated TRALI is both more common and more severe with transfusion of plasma-rich products, such as FFP or apheresis platelets. HLA antibodies have been found in approximately 15% of all female donors but are more common in those who have been pregnant more frequently or more recently,<sup>26,27</sup> and they are even more common with highly sensitive tests.<sup>28</sup> Human neutrophil antibodies are less common. Therefore, incidence of TRALI will depend, in part, on the donors recruited by the local blood center.

Lookback studies of regular blood donors whose antibody-containing plasma has been implicated in cases of TRALI suggest that many cases of TRALI are either overlooked or unreported. In addition, the infusion of an antibody to a recipient with a matching antigen does not necessarily result in TRALI.<sup>29,30</sup> Both inherited and acquired recipient variables as well as details of the transfusion will affect the likelihood of developing clinically apparent TRALI. Inherited variables have not been defined but will almost certainly include polymorphisms within immune response pathways. The presence of high levels of soluble HLA antigens in the recipient's plasma may be protective.<sup>31</sup> Acquired recipient variables include the presence of other lung insults and comorbidities. Transfusion variables include the titer and specificity of donor antibody, the volume of plasma infused, and the rate of infusion. Plasma-reduced RBCs transfused over 90 minutes rarely cause TRALI, whereas FFP given over 15 minutes—a more than 50-fold higher rate of plasma transfusion—is not uncommonly implicated.

Finally, the likelihood of diagnosing and reporting TRALI heavily depends on the treating physician's knowledge of the condition.

### Reported frequency of TRALI

One single-hospital prospective study estimated TRALI frequency for all blood components transfused without any donor selection as 1 in 5000 units.<sup>2</sup> A retrospective single-hospital study estimated the incidence as 1 in 7900 units of FFP only.<sup>22</sup> Hemovigilance data from voluntary reports in the United Kingdom found a reported incidence of approximately 1 in 30,000 units of FFP transfused.<sup>32</sup> Retrospective studies of ALI/TRALI in critically ill patients and a single prospective trial of TRALI after FFP infusion found that as many as 1 in 50–200 units of plasma from parous female donors could cause some respiratory dysfunction when compared to plasma from male donors.<sup>25,33</sup>

It is not possible to give a single figure for incidence, but the chance of female donor plasma containing an antibody matching a recipient antigen is greater than 1 in 50. Severe and clinically distinct TRALI probably occurs about 1 in 2500–4000 units of female donor plasma transfused. ALI in which transfusion is a contributory factor in a critically ill patient may be much more common.

## Management and outcome

### Management of the patient

The mainstay of treatment for TRALI is respiratory support using oxygen, alone, or in combination with either continuous positive airway pressure or mechanical ventilation. Fluid replacement is used in cases complicated by systemic hypovolemia. Severe cases often require central venous pressure or left atrial volume monitoring. Additional strategies include high-frequency ventilation and prone position ventilation. Diuretics are contraindicated because they worsen hypovolemia and hypotension.<sup>34</sup> Only in cases with concomitant fluid overload from cardiac failure (or other causes) are diuretics indicated.

There is limited evidence about the use of corticosteroids. When the diagnosis is made within six hours and the lung damage is severe, the use of high-dose steroids might *theoretically* limit further damage by inhibiting neutrophil activation. Prednisolone, methylprednisolone, and dexamethasone have all been used, but there is no evidence of efficacy. When the diagnosis is made later, high-dose steroids are unlikely to be helpful. In intractable cases, when maximal ventilation is insufficient, extracorporeal membrane oxygenation has been used to support the patient.<sup>35</sup> Plasmapheresis has also been utilized with the intent of removing the causative antibody.<sup>12</sup> Further transfusions should be given if clinically indicated, but plasma-rich products from female donors should be avoided.

### Clinical course and outcome

Most patients begin to improve within 24 hours of the initial symptoms. Milder cases improve as early as six hours. Chest X-rays usually show clearance of edema by 48–96 hours. The majority of patients recover without any long-term lung damage; however, damage in other organs, such as acute renal failure, is seen in more severe cases. It is unclear whether the organ injury seen in severe cases is due to hypoxia, hypovolemia, or damage to capillary beds in organs outside of the lungs.<sup>22</sup>

Mortality in different published series varies between 5% and 30%. This variation depends, in part, on how cases are ascertained. Where patients receiving transfusion were assessed prospectively for the complication, the incidence was higher, presumably because milder cases were more likely to be recognized, but the mortality was low (6%). Where reports depend on a physician recognizing and reporting the condition, the incidence is lower but mortality higher. As an example, the hemovigilance scheme in the United Kingdom reported seven deaths out of 28 possible, probable, or likely cases reported in 2002, a mortality of 25%.<sup>32</sup> Mortality is more likely in patients receiving larger volumes of single-donor plasma (including fresh-frozen plasma [FFP]) rather than RBCs and more likely in patients with more comorbidities. In 2020, only two cases of TRALI were reported to the UK SHOT system, with one fatality, giving the year a morality rate of 50%.<sup>18</sup>

### TRALI in neonates and children

TRALI has been reported in children with the same features as adult cases, including leukopenia, nonhydrostatic pulmonary edema, and hypovolemia. Some of the published reports attributed death of the child partly or wholly due to the transfusion reaction.<sup>36–38</sup> Age range of cases is from 0 months to 16 years, but few neonatal cases have been reported.<sup>38,39</sup> Use of blood components is more common in neonates than older children, and neonates also receive larger volumes of single-donor plasma relative to their weight. It is possible that neonates are less susceptible to TRALI.

A peculiar feature of pediatric TRALI is its occurrence after the use of directed donations from the mother. This practice has been documented to cause TRALI and can be expected to be high risk because of the high probability that the mother has leukocyte antibodies corresponding to her child's antigen specificity.<sup>40</sup> By the same rationale, directed donations from a wife to a husband, or of a leukocyte-containing component from a child to a mother or a husband to a wife, may be particularly likely to cause TRALI.

## Mechanisms of lung damage in TRALI

### Priming and activation of neutrophils

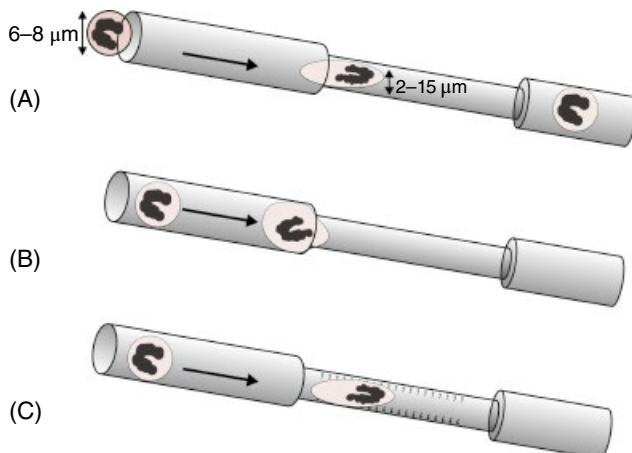

The dogma that TRALI is mediated by activated neutrophils has lost some of its cogency during recent years, mainly because TRALI still occurred in experimental animals depleted of neutrophils.<sup>41–43</sup> It appears reasonable to consider neutrophils as the major, but not the only, mediators in a process that also includes monocytes and the endothelium. Neutrophils activated by injurious agents respond by producing a range of highly toxic reactive oxygen species (ROS) and the release of preformed granular enzymes, proteins, and neutrophil extracellular traps (NETs).<sup>44,45</sup>

Neutrophils may be activated directly by one sufficiently strong stimulus, but activation more often requires two or more stimuli. The first “priming” stimulus potentiates the response to a second “activating” stimulus. A large percentage of patients who develop TRALI are sick, and there is *in vivo* evidence that surgical procedures and active infections induce neutrophil priming.<sup>46–48</sup> In response to priming agents, neutrophils become less pliable.<sup>49</sup> This “stiffening” augments mechanical retention of neutrophils within the pulmonary capillary bed, prolonging their passage through the lungs.<sup>50</sup> Prolonged, close contact between neutrophils and the endothelium provides a microenvironment in which transmembrane receptors and released mediators of each cell type can interact closely. Sequestered neutrophils, having been primed in the circulation, and endothelial cells can be activated by exogenous stimuli present in the blood bag. These transfused stimuli include antibodies, cytokines, and bioactive lipids.

Antibodies to neutrophil antigens involved in TRALI cases are able to prime and activate neutrophils in some cases without additional stimuli,<sup>14,51–53</sup> explaining why even completely healthy individuals can develop TRALI if the antibody stimulus is sufficiently strong.<sup>12</sup>

### Neutrophil passage through pulmonary microvasculature

The alveolar capillary bed is a complex, interconnected network of short capillary segments. The path of a neutrophil from arteriole to venule crosses eight or more alveolar walls and encounters more than 50 capillary segments. Approximately half of these pulmonary capillaries are narrower than the diameter of a spherical neutrophil (Figure 49.4). This forces neutrophils to slow and deform as they pass through narrow capillary segments. The

**Figure 49.4** The neutrophil's passage through the pulmonary microvasculature. Approximately 50% of all pulmonary capillaries surrounding the alveoli have a diameter smaller than the spherical neutrophil. (A) In order to pass through the capillary, neutrophils are forced to slow down and deform, assuming a "sausage shape" that allows transit through the capillary. (B) Neutrophil priming is associated with a decrease of deformability (called *stiffening*), which results in local trapping of the cell and a prolonged transit time. (C) Activation of the capillary endothelial cells results in the upregulation of surface ligands, which contributes to local trapping of the cell and a prolonged overall transit time.

transit time of neutrophils through the pulmonary microvasculature is mainly affected by the time it takes for neutrophils to deform, and slow transit accounts for significant accumulation of neutrophils in the lungs.<sup>54</sup> The pulmonary circulation normally contains about 30%, the "marginated pool," of total blood neutrophils. The stimulus-induced decrease in deformability appears to be more important than selectin-mediated rolling, a key mechanism of neutrophil adhesion in other capillary beds, but changes in surface receptors in primed neutrophils will also favor molecular adhesion to endothelial cells.<sup>54–56</sup> Under physiologic conditions, primed and locally trapped neutrophils migrate from the capillaries into the alveoli as part of a local inflammatory reaction. In TRALI, the primed and trapped neutrophil encounters a further activation signal in the form of transfused antibody or other transfused stimulus, and activates its microbicidal arsenal, inducing endothelial damage.

#### Activation of pulmonary endothelial cells

TRALI can also be triggered by activated pulmonary endothelium. In addition to constitutively expressed surface receptors, activated endothelial cells upregulate surface membrane receptors that facilitate neutrophil adhesion and priming. Primary activation of endothelial cells has been suggested as the mechanism responsible for TRALI after infusion of bioactive lipids.<sup>57,58</sup> More recently, antibodies recognizing proteins present on the endothelial surface (i.e., HNA-3a) were shown to directly interfere with endothelial function,<sup>42</sup> indicating that barrier breakdown leading to lung edema does not necessarily involve the activation of neutrophils. These experimental data are in line with a clinical report of an HLA-B44-negative patient transfused with blood containing anti-HLA-B44 antibodies who developed "half-sided" TRALI in his recently transplanted, HLA-B44-positive lung only.<sup>59</sup> These antibodies must have either reacted with transplant endothelium or, possibly, donor-type (alveolar) macrophages.

#### Activation of monocytes

In contrast to HNA and HLA class I, HLA class II antigens are usually not present on neutrophils (or endothelial cells), but are present on monocytes. Kopko *et al.* suggested a monocyte-dependent mechanism of TRALI, where HLA class II antibodies bind to monocytes, induce the release of neutrophil-activating mediators, and induce neutrophil activation.<sup>60</sup> Using human plasma with anti-HLA-DR7 and -DR52 specificity along with human neutrophils and monocytes in an ex vivo rat lung model, Sachs *et al.* showed that HLA class II antibodies can induce TRALI via such a multistep pathway, including the initial activation of monocytes and the release of interleukin-8 (IL8).<sup>61</sup> Subsequently, experiments in mice delineated that monocytes may also be involved in HLA class I-mediated TRALI because depletion of these cells suppressed HLA class I antibody-mediated TRALI, as did the blockage of MIP2 receptors, the murine analog of IL8.<sup>41,43</sup>

#### Platelets and TRALI

Studies to date have not clearly elucidated the role, if any, of platelets in the pathophysiology of TRALI;<sup>41,44,45,62–64</sup> however, some data support a pathogenic role of platelets in the development of TRALI.<sup>65</sup>

#### Neutrophil, monocyte, and endothelial cell interplay

The interplay between neutrophils, monocytes, endothelial cells, and, potentially, platelets contributes to lung damage. Neutrophils respond to monocyte and/or endothelial cell-derived mediators by activating and expressing integrins and by releasing proinflammatory mediators and granule contents. Released mediators activate endothelial cells, which, in turn, mobilize selectins, upregulate adhesion proteins, and produce inflammatory mediators; thereby, enhancing neutrophil and platelet adhesion and neutrophil, platelet, and monocyte activation. It is within this interplay that the lung barrier breaks down and allows transit of proteinaceous fluid and, later, of neutrophils into the alveolar space. Experimentally, other blood cells seem to attenuate this complex process.<sup>66,67</sup>

#### Mechanisms of lung injury by different mediators in transfused blood components

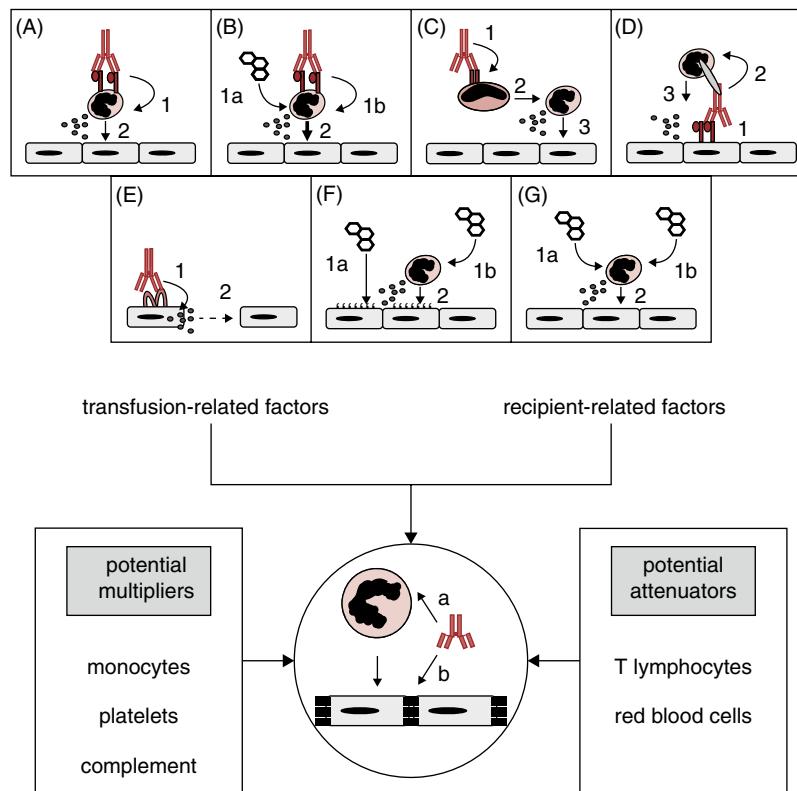

The exact pathway leading to lung damage associated with transfusion depends on the nature of the antibody or other stimulus and the interplay between it and the cellular components.

#### Antibody mediators of TRALI

Antibodies to neutrophil antigens, HLA class I, and HLA class II have all been clearly implicated in TRALI. Evidence from both hemovigilance schemes and laboratories specializing in TRALI investigation shows that the majority of cases (75–90%) are associated with HLA antibodies, and that about 50% of these antibodies are directed against HLA class II antigens.<sup>20</sup> Antibodies to neutrophil antigens are found less frequently, in about 10–25% of cases.

#### Antibodies to human neutrophil antigens (HNA)

The ability of HNA antibodies to induce TRALI has been shown in ex vivo models of lung injury.<sup>14,68</sup> In particular, antibodies with HNA-2 and HNA-4a specificity are capable of directly activating neutrophils, which appears to be the mechanism by which they induce TRALI (Figure 49.5A–B).<sup>14,51,69</sup> Of note, antibodies against HNA-3a can interact directly with endothelial cells because their cognate antigen CTL-2 is expressed not only on neutrophils but also on endothelial cells within lungs.<sup>42</sup> Binding of anti-HNA-3a to endothelial cells leads to the production of ROS within the

**Figure 49.5** Proposed mechanisms of TRALI. The activation of neutrophils and the subsequent release of toxic agents that harm the endothelium, predominantly ROS, are key mechanisms in TRALI. Epidemiological, clinical, and experimental data show that most TRALI reactions are induced by antibodies present in a transfused blood component. These antibodies recognize epitopes on the surface of (A, B) neutrophils, (C) monocytes, or (D, E) endothelial cells. Binding of HNA or HLA class I antibodies to neutrophils causes direct activation of the cell. (C) Binding of antibodies, especially of HLA class II antibodies, to monocytes has been proposed to induce the release of mediators that activate the neutrophil. (D) Experimental data demonstrate that neutrophils may also be activated indirectly when HLA class I antibodies are bound to the endothelium of the lung, where they can recruit neutrophils via their Fc receptors binding to the Fc parts of these antibodies. (E) Further evidence also indicates direct endothelial effects of antibodies, such as anti-HNA-3a. (F, G) Biologically active substances other than antibodies (e.g., bioactive lipids and CD40L derived from cellular blood components) are thought to cause some cases of TRALI. These substances are usually too weak to activate neutrophils directly, but may induce TRALI in concert with other factors that activate endothelial cells or neutrophils. See the text for details.

endothelium, causing the endothelial cells to lose cohesion, allowing fluid to shift to the alveolar space (Figure 49.5E). It is suggested that this direct mechanism of TRALI induction accounts for a higher rate of fatal cases of TRALI associated with HNA-3a antibodies.<sup>70</sup> The activation of endothelial cells by direct binding of HNA-3a antibodies also leads to cellular activation and neutrophil recruitment, indicated by the fact that these antibodies can induce (milder) TRALI in a murine model in the absence of neutrophils, but induce more severe TRALI when neutrophils are present,<sup>42</sup> corroborating the idea that once the process is started, multiple players become involved.

#### Antibodies to HLA class I antigens

HLA class I antibodies are frequent in the donor population. The presence of HLA class I antibodies in transfused plasma is a common cause of TRALI (Figure 49.5D). The cognate antigens recognized by these antibodies are expressed on all of the cell types that we understand to play a role in TRALI. HLA class I antibodies can directly bind to neutrophils and prime oxidases in both humans and rats.<sup>71,72</sup> Not surprisingly, there are anecdotal reports of TRALI associated with HLA class I antibodies, especially of anti-HLA-A2 specificity, which is directed against a commonly occurring HLA

antigen. However, HLA class I antibodies were not associated with increased risk of TRALI in several observational studies.<sup>15–17</sup>

Most TRALI animal experiments utilized anti-MHC (major histocompatibility complex) class I antibodies. Of note, only one of the tested monoclonal MHC class I antibodies induced TRALI in mice when infused (anti-H2K<sup>d</sup>, clone 34.1.2s), and results obtained with these experiments, albeit highly informative, should be interpreted cautiously, especially when it comes to their impact on transfusion medicine. The various experimental findings reported for HLA class I antibodies make it likely that numerous activation steps must occur before a reaction commences in a patient. This may involve antibody binding to neutrophils, endothelial cells, or monocytes. The fact that human antibodies—in contrast to the monoclonals used in animal studies—are polyclonal and differ in their binding characteristics and avidity may explain the lack of a clear association of HLA class I antibodies and TRALI in studies of donor risk factors.

#### Antibodies to HLA class II antigens

In contrast to HNA and HLA class I antigens, HLA class II antigens are usually not present on neutrophils (or endothelial cells) but are present on monocytes. Neutrophils and endothelial cells may express HLA class II following stimulation, but HLA class II

antigen expression was not found on vascular endothelium of pulmonary capillaries or intravascular neutrophils in a patient who experienced fatal TRALI caused by an HLA class II antibody.<sup>73</sup> Although a direct mechanism between HLA class II antibodies and neutrophils or pulmonary capillary endothelium cannot formally be excluded, monocytes appear currently as major target cells for these type of antibodies (Figure 49.5C).<sup>60,61,74</sup> Intact endothelium likely prevents transfused antibodies from accumulating in the alveolar space in sufficient concentration to induce release of cytokines or subsequent activation of neutrophils and/or endothelial cells, but where there is already some damage to the pulmonary endothelium, such a reaction may exacerbate ALI.

It remains possible that the detection of antibodies to HNA and HLA could be surrogates for antibodies to as-yet-unknown antigens on other cell types (e.g., on monocytes). Alloantibodies to these or other cells might explain some apparently antibody-negative cases.

### Inverse TRALI: transfusion of neutrophils

In most cases of TRALI, the causative agent for the pulmonary reaction are antibodies or neutrophil-priming agents present in the transfused component. However, TRALI has also been reported in alloimmunized patients receiving blood components that contain neutrophils. Viable neutrophils may still be present in blood components, and Popovsky and Moore estimated that 6% of observed TRALI cases were caused by antibodies present in the recipient.<sup>2</sup> Universal leukocyte reduction has likely reduced the incidence of such reactions from platelet concentrates (PCs) and red blood cells (RBCs). Inverse TRALI will remain of particular relevance to patients receiving granulocyte transfusions.<sup>39,75</sup>

### Nonantibody mediators of TRALI

#### *Biologically active lipids*

Blood components can accumulate intermediate metabolic products, including biologically active (bioactive) lipids, throughout their storage. These substances are breakdown products of membrane lipids, including lyso-phosphatidylcholines (lysoPCs), which prime respiratory burst reactions in neutrophils. The longer that RBCs are stored, the more proinflammatory mediators accumulate in the unit to be transfused. These neutrophil-priming agents do not develop in stored, acellular plasma because their generation depends on the presence of blood cells. The changes in stored RBCs may mediate antibody-negative cases of TRALI. Indeed, the administration of supernatant from stored (but not fresh) human RBCs caused TRALI in ex vivo and in vivo animal models of TRALI (Figure 49.5F and 49.5G).<sup>57,71</sup> The metabolic products that accumulate are able to activate endothelial cells in the pulmonary microvasculature through upregulated ICAM-1 expression causing increased PMN adherence and subsequent BLT2 receptor-mediated activation of protein kinase C.<sup>76</sup>

Biologically active breakdown products were also investigated in the setting of platelet transfusions. In a cross-species study, supernatant of aged human platelets, but not of fresh platelets, caused ALI in an ex vivo rat lung model.<sup>58</sup> In a syngeneic rat model, whole aged rat platelet suspensions, but not fresh ones, led to neutrophil adherence and pulmonary edema. However, when LPS was used to mimic patient-related risk factors, stored platelets no longer induced TRALI despite an increased lysoPC content.<sup>77</sup>

In summary, there is currently no clear evidence on whether lysoPCs (or other bioactive lipids)<sup>78</sup> are involved in TRALI or not. It

should be noted that cumulative data from three large clinical trials are not supportive for a role of RBC storage time and/or lysoPC content as relevant risk factors for TRALI.<sup>15–17</sup>

#### *CD40 ligand (CD40L)*

The contribution of CD40L to TRALI is incompletely defined. Like bioactive lipids, CD40L is another breakdown product that can prime neutrophils. CD40L is platelet-derived, proinflammatory mediator found in both cell-associated and soluble (sCD40L) forms. It is found in PCs and accumulates throughout product storage.<sup>79</sup> sCD40L binds to CD40 present on the surface of monocytes, macrophages, and neutrophils.<sup>80</sup> CD40L–CD40 interaction causes neutrophil priming and may be associated with TRALI following platelet transfusions because platelet units involved in TRALI cases were found to have higher concentrations of sCD40L. In vitro, human microvascular endothelial cells preincubated with LPS experienced severe damage when sCD40-primed neutrophils were added, whereas unprimed neutrophils did not induce such damage.<sup>80</sup> Others have questioned the role of CD40L in TRALI.<sup>81</sup> For instance, patients with TRALI after cardiac surgery did not differ in their sCD40L levels from controls.<sup>82</sup>

#### *Immunoglobulins*

IgG has been postulated to activate neutrophils in a patient with osteopetrosis being treated with gamma interferon, granulocyte stimulating factors, and monocyte colony-stimulating factors.<sup>36</sup> The patient had very low levels of endogenous IgG1 and IgG2 and developed severe lung injury shortly after transfusion of platelets from an untransfused male donor. No leukocyte antibodies could be found in either donor or recipient. It is suggested that transfused IgG binding to the neutrophils, which were already primed by interferon and colony-stimulating factor, was sufficient to cause neutrophil activation and lung injury. This case may be considered a good example of “multiple hit” TRALI.

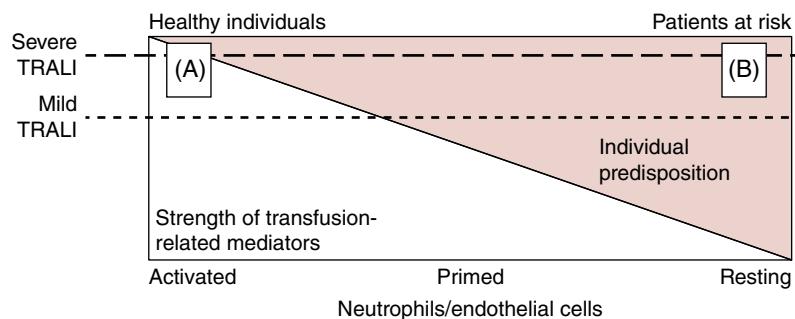

Reports of lung injury following intravenous IgG infusion are rare and seem to be associated with high doses or concentrates prepared intentionally with a high level of leukocyte antibodies.<sup>12,83</sup> It is possible that antibodies are both diluted and neutralized during the preparation of the pooled product, as suggested for pooled pathogen-inactivated plasma.<sup>84,85</sup>

#### **Multiple-hit/threshold theory of TRALI causation**

The two-hit theory of TRALI suggests that the first hit is the patient’s underlying clinical condition and that the second hit is delivered by the transfused blood product.<sup>65</sup>

Most patients receiving transfusion and especially transfusion of plasma have significant comorbidities, which may result in priming or activation of neutrophils or cause damage to pulmonary endothelium. It has been suggested that TRALI will be more common in patients with certain chronic conditions such as alcohol abuse, tobacco use, and systemic inflammatory disorders, as well as patients with acute insults such as shock and liver surgery.<sup>65</sup> Early reports noted that most patients with TRALI had recently undergone surgery and suggested that this in itself was a sufficient stimulus in many cases.

The second hit is delivered by the transfused product. In 80% of the cases, the second hit is an antibody against the patient’s leukocytes: either anti-HLA class I, anti-HLA class II, or anti-HNA. Some experimental evidence for the “two-hit” or “multiple-hit” theory has been provided by studies on bioactive lipids described earlier.<sup>58</sup> The multiple-hit theory has been further developed by Bux

**Figure 49.6** The Bux–Sachs TRALI threshold model. The TRALI threshold model proposes that a certain threshold must be overcome to cause a TRALI reaction. The threshold of mild TRALI, in which oxygen supply is sufficient, is lower than that of severe TRALI, in which patients require mechanical ventilation (horizontal lines). In order to overcome this threshold, numerous factors must act in concert. These factors can be summarized as strength of exogenous transfusion-related mediators (white wedge) and individual predisposition of the patient (lavender wedge). The individual predisposition covers both constitutive (genetic) factors and dynamic or acute influences (i.e., acute infection or trauma). A strong exogenous transfusion-related mediator, such as a strong neutrophil-specific antibody, will precipitate a TRALI reaction even if the influence of the individual predisposition is low (example (A), in an otherwise healthy recipient). In contrast (example (B), an individual “at risk,” e.g., a septic patient with an activated pulmonary endothelium), a relatively mild exogenous transfusion-related mediator with low neutrophil-priming activity will be sufficient to overcome the threshold. Source: Bux and Sachs (2007).<sup>86</sup>

and Sachs,<sup>86</sup> who suggest that neutrophil and endothelial cells are central to the pathogenesis of TRALI and that activation of these cells requires sufficient stimuli from one or more sources to reach a certain threshold, at which point full activation and lung damage will ensue (Figure 49.6). Depending on the degree of neutrophil or endothelial cell response, the lung damage can be mild or severe with corresponding clinical effects.

This theory of TRALI holds that given sufficiently strong stimulus to endothelial and neutrophil activation, lung damage can occur in an otherwise healthy individual. Evidence for this comes from reports of TRALI in transfused volunteers and plasma transfusions used for clinical reasons in otherwise healthy individuals. These cases are uncommon.

### TRALI and transfusion in critically ill patients

Clinical evidence for the “multiple hits” theory of TRALI has been provided by studies of critically ill patients who are known to be susceptible to ALI. Retrospective studies have suggested a relationship between the amount of blood transfused and morbidity and mortality. All these studies are confounded by the factor of how much blood the patient required also being a marker for severity of illness. The Transfusion Requirements in Critical Care (TRICC) trial was both prospective and randomized; it found a higher incidence of pulmonary edema and of ALI in patients receiving more transfusion with relatively plasma-rich components.<sup>87</sup> Gajic *et al.*<sup>88</sup> studied ALI developing in critically ill patients during mechanical ventilation. They found a strong association with transfusion of plasma, but not with red cell transfusion, the age of transfused red cells, the leukocyte content of transfused red cells, or platelet transfusion. Further studies identified the transfusion of female plasma as being particularly associated with the development of ALI in keeping with an antibody-mediated mechanism.<sup>89</sup> A prospective study in intensive care patients comparing male donor and parous female plasma found similar results.<sup>33</sup> The incidence of ALI associated with transfusion in these studies was of the order of 1 in 50–200 units of female plasma transfused, a far higher incidence than the reported incidence of TRALI in other circumstances. These findings reaffirm the Bux–Sachs threshold model of TRALI in which

highly susceptible patients subject to multiple insults to neutrophils and endothelial cells develop lung damage after a relatively mild additional stimulus from transfusion.

### Donor investigation

Strategies of donor investigation vary among blood centers. The aim of investigation is twofold: to help establish the diagnosis and to allow appropriate management of implicated donors. A typical scheme adapted from Su and Kamel<sup>90</sup> is shown in Figure 49.7. Investigation of donors is undertaken only when a diagnosis of TRALI is considered probable or possible. Donations transfused within the six hours before the development of lung injury are considered to be under suspicion. Where the number of possibly implicated donors is small (four or fewer), all donors should be investigated. Where the number of possibly implicated donors is greater, the high-risk donors with a history of pregnancy or transfusion are investigated initially. If a donor or donors are found with an antibody that matches a cognate antigen, investigation of the lower risk donors is not undertaken. If no donor is implicated in the initial investigation, lower risk donors can be further tested in those cases that are considered to be probable TRALI. A further selection policy is to initially investigate only those donors of plasma-rich components. Investigations are undertaken at a qualified laboratory with adequate sensitivity and specificity for HLA class I and II antibodies, and HNA antibodies. Recipient HLA and HNA typing may be performed prospectively or only when a donor antibody is found. Tests for recipient antibodies may be undertaken when the lung injury followed transfusion of granulocyte concentrate or following nonleukocyte-reduced component transfusion in which no match can be identified between donor antibodies and recipient antigens. When a nonantibody mechanism is suspected, or if an antibody-related etiology has been largely excluded, tests on the residual donation for abnormal lipids or other bioactive substances may be carried out at a research or reference center.

### Management of implicated donors

Management of implicated donors varies. It is possible to permanently defer all donors who are implicated in a case of TRALI by virtue of having leukocyte antibodies of any specificity. This would

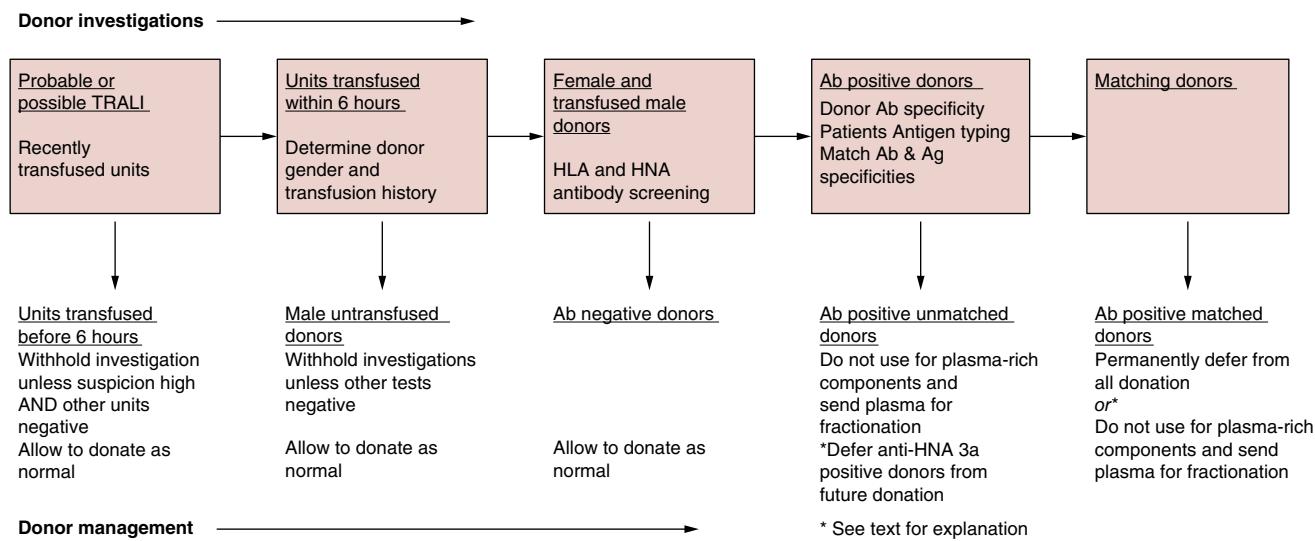

Figure 49.7 Flowchart for investigation and management of donors.

undoubtedly exclude many donors unnecessarily, and the logical extension of such a policy is that all donors with leukocyte antibodies should be deferred whether or not they have been possibly implicated in a case of TRALI. Alternatively, only those donors with antibody matching a recipient antigen are excluded from future donation. This policy assumes that some feature of the antibody in that donor makes them more likely to have caused TRALI in the index case, and thus to cause TRALI with further donations. Finally, it is possible to defer donors who are either possibly or definitely implicated only from donation of plasma-rich components. In addition, some centers automatically permanently defer any donor found to have anti-HNA-3a because of the high frequency of the antigen in the recipient pool (95%) and the common association with severe TRALI.

## Prevention

The majority of severe TRALI cases are related to antibodies. Therefore, prevention is largely aimed at reducing the likelihood of causative antibodies being transfused. There are several strategies in practice.

### Avoidance of unnecessary transfusion of plasma

This includes unjustified transfusion of plasma components such as FFP and unnecessary transfusion of plasma associated with RBCs. Use of FFP considerably varies among countries, and it has been demonstrated that use to correct minor coagulopathies is ineffective and unnecessary.<sup>91,92</sup> Avoidance of unnecessary FFP transfusion will reduce the potential for transfusion of units containing antibodies with the potential to cause TRALI. RBCs in additive solution containing less than 20 mL residual plasma are uncommon causes of TRALI, and in those recorded cases there have usually been multiple antibodies in the donor plasma matching cognate antigens in the recipient. Whole blood donations, particularly from high-risk donors (parous female or previously transfused donors), can be processed into RBCs in additive solution with minimal remaining plasma. Similarly, the use of platelet additive solution (PAS) and pathogen inactivation reduces the

volume of plasma within platelets units. While evidence is still emerging about the incidence of TRALI in pathogen-reduced platelet products, in one study of nearly two thousand units of pathogen-reduced platelet components, there were zero instances of TRALI.<sup>93</sup>

### High-risk donor exclusion

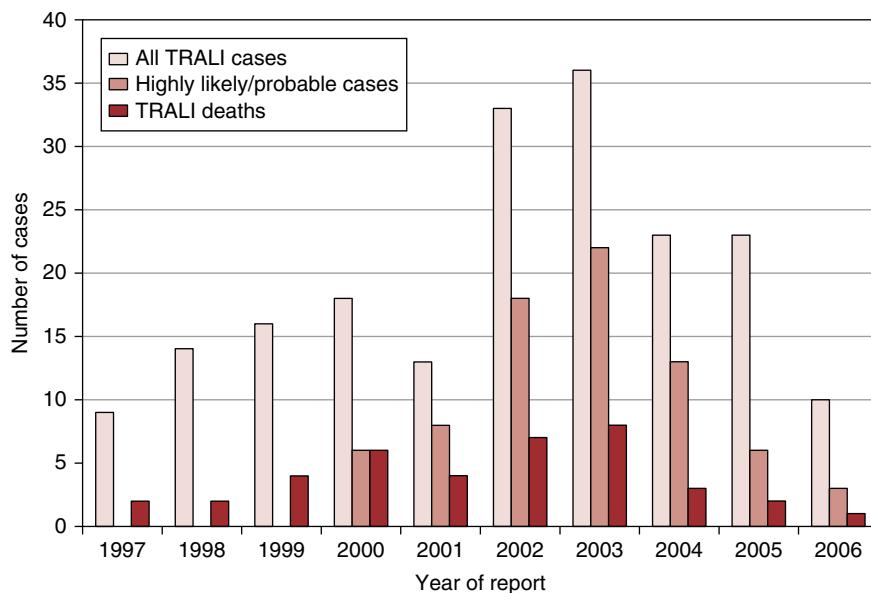

The most straightforward form of this policy is to exclude female donations of plasma-rich components. Some individual blood centers have followed such policies at the loco-regional level for years.<sup>94</sup> The effectiveness of this intervention was demonstrated in the United Kingdom, where such a policy was instituted nationally in 2003. An active hemovigilance scheme clearly showed a decrease both in the incidence of probable TRALI and in associated deaths over the next three years (Figure 49.8).<sup>95</sup> Further developments of this policy either exclude only those females with a history of pregnancy or exclude any donor with a history of blood transfusion or organ transplantation. Evidence of the efficacy of excluding female donor plasma comes from many countries, including those in North America and in the Netherlands, Germany, and Australia.

### Antibody testing

By testing donors for HLA and HNA antibodies, it is possible to exclude all donors with detectable antibodies, or those with antibodies of certain specificities or titer, either from all blood donation or just from donation of apheresis-collected, plasma-rich components. This strategy is attractive in that unnecessary exclusion of valuable donors is avoided but it also depends on the sensitivity and specificity of the antibody tests. It has been used with apparent success in some centers.<sup>96</sup> However, the cost of screening all patients will be prohibitive for some blood collection centers.

### Use of pooled plasma

Pooled solvent/detergent-treated plasma does not appear to cause TRALI. It is hypothesized that this is because of dilution of antibodies, neutralization of HLA antibodies by soluble HLA

**Figure 49.8** Cases of TRALI reported to the UK hemovigilance scheme from 1996 to 2006. After 1998, all cases were considered by an expert panel and classified as highly likely, probable, possible, or unlikely. From 1996 to 2003, case ascertainment rose steadily with increasing knowledge of the condition among physicians. From October 2003, a policy to procure FFP from only male donors was introduced. Following the change, there was a decrease in reports, and a marked decline in highly likely or probable TRALI and in deaths from TRALI (note that cases were recorded by the year that the report was made and that many cases documented for 2004 occurred in 2003). Source: Data from Dr. C Chapman on behalf of SHOT UK (<http://www.shotuk.org>).

antigens in the plasma of other donors, and subsequent removal of the immune complexes in processing.<sup>84,85</sup> Extensive use of solvent/detergent-treated plasma in Europe has not been associated with TRALI.<sup>97,98</sup>

#### Nonantibody TRALI and inverse TRALI

Leukocyte reduction decreases the production of cellular activation or breakdown products that have been implicated in TRALI. It also will prevent the rare but distinct cases of inverse TRALI related to bystander granulocyte transfusion.

### Other respiratory-related transfusion reactions

#### Transfusion-associated circulatory overload

TACO has become increasingly recognized through hemovigilance schemes. Like TRALI, there is a temporal connection to transfusion; however, in contrast to TRALI, the pathogenesis is essentially increased pulmonary capillary pressure leading to hydrostatic pulmonary edema. Patients particularly at risk are the small and elderly, those with preexisting cardiac disease and those with relative fluid overload such as some patients with renal failure. Obstetric cases are also reported and may be related in part to the increased blood volume during pregnancy or the cardiac effects seen in preeclampsia. Transfusion of any fluid can lead to cardiac overload. Where blood transfusion is involved, all components have been implicated, and unlike TRALI, high-volume plasma component transfusion is not over-represented among cases. There is no clear evidence that red cells themselves are implicated other than their volume being more restricted to the intravascular compartment. It remains possible that stored red cells with relatively poor oxygen delivery characteristics may contribute to cardiac ischemia and thus cardiogenic edema, but there is no clear evidence in favor of this hypothesis.

#### TACO: definition

The hemovigilance working party of the International Society of Blood Transfusion revised their definition of TACO in 2018.<sup>99</sup> The chief priority of the revision was to adopt a standard definition to improve recognition, reporting, and research with the ultimate goal of reducing adverse events associated with transfusion (Table 49.2).<sup>99</sup>

**Table 49.2** International Society of Blood Transfusion Definition of TACO (2018)<sup>99</sup>

- Cases of TACO are characterized by acute or worsening respiratory compromise and/or evidence of pulmonary edema during or up to 12 hours after transfusion and presence of a total of three or more of the criteria below
- Acute or worsening respiratory compromise
  - Evidence of acute or worsening edema based on either clinical examination and/or radiographic chest imaging and/or another noninvasive assessments of cardiac function
  - Evidence for cardiovascular system changes not explained by the patients underlying medical condition, including development of tachycardia, hypertension, widened pulse pressure, jugular venous distension, enlarged cardiac silhouette and/or peripheral edema.
  - Evidence of fluid overload including any of the following: a positive fluid balance; response to diuretic therapy, e.g., from diuretic therapy or dialysis combined with clinical improvement; and change in the patient's weight in the peri-transfusion period
  - Supportive result of a relevant biomarker, e.g., an increase of B type natriuretic peptide level (e.g., BNP or NT-pro BNP) above the age-group-specific reference range and greater than 1.5 times the pretransfusion value. A normal post-transfusion NP level is not consistent with a diagnosis of TACO; serial testing of NP levels in the peri-transfusion period may be helpful in identifying TACO.

Source: Adapted from Wiersum-Osselton et al. (2019).<sup>99</sup>

### TACO: epidemiology

Heart failure and pulmonary edema worsened or caused by transfusion have been recognized for many years. Patients with severe anemia due to vitamin B<sub>12</sub> deficiency were particularly known to be susceptible to sudden cardiac decompensation after transfusion. The rising incidence of cardiac overload due to transfusion was first highlighted by hemovigilance data from Quebec in 2010.<sup>100</sup> Subsequently, with increased recognition and reporting, it has emerged as a major cause of transfusion-related morbidity and mortality in many countries, including Ireland and the United Kingdom. Reports from the UK hemovigilance system (SHOT UK) show an increase in reports from 18 in 2008 to 139 in 2019.<sup>18</sup> And although more cases are being recognized, prospective surveys suggest a higher rate still, perhaps as high as 1%.<sup>25,101</sup> The incidence-per-unit is higher after red cell transfusion than with plasma or platelets alone, although this may be due to the patient's underlying illness and indication for transfusion rather than a specific effect of component type. Morbidity and mortality may be difficult to ascribe only to blood transfusion in a vulnerable patient who may also receive other fluids, but there is no doubt that transfusion appears to be a factor in many cases. The majority of patients developing TACO are elderly with a history of cardiac disease, respiratory disease, renal failure, or a combination of these conditions. A small number have no known cardiorespiratory comorbidities. Though patients are typically elderly with known cardiac failure, younger previously fit patients may also be affected.<sup>102</sup> Others have identified an unexpectedly high incidence in obstetric patients, perhaps related to the expanded blood volume seen in pregnancy.<sup>103</sup>

The diagnostic criteria outlined by the International Society of Blood Transfusion's working group on hemovigilance have not yet been adapted to evaluate TACO in pediatric patient populations. The reported incidence of TACO in pediatric patients receiving blood has varied from 1.5% to 4% in the literature. Part of this variation is a result of different study designs, but some of the studies used alternative definitions of TACO, highlighting the need of consistent definitions and diagnostic criteria.<sup>104</sup>

### TACO: diagnosis

Diagnosis is by identification of hydrostatic pulmonary edema as in Figure 49.3 and accompanying text on the differential diagnosis of TRALI/ALI and TACO/cardiac failure. Hypertension is one more characteristic of TACO, compared to the hypotension typifying TRALI. It is not impossible for a patient to have both volume overload due to poor fluid management and a capillary leak whether due to TRALI or to ALI from other causes. Radiographically, cardiogenic edema typically shows upper lobe venous distension and edema in the perihilar and basal areas. Edema in overhydration or renal failure is typically perihilar and shows no air bronchograms as seen in TRALI.

### TACO: treatment

Treatment is that of cardiac failure or volume overload, putting the patient in an upright position, and giving oxygen and diuretics, fluid restriction, and even phlebotomy. Continuous positive airway pressure or mechanical ventilation may be necessary, and in patients with marked renal failure, dialysis with removal of fluid may be used.

### TACO: prevention

The best preventive measure for TACO is avoiding unnecessary transfusion. Transfusion is rarely necessary in the absence of active bleeding and should be avoided in patients with otherwise correctable chronic anemia. Pretransfusion assessment for risk factors for TACO, such as low body weight, fluid overload, or poorly controlled heart failure, may allow a careful transfusion protocol with diuretic coverage and close observation.

Hypertension, tachypnea, tachycardia, and reduced oxygen saturation are all signs of cardiac overload. Early recognition may allow reduction in transfusion rate, discontinuation of transfusion, or use of oxygen and diuretics to halt or reverse the developing volume overload.

### Respiratory consequences of allergic transfusion reactions

Allergic transfusion reactions (ATRs) are some of the most common transfusion reactions and are usually mild; however, some ATRs are severe and can present with respiratory compromise and/or anaphylaxis. Similar to TRALI, plasma-containing products are the most often implicated. Reactions are usually within minutes of starting the transfusion and almost always occur within four hours. ATRs can be caused by preformed IgE antibodies in the recipient against donor plasma antigens, but most cases are idiopathic. Localized angioedema in the airway can cause bronchospasm and stridor.<sup>106,107</sup>

### Transfusion-associated dyspnea (TAD)

TAD is defined by increased breathlessness not meeting the criteria for TRALI or TACO or an allergic reaction and occurring within 24 hours of transfusion. Respiratory distress should be the most prominent clinical feature and should not be explained by the patient's underlying condition or any other known cause.<sup>105</sup> It is important to record and classify such reactions, but given the uncertainty as to whether there is a specific pathophysiology, their clinical usefulness in managing transfusion is uncertain.<sup>106</sup>

### Conclusion

It has taken over 50 years for the full extent of TRALI to be appreciated as a major but preventable adverse outcome of transfusion. Female donor exclusion has proven a highly effective preventive strategy. Loss of donor plasma for transfusion has not been a major problem partly because more rational and evidence-based use of plasma has reduced demand. TACO typically occurs in patients with cardiac failure, expanded blood volume due to pregnancy, renal failure, or other causes. With the reduction in TRALI-related deaths and introduction of hemovigilance schemes, TACO has emerged as an important cause of transfusion-related morbidity and mortality.

## CHAPTER 50

# Transfusion-associated graft-versus-host disease

Eric A. Gehrie<sup>1</sup> & Courtney E. Lawrence<sup>2</sup>

<sup>1</sup>The American Red Cross, Biomedical Services Division, Baltimore, MD, USA

<sup>2</sup>Department of Pediatrics and Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Transfusion-associated graft-versus-host disease (TA-GVHD) is a rare but almost uniformly lethal complication of blood transfusion. Although the graft-versus-host disease (GVHD) that occurs after allogeneic bone marrow transplantation (BMT) and TA-GVHD shares some clinical similarities, GVHD after BMT is not uncommon and often responds positively to immunosuppression.<sup>1</sup> The much rarer TA-GVHD, however, is associated with destruction of the recipient's bone marrow, does not usually respond to immunosuppressive therapy,<sup>1</sup> and is generally fatal.<sup>2</sup> Because there are no effective treatments for TA-GVHD, the management of this complication focuses almost entirely on prevention by irradiation or other means of inactivation of residual T cells found in cellular blood components (whole blood, red blood cells [RBCs], granulocytes, and platelets) intended for transfusion to susceptible recipients. Over the past 20 years, the use of irradiated products for high-risk patient populations has reduced the incidence of TA-GVHD in the Western world and Japan to almost undetectable levels. In this chapter, we review the pathophysiology and incidence of TA-GVHD, characteristics of blood transfusion recipients that make them susceptible to the development of TA-GVHD, and strategies to prevent, diagnose, and treat TA-GVHD.

### Pathophysiology of TA-GVHD

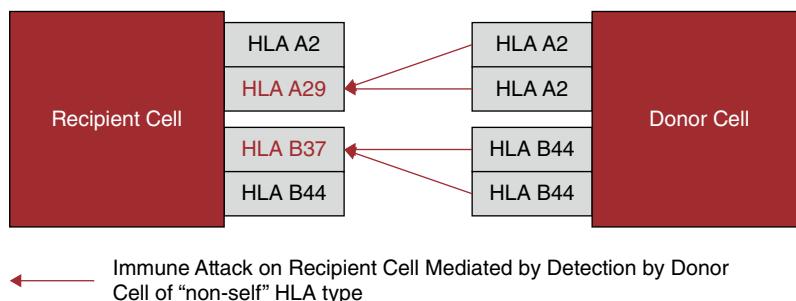

The development of TA-GVHD requires infusion of viable allogeneic donor ("non-self") lymphocytes, which in rare circumstances can proliferate and attack recipient ("self") tissues. Unlike BMT-associated GVHD, in which the transplanted donor hematopoietic cells in the engrafted marrow are the cells that mediate the attack on host (recipient) tissues, TA-GVHD results in the destruction of both the host tissues and host bone marrow by donor T lymphocytes that proliferate in the recipient following transfusion. It is the host bone marrow aplasia that occurs only in TA-GVHD that primarily drives its lethality.

The biologic basis for the differentiation of "self" and "non-self" involves immune recognition of specific cell surface proteins, most importantly human leukocyte antigens (HLA) expressed on the surface of both immune and nonimmune cell types. In most

situations, transfused donor lymphocytes contained within cellular blood components are identified and eliminated by the host immune system due to their expression of donor "non-self" HLA proteins. In individuals with intact immune systems, donor lymphocyte clearance appears to occur within a week;<sup>3</sup> this clearance likely occurs more quickly in donor lymphocytes from irradiated blood products that lack ability to proliferate. However, in rare situations, transfused donor lymphocytes are not recognized as "non-self" by the recipient immune system. If the transfused donor lymphocytes are sufficiently viable to proliferate within the recipient, TA-GVHD can result.

Given its rarity, the precise circumstances needed to induce TA-GVHD are not known. Transfusion-associated microchimerism (TA-MC) is a condition that occurs after transfusion of cellular blood components, in which a small number of donor allogeneic lymphocytes proliferate within a host and remain detectable for years. TA-MC is associated with perhaps 10% of patients transfused after sustaining traumatic injury, but is not known to have any clinical sequelae.<sup>4</sup> Distinguishing the factors that influence why T-lymphocyte engraftment sometimes results in severe disease (TA-GVHD), and sometimes results in no disease manifestations (TA-MC), has been the subject of ongoing investigation, but remains unknown. However, understanding immunomodulatory circumstances that allow TA-MC may also be revealing for the potential setup for TA-GVHD, given that there may be overlapping factors influencing prolonged donor lymphocyte survival and proliferation.

In many cases, the presence of severe acquired or congenital immune deficiency in the transfusion recipient serves as a prerequisite to the development of TA-GVHD. TA-GVHD, however, has also been reported to occur in the absence of a recognized immune deficiency, particularly in situations where the blood donor is homozygous for HLA antigens for which the recipient is heterozygous.<sup>2</sup> In this scenario, all HLA antigens expressed by the donor are also expressed by the host, but the host expresses HLA antigens that are not expressed by the donor. This can result in *unidirectional tolerance*, where donor lymphocytes are spared from attack by the host immune system, whereas host tissues are left vulnerable to attack by donor lymphocytes and their progeny (Figure 50.1).

**Figure 50.1** Unidirectional tolerance occurs when donor lymphocytes mediate an attack on host tissues while simultaneously being viewed as “self” by the host immune system. In this example, recipient cells expressing HLA A29 and HLA B37 antigens are attacked by donor lymphocytes that do not express these antigens; however, donor-derived HLA A2 and HLA B44 expressing cells are not targeted by the recipient immune system because these antigens are also expressed by recipient cells. The scenario depicted is similar to a case report by Benson *et al.*<sup>7</sup>

### Incidence of TA-GVHD

As mentioned previously, TA-GVHD has become an extremely rare phenomenon over the past 20 years. In the United Kingdom, more than 55 million cellular blood components have been transfused since 1999 (Table 50.1). During that interval, there have been 14 cases of reported TA-GVHD with only one case reported since 2002. Similar data compiled by the US Food and Drug Administration (FDA) identified only three cases of fatal TA-GVHD in the United States from 2005 to 2018, during which time more than 210 million cellular blood components were transfused (Table 50.2). In both the United Kingdom and the United States, widespread use of blood component irradiation in at-risk populations has contributed to the low incidence of TA-GVHD.

In Japan, there is substantially less HLA diversity than in the United States or the United Kingdom. In addition, Japan historically has a high rate of directed-donor blood collections where relatives donate blood for other family members.<sup>5–6</sup> As a result, Japan has had a higher reported rate of TA-GVHD with a large proportion of TA-GVHD case reports published by Japanese authors.<sup>5,6</sup> Indeed, in Japan prior to the routine irradiation of blood components, TA-GVHD had a calculated expected incidence of 1 in 874 transfusions when donor and recipient were unrelated, and 1 in 102 when donor and recipient were a mother-child pair.<sup>5</sup> Routine irradiation of

cellular blood components was introduced in Japan in 1998, and there were no cases of TA-GVHD reported to the country’s hemovigilance network between 2000 and 2013.<sup>2</sup> Similar scenarios are found in other countries where there is substantially less HLA diversity among the donor-recipient population.

### Clinical scenarios associated with TA-GVHD

#### Patients without recognized immunodeficiency syndromes

Prior to the widespread irradiation of cellular blood components in Japan, the reported rate of TA-GVHD in Japan was higher than in Western Europe or the United States. The Japanese medical literature describes numerous cases of TA-GVHD in patients without a recognized immunodeficiency.<sup>44</sup> Uchida *et al.* reported that, among 66 confirmed cases of TA-GVHD in Japan from 1992 to 1999, 65 of the patients were not considered by the study authors to be immunosuppressed.<sup>2</sup> The majority of these patients received transfusions either during the treatment of solid tumors or for surgical or traumatic bleeding episodes.<sup>2</sup> Similarly, Juji *et al.* reported 96 cases of TA-GVHD among immunocompetent patients who underwent cardiac surgery in Japan between 1981 and 1986.<sup>45</sup>

\* Apheresis equivalent units.

There are several factors that appear to play a role in the pathogenesis of TA-GVHD among patients without recognized immunodeficiency syndromes. One contributing factor is likely the relative HLA homogeneity in Japan, where many of the cases were reported. A study of 655 Japanese found the frequency of the most common HLA haplotype to be 7.5%, and the second most common HLA haplotype had a frequency of 5%. In contrast, the same study found the frequency of the most frequent HLA haplotype among US Caucasians to be only 4%, and the most common HLA haplotype among Italians was identified in only 2.2% of the population.<sup>5</sup> It is likely that the lack of HLA diversity among the Japanese population resulted in unidirectional tolerance more frequently in Japan than in other parts of the world, helping to explain the historically high levels of TA-GVHD in Japan prior to widespread irradiation of cellular blood components. However, the anticipated incidence of TA-GVHD based on rates of HLA similarity is much lower than the actual reported incidence of TA-GVHD,<sup>1,46</sup> indicating that a lack of HLA diversity is only one of many factors that influence the pathogenesis of TA-GVHD.

Another factor that may contribute to TA-GVHD in some patients is trauma or major surgery, particularly cardiac surgery.<sup>47</sup> Although the mechanism of immune suppression, if any, contributing to TA-GVHD in these patient populations is not known, it has been reported that hospitalized patients, compared to healthy volunteers, are less likely to generate antibodies after exposure to allogeneic, minor blood group antigens via transfusion.<sup>48</sup> Consequently, it is possible that although hospitalization and surgery help to prevent alloimmunization to minor red blood cell antigens, they simultaneously increase the risk of developing TA-GVHD due to incompletely understood changes to the immune system that result from trauma or cardiac surgery. This hypothesis may also help explain the reported relatively high (10%) incidence of TA-MC seen after transfusion following a traumatic injury.<sup>4</sup>

Besides cardiac surgery and HLA similarity between donor and recipient, other factors that have been associated with TA-GVHD in immunocompetent individuals have also been described, including transfusion of recently collected (<72 hours old) whole blood or cellular components<sup>44,49</sup> and use of blood collected from first- or second-degree relatives.<sup>44</sup> These factors likely enhance the probability of developing TA-GVHD by either enhancing the viability or dose of transfused lymphocytes (e.g., using fresh or nonleukoreduced or nonirradiated blood components) or increasing the likelihood of HLA similarity between donor and recipient (e.g., using blood from close family relations).

### **TA-GVHD in immunosuppressed patients**

Although cases of TA-GVHD are reported among patients without recognized immunodeficiency, many more reported cases involve patients who are profoundly immunosuppressed.<sup>46</sup> Among immunosuppressed patients, those considered at highest risk for the development of TA-GVHD include patients with severe T-cell immunodeficiency syndromes (e.g., severe combined immunodeficiency or DiGeorge syndrome), patients undergoing allogeneic or autologous bone marrow transplant, patients diagnosed with Hodgkin's lymphoma or aplastic anemia on immunosuppressive therapy, neonates, a fetus receiving intrauterine transfusions, and patients being treated with purine analogs (fludarabine, cladribine, or deoxycoformycin) or alemtuzumab (anti-CD52).<sup>46,50,51</sup> Although rare cases of TA-GVHD have been reported in patients after organ transplantation, patients undergoing treatment for solid tumors, or for patients with either non-Hodgkin's lymphoma

or acute leukemia (without stem cell transplantation), the risk is generally considered to be lower compared to the first groups listed above.<sup>50,51</sup> No cases of TA-GVHD attributed only to immunodeficiency caused by HIV/AIDS (in the absence of other conditions listed above) have been reported in the medical literature to date.<sup>50,51</sup> A described murine model of TA-GVHD suggests that functional recipient CD8 T-lymphocytes and natural killer cells have a particularly important role in the suppression of TA-GVHD development.<sup>1</sup> Recipient mouse CD4 T-lymphocyte depletion increased the threshold for viable donor lymphocytes needed to induce TA-GVHD, which may in part explain the apparent lack of susceptibility of HIV/AIDS patients to this complication.<sup>52</sup> AABB guidelines, as well as national guidelines from the United Kingdom and Australia, address the importance of ensuring that all cellular blood products used in high-risk settings are appropriately irradiated.<sup>50,51,53</sup>

The last known TA-GVHD case in the United Kingdom occurred in 2012. In that case, two intrauterine transfusions were administered to a fetus (hemoglobin 4.4 g/dL) at 21 weeks gestation who was anemic due to a maternal parvovirus infection. The transfusions were performed using a total of 33 mL of nonleukoreduced, nonirradiated blood that had been collected from the mother.<sup>23,54</sup> Although cellular blood components (including whole blood) intended for intrauterine transfusions are generally leukoreduced and irradiated in the United Kingdom, these product modifications were not made in this case due to the emergent need for the transfusions. At 32 weeks gestation, the fetus was delivered hydropic and pancytopenic. Two months after birth, a bone marrow biopsy revealed an aplastic marrow, and maternal engraftment was detected by chimerism studies. HLA typing performed on the mother found her to be HLA homozygous and showed unidirectional tolerance for her child. The neonate was diagnosed with TA-GVHD and died despite attempted allogeneic stem cell transplantation using stem cells collected from the mother.

### **Diagnosis of TA-GVHD**

It is important to emphasize that the incidence of TA-GVHD is extremely low and thus cases will only be detected if there is clinical awareness that the diagnosis is a possibility. Historically, the most common reported signs and symptoms of TA-GVHD were fever, maculopapular rash progressing to generalized erythema, pancytopenia, bone marrow aplasia, diarrhea, and hepatitis; these generally occurred within 1–2 weeks of transfusion but can be seen up to 30 days after transfusion.<sup>2,6</sup> The case fatality rate for TA-GVHD approaches 100%.<sup>2,8–10,12,23,31,34</sup> The relatively long latency period between transfusion and the development of symptoms (up to 30 days) is another reason why cases may not be recognized clinically. In addition, if patients are critically ill at the time of their transfusion, it may be difficult to differentiate the clinical signs of TA-GVHD from their underlying illness. For these reasons, TA-GVHD may be underdiagnosed.<sup>55</sup> Nonetheless, a diagnosis of TA-GVHD should be considered in any patient with fever, erythema, cytopenias, gastrointestinal symptoms, and hepatitis within 30 days of a transfusion with nonirradiated cellular blood products (whole blood, RBCs, granulocytes, or platelets). It is notable that reports of TA-GVHD have never been attributed to transfusions with plasma, cryoprecipitate, factor concentrates, albumin, intravenous immunoglobulin, or previously frozen, deglycerolized RBCs. This is presumably due to the absence of sufficient viable donor lymphocytes in these products.<sup>50</sup>

If TA-GVHD is suspected clinically, confirmation should be obtained by testing for donor chimerism in the patient. Donor lymphocytes can be differentiated from host lymphocytes by measuring differences in restriction fragment length polymorphisms or numbers of short tandem repeats between the donor and the host, although modern molecular pathology laboratories may choose a more modern approach to identity testing. Consultation with a molecular pathology specialist is recommended to choose the optimal testing approach at a given hospital. In most situations, molecular pathologists will essentially recommend the same molecular assays that they routinely employ to detect donor-recipient chimerism in patients who have undergone allogeneic stem cell transplantation.<sup>55</sup> One strategy is to biopsy both affected and unaffected patient tissues and to compare the results to samples obtained from the blood donor (if available).<sup>50</sup> In older reports, detection of the Y chromosome was used to diagnose TA-GVHD resulting from a blood transfusion from a male donor to a female recipient.<sup>56</sup> Today, this approach is considered to be relatively insensitive in most circumstances, and would be of no use in cases of TA-GVHD suspected in male recipients, in patients who have undergone a sex-mismatched stem cell transplant or in cases involving the transfusion of a blood component collected from a female donor.

### **Prevention of TA-GVHD**

Although the introduction of universal leukoreduction is associated temporally with a reduction in the reported incidence of TA-GVHD, cases of TA-GVHD have been reported in patients receiving leukoreduced (but nonirradiated) cellular blood transfusions, and neither AABB standards nor other national standards accept leukoreduction alone as an adequate preventive measure of TA-GVHD in vulnerable populations.<sup>57</sup> In addition, the minimum dose of lymphocytes required to cause TA-GVHD in humans is not precisely known, and it may be influenced by factors that are not likely to be fully known prior to transfusion. These factors include the degree of HLA match between donor and recipient, the viability of the remaining transfused lymphocytes, and the degree of immunosuppression of the recipient. Consequently, leukoreduction alone is not considered to be sufficient prophylaxis against TA-GVHD; irradiation of cellular blood components is the only widely recognized method to prevent TA-GVHD in all cellular blood components.<sup>50,51,53,58</sup>

In the United States, in order to render lymphocytes contained in RBCs, platelets, granulocytes, or whole blood incapable of engraftment, 25 Gy must be directed at the center of the blood component being irradiated, with a minimum of 15 Gy at any part of the bag, if the intended recipient of the product is at high risk for TA-GVHD.<sup>53</sup> Of note, standards in the United Kingdom require a minimum dose of 25 Gy, with no more than 50 Gy delivered to any portion of the bag.<sup>50</sup> Special, radiation-sensitive labels are used to verify and permanently document that a blood product was irradiated. The expiration date of irradiated RBCs is shortened to 28 days from the date of irradiation, or the product's original expiration, whichever comes first.<sup>53</sup> In contrast, platelet component expiration is not affected by irradiation due to the short shelf life of platelets. Blood products that are inadvertently irradiated more than once or at a dose not in accordance with

standards should generally be discarded. It must be noted that bone marrow, peripheral blood stem cells, or donor lymphocytes infused as part of a hematopoietic stem cell transplant program must *never* be irradiated.

Of note, platelets that are treated with ultraviolet light-based pathogen reduction technology generally do not need to be irradiated because the pathogen inactivation process induces strand breakage of lymphocytic DNA, rendering any residual lymphocytes incapable of engraftment or proliferation.<sup>59-63</sup> This process has the additional benefit over standard irradiation in that it also effectively eliminates the ability of most infectious agents to replicate, reducing the risk of transfusion-transmitted infections. Blood banks using pathogen-reduced platelets should follow the guidance of their national regulatory authority regarding the need for irradiation. In the United States, the package insert for the psoralen/UVA-light-based pathogen inactivation system for platelets states that the pathogen inactivation process is "an alternative to gamma irradiation for prevention of TA-GVHD".<sup>64</sup> At present, pathogen inactivation systems are not available for clinical use with RBCs, whole blood, or granulocytes. It is anticipated that, in the coming years, pathogen reduction approaches to RBCs, and whole blood that obviate the need for routine irradiation will become widely available.

Most blood banks or blood centers use <sup>137</sup>Cs,<sup>60</sup> Co, or X-rays as a source of ionizing radiation.<sup>58</sup> In order to remove sources of ionizing radiation from hospital blood banks or blood centers that could be used for domestic terrorism, the US government is actively facilitating the elimination of irradiators that use <sup>137</sup>Cs or <sup>60</sup>Co and replacing them with X-ray-based irradiators.

Due to the rarity of cases of TA-GVHD, and the limited availability of irradiation in hospitals in some rural areas of the United States, there is not universal consensus on the specific medical conditions that require the use of irradiated cellular blood products, beyond directed donations, intrauterine transfusions, and neonatal transfusions. Some of the most common indications for irradiation are summarized in Table 50.3. As universal irradiation of all cellular blood products is not practiced in most countries, patients with TA-GVHD risk factors are occasionally transfused with nonirradiated blood.<sup>65</sup> Fortunately, the incidence of TA-GVHD is still very low among patients with risk factors who should have received irradiated blood. For example, in the United Kingdom between 2006 and 2010, there were 389 instances where patients inadvertently received nonirradiated cellular blood components when irradiation was indicated. This cohort included 178 patients undergoing purine analog therapy, 68 patients with lymphoma (including Hodgkin's lymphoma), and 44 patients undergoing stem cell transplant. None of these patients developed TA-GVHD as a consequence of their transfusion.<sup>65</sup> It was recently reported that from 1999 to 2018 in the UK, there were 1478 instances where leukoreduced, but nonirradiated cellular blood products were administered when irradiated components were indicated. None of these patients developed TA-GVHD.<sup>28</sup> Possible explanations include lack of HLA similarity between donors and recipients or decreased lymphocyte viability due to the storage time of the blood component before transfusion. In situations where irradiated red cell products would be indicated but are not available, some guidelines recommend preferential use of older (>14-day-old) products.<sup>66</sup> Regardless, if a

patient at risk for TA-GVHD is transfused with a nonirradiated cellular blood component, they should be monitored for signs of TA-GVHD for 30 days.

### Treatment of TA-GVHD

There are only rare reports of patients surviving TA-GVHD. In one case, recovery was attributed to treatment with anti-CD3 monoclonal antibody and cyclosporine.<sup>67</sup> Another case of TA-GVHD resolved spontaneously, although the patient's skin biopsy did not show several classic histologic features of TA-GVHD despite the presence of Y-chromosome DNA in the sample of this female patient.<sup>68</sup> However, overall, one of the distinguishing characteristics of TA-GVHD, compared to post-bone-marrow transplant GVHD, is that TA-GVHD does not usually respond to immunosuppressive therapy.<sup>1</sup> This is highlighted in one systematic review that showed similar rates of immunosuppressive therapy used in both survivors and nonsurvivors of TA-GVHD.<sup>69</sup> Bone marrow transplant has been performed in rare cases, several of which resulted in patient survival.<sup>69</sup> However, the quick time course from diagnosis of TA-GVHD to death significantly hinders the ability to find an appropriate BMT donor. Unfortunately, treatment is typically limited to supportive care and the case fatality rate approaches 100%.

### Conclusion

TA-GVHD is a rare but almost uniformly fatal consequence of transfusion with cellular blood components. Although the incidence of TA-GVHD in the United States, the United Kingdom, and Japan has become very low in the past 10–15 years, there are still sporadic case reports. Therefore, vigilance—in terms of both avoidance of unnecessary transfusions and irradiation of blood components given to high-risk patients who are susceptible to TA-GVHD—must continually be borne in mind.

## CHAPTER 51

# Transfusional iron overload

Sujit Sheth

Department of Pediatrics, Weill Cornell Medical College, New York, NY, USA

## Introduction

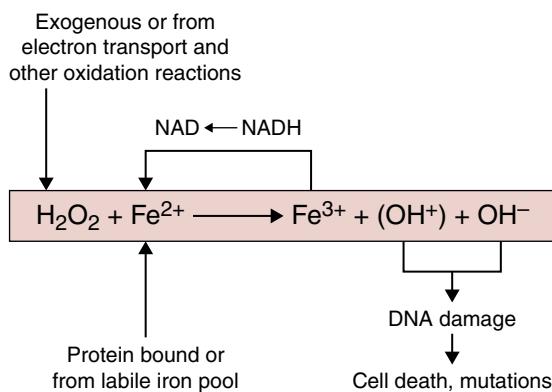

Tissue iron overload inevitably results in patients who receive regular red blood cell (RBC) transfusions for congenital or acquired anemias. Iron is initially sequestered in normal storage sites, namely the liver and monocyte-macrophage (reticuloendothelial) system, but as these tissues become increasingly saturated, iron begins to deposit in other organs such as the endocrine glands and the heart. The body lacks an effective means of eliminating this excess iron, and without therapy, cirrhosis, heart disease, diabetes, and other disorders develop; death is usually the result of cardiac failure. Transfusional iron overload, with its resulting morbidity and mortality, is an important health issue in patients of all ages. Children with thalassemia major (TM), or other inherited disorders such as Diamond-Blackfan anemia (DBA), congenital dyserythropoietic anemia (CDA), and congenital aplastic anemia, are dependent on regular red cell transfusions to maintain their well-being. Children with sickle cell disease (SCD) who are found to be at increased risk of stroke based on transcranial Doppler (TCD) evaluation, or who have developed silent infarcts in the brain, may be placed on a regular transfusion program to reduce the risk of progressive neurologic disease.<sup>1,2</sup> Adults with severe aplastic anemia (SAA) or myelodysplasia syndrome (MDS) may also become dependent on regular red cell transfusions. In addition, with chemotherapeutic regimens becoming more intense and myelosuppressive, patients undergoing treatment for various forms of cancer, particularly leukemias and lymphomas, may also receive a large number of red cell transfusions. Transfusions around stem cell transplantation may lead to iron overload when the indication is non-hematologic or worsen premorbid transfusional hemochromatosis. With advances in the medical management of many of the conditions enumerated above, including improved chelation regimens, patients also have a better survival probability, thus increasing the number of individuals in whom transfusional iron overload requires close medical attention. Most long-term experience in the management of transfusional iron overload comes from studies in patients with TM. We now understand that the pathophysiology of iron loading is different based on the underlying condition, and consequently the management must be adapted to minimize complications of iron toxicity. There has been much debate on the relevance of transfusional iron overload in MDSs yet without consensus on who requires treatment

or on the benefits of such therapy.<sup>3</sup> There are no uniform guidelines for assessment and management, and individual tailoring of therapy is recommended.

## Pathophysiology

Iron is an essential nutrient required by every cell. It is present in the human body in hemoglobin, myoglobin, and several mitochondrial respiratory enzymes. It serves as a carrier for oxygen and electrons and acts as a catalyst for a variety of oxygenation reactions. It is able to perform these functions in part because of its ability to reversibly and readily cycle between its ferrous and ferric forms. This very property also makes it potentially toxic, capable of producing free radicals, which can cause cellular damage (Figure 51.1).

The normal body iron concentration is approximately 40–50 mg Fe/kg body weight (~4–5 g in total); women have lower amounts, and men somewhat higher.<sup>4</sup> Three-quarters of this iron, about 30 mg Fe/kg, is contained in the circulating red cell compartment as hemoglobin, and approximately 5–6 mg Fe/kg is present in functional form in a variety of heme compounds (myoglobin and cytochromes) and iron-dependent enzymes. The remainder (5 mg Fe/kg in women and 10–12 mg Fe/kg in men) is held in reserve in the two primary storage forms, ferritin and hemosiderin, in the liver, bone marrow, spleen, and muscle, readily available when required for erythropoiesis. Normally, iron balance is maintained by controlling iron absorption: iron stores and iron absorption are reciprocally related so that as stores increase, absorption declines, and these processes are closely managed by the iron regulatory "hormone" hepcidin,<sup>5</sup> which plays a critical role in iron metabolism. It regulates the absorption of iron from the gastrointestinal tract through its effect on levels of ferroportin, the protein present on the basolateral membrane which is the primary iron exporter from cells. Red cells are normally broken down by cells of the monocyte-macrophage system, and the iron contained in hemoglobin is usually returned via transferrin to the erythroid precursors in the bone marrow, for recycling into new red cells. Hepcidin controls the release of iron from macrophages, an effect also mediated by ferroportin. In the normal host, when the body has adequate or increased amounts of iron, hepcidin is upregulated, iron absorption from the intestine is inhibited, and iron is

**Figure 51.1** Iron-induced oxidative tissue damage caused by free radicals generated through the Fenton reaction.<sup>92</sup> These reactive oxygen species (ROS) affect all tissues, but the heart and endocrine organs may be particularly susceptible.

sequestered in its storage sites, the macrophages and hepatocytes. The body lacks any effective mechanism for the excretion of excess iron. Iron exchange is limited so that the adult male absorbs and loses only about 0.01 mg Fe/kg/day.

Iron overload may result from repeated blood transfusion, excessive iron absorption from the gastrointestinal tract, or a combination of these processes.<sup>4</sup> In patients with severe congenital anemias, such as the thalassemias, DBA, or CDA, death from severe anemia in infancy is averted by a regular transfusion program that, if adequate, allows for normal growth and development during the first decade of life. Individuals with MDS or SAA usually begin transfusions later in life. As in normal individual, macrophages process senescent red cells (transfused in these patients) and extract iron from heme. With no effective means for the excretion of this iron, there is gradual tissue accumulation of this iron, which eventually exceeds the body's capacity for safe storage. As the amount of iron increases, there is virtually no change in the amount that is contained within the functional or transport (transferrin-bound) pools, and almost all of the excess iron is stored. Initially, the iron is sequestered in the cells of the monocyte-macrophage system and the liver (hepatocytes and Kuppfer cells), both normal storage tissues, but with continued accumulation, iron spills over and is deposited in other tissues, including the heart, pancreas, and other endocrine organs. Transfusion-dependent individuals may be broadly categorized as those having ineffective erythropoiesis, such as individuals with thalassemia, some MDS, or some forms of sideroblastic anemia; those with effective erythropoiesis, such as individuals with sickle cell anemia or hereditary spherocytosis; and those with decreased or absent erythropoiesis, such as patients with other myelodysplastic syndromes, SAA, or DBA. The "effectiveness" of erythropoiesis, with the ability to incorporate iron into hemoglobin in mature red blood cells, is a critical determinant of the pathophysiology of iron loading in transfusion-dependent patients. Once transfused red cells are phagocytosed by macrophages, hepcidin levels determine the fate of iron released from heme. If hepcidin levels are high, more iron remains sequestered in these storage cells, and less is released for potential deposit in other tissues. Iron stored in the hepatocyte is similarly retained. In contrast, if hepcidin levels are low, more iron is released from these cells and may be available for deposition in other parenchymal tissues. Thus, hepcidin helps determine the partition and internal redistribution of the excess

iron between the monocyte-macrophage and parenchymal sites,<sup>5</sup> another crucial factor in tissue toxicity.

Ineffective erythropoiesis (IE) and, to a lesser degree, anemia result in a downregulation of hepcidin expression and result in enhanced absorption of iron from the intestine.<sup>6</sup> Patients with TM or thalassemia intermedia (TI), paradoxically, have relatively low levels of hepcidin even in the presence of iron overload, as a result of their marked ineffective erythropoiesis. In patients with SCD, who have intact erythropoiesis, hepcidin expression varies inversely with erythropoietic drive,<sup>7</sup> with untransfused patients excreting less hepcidin in the urine. Similarly, patients with DBA or SAA, who have almost no erythropoiesis, likely have appropriately elevated hepcidin levels when iron loading occurs. Thus, patients with TM or TI not only have higher iron burdens because of increased intestinal absorption, but also have a greater risk of parenchymal tissue deposition than the latter groups. In fact, patients with TI who have received very few or no red cell transfusions may have profound iron overload as a result of marked hepcidin inhibition<sup>8</sup> as a result of their ineffective erythropoiesis. In patients with TM or TI, regular transfusion suppresses ineffective erythropoiesis to some extent, and hepcidin levels may rise somewhat, but they remain inappropriately low in relation to the higher body iron burden, resulting in iron loading through gastrointestinal absorption. A recently described hormone, erythroferrone (ERFE), has been shown in mice to suppress hepcidin expression.<sup>9</sup> When erythropoiesis is active, even if ineffective, maturing erythroid precursors may produce ERFE, which could suppress hepcidin leading to iron mobilization from stores and deposition in tissues. In thalassemic mice, another growth differentiation factor (GDF15) has been identified, which is secreted during erythroblast maturation and suppresses hepcidin production.<sup>10</sup> Its role in human disease is not completely clear. Therefore, variability in the hepcidin response to the underlying erythropoietic status produces differences in the partition and distribution of the excess iron, even when the volume of red cells transfused is similar. This likely explains the variability of iron deposition in different transfusion-dependent conditions.

Although hepcidin levels are critical in modifying the pathophysiology of iron loading in transfusion-dependent patients, several other variables are important in determining the morbidity related to the increased body iron burden. These include (1) the age at which transfusion therapy began, (2) the duration of transfusion therapy, and (3) the initiation and maintenance of effective chelation. Additional modifying factors include other genetic determinants, alcohol use, coexisting viral hepatitis, and other drugs and medications that the patient may be taking. The complex interplay between the underlying disorder and these factors in each individual plays a key role in the pathophysiology of iron toxicity.

Even though the body has the ability to safely store increased amounts of iron, deposition in nonstorage tissues eventually occurs as the body iron burden rises. Tissue toxicity depends on three factors: (i) the inherent sensitivity of the tissue to iron loading, (ii) the amount of iron in that tissue, and (iii) the duration of time for which that tissue remains exposed to abnormally high levels of iron. Without treatment, patients with thalassemia, who begin transfusions in infancy, develop growth retardation, diabetes, and other endocrine disturbances in the first decade of life, and death owing to iron loading of the myocardium occurs during the second decade. Patients with SCD, who receive regular transfusions to prevent the occurrence of strokes, may begin these transfusions later in childhood, and may already achieve normal growth and sexual maturation before the threshold for tissue damage is reached.

A comparative study of regularly transfused patients with TM and SCD with similar transfusional iron burdens showed that the latter group had fewer cardiac and endocrine complications.<sup>11,12</sup> The SCD group began regular transfusions at a later age, and had been transfused for approximately half as long as the thalassemia patients, possibly contributing to the observed differences in clinical manifestations. It has been reported that patients with DBA who begin transfusions in early infancy may have higher cardiac iron burdens and may be at higher risk for cardiac mortality.<sup>13</sup> Patients with MDS who begin transfusions in adulthood may not have any endocrine abnormalities, although the iron may contribute to some extent to the diabetes or sexual dysfunction that these older individuals may have. These observations emphasize the relevance of the age at which transfusions are begun, particularly with regard to growth, development, and sexual maturation. As the duration of transfusion increases, severe iron loading may occur in all transfusion-dependent patients who are not effectively chelated, and diabetes and cardiac disease may develop, the latter remaining the major cause for morbidity in all of these patients.

In recent years, there has been much interest and some controversy surrounding iron overload in patients with MDS, specifically the role in pathophysiology and the need for treatment. The major cause of siderosis in these individuals is mostly red cell transfusions, but ineffective erythropoiesis may play some role. Iron deposition in the different organs is not as consistent as it may be in TM, and the role of iron in organ dysfunction is also not clear. Excess iron has been demonstrated in the liver after just 20 units of packed RBCs, and in the heart after 75 units.<sup>14</sup> Iron has been demonstrated in the pituitary and pancreas of these individuals as well,<sup>15</sup> and although hepcidin levels are variable, they are usually lower in low-risk MDS patients.<sup>16</sup> However, the removal of iron may improve trilineage erythropoiesis and reduce transfusion requirements,<sup>17,18</sup> with postulated mechanisms including reduction in oxidative stress, increase in erythropoietin, and inhibition of nuclear factor κB (NF-κB).<sup>19</sup>

Iron overload has also been described in the setting of stem cell transplantation, with several studies showing that the incidence of iron overload in these patients is generally high,<sup>20</sup> with higher burdens conferring a poorer prognosis on patients with MDS or acute myeloid leukemia undergoing transplantation,<sup>21</sup> possibly related in part to an increased risk of invasive fungal infections.<sup>22</sup> More prospective studies related to iron in this setting are underway.

As the body accumulates iron from transfused red cells, chelation therapy is usually begun to prevent deposition and damage to parenchymal tissues. Just as the rate of uptake of iron by these tissues is influenced by transfusion parameters and hepcidin levels, the variability of the chelation regimen also plays an important role. The timing of initiation, choice of chelator and dosing, and compliance with the regimen are some of these variables. When transfusion and chelation are occurring simultaneously, there is likely a complex and dynamic balance between transfusional iron loading and chelator-induced iron purging.<sup>23</sup> Different organs may take up iron at different rates and likely have different thresholds for when tissue damage occurs. It has been demonstrated that in transfused and chelated patients with thalassemia and SCD, the relationship between the liver iron concentration and myocardial iron levels is nonlinear and variable.<sup>24</sup>

In summary, the pathophysiology of iron metabolism in the condition underlying the transfusion-dependent anemia, as well as the factors directly related to the initiation, intensity, duration, and effectiveness of both the transfusion regimen and the chelation

regimen, contributes to the pathology of transfusional iron overload.

Storage iron is present in the body predominantly in two high-molecular-weight forms, ferritin and hemosiderin. Both forms are stained on pathological specimens by Prussian blue, via the Pearl's reaction. Hemosiderin is insoluble and deposited in aggregates of varying sizes, whereas ferritin is soluble and more homogeneously distributed within cells. Under physiologic conditions, iron is distributed approximately equally between these storage forms, but as the body's iron load increases, the proportion stored as hemosiderin increases dramatically. A small amount of iron is present in a low-molecular-weight intracellular pool, likely the most toxic form of iron, because of its propensity for producing free radicals, which cause oxidative damage. It is likely that the ferritin fraction is in closer equilibrium with the low-molecular-weight iron pool.<sup>25</sup> As the magnitude of iron excess grows, some stored iron may be mobilized into the circulation from macrophages or hepatocytes. As transferrin is increasingly saturated, some plasma nontransferrin-bound iron (NTBI) may appear. This iron may be more easily taken up by parenchymal tissues that do not normally store iron, leading to toxicity. Thus, it is critical to ensure that effective chelation therapy is ongoing to bind this iron and prevent its entry into cells, thereby avoiding organ damage.

Histopathological examination of the liver in mild transfusional iron overload reveals predominant Kupffer cell iron deposition, with preserved hepatocyte architecture and no fibrosis. As iron loading continues, the hepatocytes also demonstrate increased iron uptake, and there is some disruption of the architecture and some scarring and fibrosis. Until this point, these changes are reversible with appropriate chelation. With massive overload, there is bridging fibrosis and progression to cirrhosis, which may or may not be reversible.<sup>26</sup> Myocardial iron distribution is heterogeneous, with more in the left heart than the right, the ventricles than the atria, and the epicardium than the endocardium.<sup>27</sup> It has been suggested, based on studies in the iron-loaded gerbil model, that iron in myocardial fibers may cause impaired repolarization of the myocytes,<sup>28</sup> which interferes with generation and orderly propagation of the electrical impulse and may lead to a variety of arrhythmias. With progressive loading, fibers may not contract normally, and a restrictive cardiomyopathy with impaired filling and diastolic dysfunction may result, eventually leading to congestive heart failure. Heart failure is reversible in part, and with improved chelation, cardiac function may be recovered substantially.<sup>29,30</sup> Therefore, long-term monitoring of transfused and chelated patients should include serial measurement of myocardial iron deposition as well as the liver iron concentration.

### Transfusional iron burden

The total amount of iron that enters the body via red cell transfusion may be estimated. As the magnitude of the iron burden is critical in the development of complications, it is of great importance to maintain accurate records, in each patient, of the amount of red cells transfused. The total amount of transfused red cells is calculated as the total amount of blood in milliliters multiplied by the hematocrit of each unit (as a percentage) divided by 100. Each milliliter of red cells contains 1.08 mg of iron, and the total amount of iron introduced ( $K_{in}$ ) is calculated as

$$K_{in} = (\text{total amount of red cells transfused [in mL]}) \times 1.08$$

Alternatively, if the exact volume is not available, the iron burden may be estimated from the number of units transfused. Each unit of transfused red cells contains 200–250 mg of iron. Using one of these methods, the total iron burden may be calculated. Transfusion-dependent patients usually require 200–300 mL/kg/year of blood, an amount equivalent to 0.25–0.40 mg Fe/kg/day.

With no physiologic means of excreting this excess iron, and the inapplicability of phlebotomy in patients who are regularly transfused, these individuals must receive iron chelation therapy in order to facilitate excretion. A minimum chelator-induced excretion of 0.25–0.40 mg Fe/kg/day would maintain iron balance in such individuals. Higher levels of excretion would be necessary to produce a negative iron balance.

Iron balance may be monitored during chelation therapy to assess the efficacy of such treatment. The total body iron ( $U_s$ ) at any point in time  $t$  may be extrapolated from the liver iron concentration (in mg Fe/g dry weight [dw]) using the formula published by Angelucci *et al.*:<sup>31</sup>

$$U_s(t) = 10.6 \times \text{liver iron concentration} \times \text{body weight (in kg)}$$

For patients who are being chelated as well, there is an ongoing change in the body iron balance as the iron entering the body through transfused red cells is removed by the chelator. In these situations, it is important to monitor the total body iron excretion between measurements of liver iron concentration. This may be calculated based on the amount of red cells transfused ( $K_{in}$  = iron introduced in mg) and on the changes in total body iron between measurements of liver iron concentrations at baseline ( $t_0$ ) and a later time ( $t$ ), expressed as milligrams of iron excreted per day:<sup>32</sup>

$$\text{total body iron excretion} = \left( K_{in} + [U_s(t_0) - U_s(t)] \right) / (t - t_0)$$

### Clinical features

Although iron deposition in tissues begins soon after the initiation of regular transfusions, signs and symptoms of iron toxicity usually occur after a few years of iron loading, when the usual storage sites for iron have been almost saturated, and there is deposition in other tissues that do not normally store iron. Organs suffer damage, often irreversible, resulting in significant morbidity and sometimes an early death, most commonly as a result of cardiac failure.<sup>33,34</sup> A cross-sectional study of patients with thalassemia born after 1970 in Italy found that 7% had heart failure, 6% had diabetes, 11% had hypothyroidism, and 55% had hypogonadism.<sup>35</sup> A third of these patients had died, the cause of death in 68% being heart failure. Such data are not available for other transfusion-dependent anemias or MDS.

Liver disease of transfusional iron overload may be manifested as hepatomegaly; abnormalities in function; fibrosis, which may lead to scarring, bridging fibrosis and micronodular regeneration, and cirrhosis; and hepatocellular carcinoma.<sup>36,37</sup> Patients may be asymptomatic, or have mild-to-moderate icterus with progression, symptoms, and signs of cirrhosis and hepatic failure.

Heart failure remains the leading cause of mortality in transfusional iron overload. Unfortunately, symptoms do not appear until the myocardium has large amounts of deposited iron, and routine testing by conventional echocardiography and Holter monitoring early in the course almost always yields normal results. With

progressive deposition, patients manifest symptoms. Early signs may include a variety of arrhythmias, including supraventricular or ventricular tachycardias, premature of extra systoles, heart block, and atrial fibrillation. Contractile dysfunction affects diastole early,<sup>38</sup> likely the reason that conventional echocardiography, which mainly assesses systolic function, indicates “normal” ejection fractions. The onset of cardiac failure is late, and often sudden, and it is an ominous sign. Both complications are often refractory to treatment. Therefore, the prevention of myocardial iron loading should be one of the main thrusts of therapy.

In patients who begin receiving transfusions in early childhood, the developing endocrine organs are particularly susceptible to iron deposition if effective chelation is not initiated at the appropriate time. The anterior pituitary is most often involved, resulting in slow growth, delayed sexual maturation, and often infertility, the latter being the result of direct iron deposition in the gonads as well. Supplemental growth hormone or sex hormone therapy is often required to treat these complications. The pancreatic islet cells are also susceptible to the toxic effects of iron. Impaired insulin secretion and abnormal glucose tolerance usually precede the development of insulin-regulated diabetes and may occur in highly loaded individuals at any age.<sup>39,40</sup> Older males may experience dysfunction in sexual performance, and females may develop secondary amenorrhea related to gonadal iron deposition and disturbances in sex hormone secretion. Thyroid dysfunction, although uncommon, may also manifest at any age.<sup>36</sup>

Other manifestations include arthropathy and skin pigmentation, which are directly related to iron deposition in these tissues. Patients with marked hemosiderosis appear bronzed initially, and with progression may appear darker, or grayish. Complicating the manifestations of iron toxicity are the clinical signs and symptoms of chelator side effects, which are described further in this chapter.

### Measurement of iron burden

The goal of therapy for individuals with transfusional iron overload is to maintain iron balance at low levels of tissue iron, thereby preventing the development of overload and complications. When there is little or no ineffective erythropoiesis, simply keeping track of the volume of packed red cells transfused would provide a measure of the body iron burden in transfused patients who are not being chelated. However, different degrees of IE and the concomitant use of chelation change the balance of iron coming in and out of the body, and thus a regular monitoring of iron levels is required to assess the efficacy of the chelation regimen. In addition, different tissues load iron at different rates, and the balance between loading via transfusion and removal by chelation is also a determinant in the differential deposition of iron. Thus, monitoring iron deposition in any one organ is not representative of the others. The ideal means of monitoring iron overload would be to periodically assess tissue iron levels in each of the different organs affected using a technique that is safe, accurate, noninvasive, and valid over a wide range of concentrations. Magnetic resonance (MR)-based methods meet almost all of these criteria, and have become accepted as the standard for these tissue iron measurements, although access to centers offering them is still limited.

The reference method for assessing the liver iron concentration (LIC) (normal <1.6 mg/g dry weight) has been the quantitative chemical estimation of nonheme iron in liver tissue obtained by biopsy. To obtain accurate results by this method, several requirements must be met: the patient should not have cirrhosis or focal

lesions, the biopsy must weigh at least 1 mg dw (or 4 mg wet weight), and it should be processed using strictly iron-free methods. There may also be sampling variability since the iron deposition may be heterogeneous in some cases. Serial biopsies would ideally allow monitoring of not only the rate of iron loading and the efficacy of chelation therapy in the liver, but also the detection of the development of, and the rate of progression of, fibrosis or scarring. Since liver biopsy is an invasive procedure with considerable risks, biopsy is only recommended now for the monitoring of progression of fibrosis or hepatitis.

Instead, magnetic resonance imaging (MRI) techniques have been developed to noninvasively measure the liver iron concentration. Hemosiderin and ferritin iron affect the relaxation of hydrogen atoms present in the nuclei of tissue water molecules. Initial limitations in the technology have been overcome, and more sensitive instruments capable of measuring more rapid signal decay (very short relaxation times) are now used to quantify hepatic and cardiac iron concentration. Two widely used MRI techniques are (1) a gradient echo T2-based sequence, which measures the signal intensity ratio of liver to skeletal muscle,<sup>41</sup> and (2) a stimulated spin-echo R2-based sequence scan ([www.resonancehealth.com/rh\\_ferriscan](http://www.resonancehealth.com/rh_ferriscan); Ferriscan).<sup>42</sup> Correlation between these magnetic measurements and tissue iron content as assessed by biopsy has improved over time, and this method now provides a safe, accurate, and noninvasive means of assessing LIC.<sup>41–43</sup> The relationship between estimates of liver iron concentration by MR methods and the serum ferritin has been variable.

The liver iron concentration (LIC) has been used as an indicator of the body's total iron burden. In patients with TM, who had been cured by stem cell transplantation, phlebotomy was used as a means of removing excess iron that had accumulated from years of red cell transfusions. A serial decline in the liver iron concentration correlated well ( $R = 0.98$ ;  $P < 0.001$ ) with the amount of iron removed by phlebotomy, supporting the idea that the liver iron concentration is a reflection of the total body iron load.<sup>25</sup> It has also been demonstrated that whereas patients with thalassemia who had liver iron concentrations of 6–13 mg Fe/g dw had an almost twofold risk of progression of fibrosis; in those with liver iron concentrations of 13–41 mg Fe/g dw, the hazard rate was almost 9.<sup>44</sup> Furthermore, coexisting infection with the hepatitis C virus (HCV) independently increased the risk for progression of fibrosis threefold. These observations confirmed the results of previous studies that had reported that LIC  $>7$  mg Fe/g dw is associated with an increased risk of hepatic fibrosis, diabetes, and other complications of iron overload. Based on these data, it has been suggested that maintaining LIC in the “ideal range” of 3–7 mg Fe/g dw in regularly transfused and chelated patients should minimize iron deposition in nonstorage parenchymal sites and prevent significant toxicity.<sup>45</sup> In addition, individuals who are heterozygous for hereditary hemochromatosis may be asymptomatic with LIC in that range. However, more recently it has been suggested that maintaining LIC closer to the upper limit of normal is more ideal in TM patients, but there are only limited data to support this.<sup>46</sup> Since the correlation between hepatic and cardiac iron concentrations is not linear,<sup>24</sup> independent assessment of myocardial iron should be performed.

Although the liver iron concentration can be measured directly by biopsy or noninvasive means, direct tissue quantification of myocardial iron is not feasible. A surrogate for cardiac iron burden, myocardial T2' (decay of transverse magnetization as a result of spin–spin relaxation and magnetic field inhomogeneity) (normal  $> 20$  milliseconds), also measured by MRI, has been shown to

correlate with function<sup>47–50</sup> and is currently used in several centers. Iron concentrations in the myocardium are much lower than those in the liver, and the iron is distributed heterogeneously in different areas of the heart. A multiecho spin-echo T2' technique is the most widely used method of assessing myocardial iron. All individuals with clinical cardiac disease had T2' measures of  $<20$  milliseconds, and all subjects with T2' values above 20 milliseconds had normal cardiac function.<sup>47</sup> An algorithm has been developed to assess risk for iron-induced cardiac disease, and abnormalities in both contractile and electrical function, based on T2' values.<sup>50</sup>

More recently, methods for assessing iron deposition in other tissues such as the pancreas and anterior pituitary have been described with some correlation with endocrine function in these two organs.<sup>51,52</sup> However, these techniques are not universally available, and current ideal monitoring includes periodic assessment of hepatic and myocardial iron deposition only. Such serial measurements would be an accurate and reliable means of monitoring the progression of iron loading and the efficacy of chelation therapy.

Magnetic biosusceptometry has been validated to be a safe, accurate, and noninvasive method of quantitatively measuring the liver iron concentration over a wide range of body iron burdens. The principle is that storage iron (both hemosiderin and ferritin) is paramagnetic: That is, when a steady magnetic field is applied, these molecules will induce a field change that is proportional to the number of iron atoms present. An extremely sensitive sensor, or SQUID (superconducting quantum interference device), measures this response. A strong linear correlation ( $R = 0.99$ ) between liver iron concentration determined by biopsy, and by SQUID susceptometry, has validated this technique,<sup>53</sup> but the use of this method has been limited because of the complexity and high cost of building, installing, and maintaining the instrument. Currently, only four centers around the world are using this technique. Other limitations include use in individuals who are obese, are very small, or have metal implants or devices that may not be removed prior to the study. In addition, susceptometric methods cannot be used to quantify iron in other organs that may be loaded with iron, such as the heart, pancreas, and other endocrine organs. A new high transition temperature device, cooled using liquid nitrogen and with better resolution of the signal from surrounding tissues, is under development,<sup>54</sup> but the complexity of the device and its maintenance have led to increased reliability on magnetic resonance methods.

Traditionally, the serum ferritin level has been used as an indirect estimate of the body iron burden. Although several studies have shown a significant correlation between the serum ferritin level and the liver iron concentration estimated by biopsy in patients with thalassemia,<sup>55,56</sup> the coefficient of correlation in most studies was poor, with marked scatter around the correlation line. A recent study in patients with SCD also showed poor correlation between serum ferritin levels and the liver iron concentration measured in biopsy tissue in patients with SCD.<sup>57</sup> There are several reasons for this variability in the serum ferritin level, which do not necessarily reflect a change in the body iron burden. Ferritin is well known to be an acute phase reactant, and serum levels may be increased by infection, inflammation, hepatic dysfunction, tissue injury, or hemolysis, and decreased when there is chronic hypoxia or a deficiency of ascorbic acid. Thus, it is at best an indirect marker of iron overload; and, although it is practical and easy to measure, it is not reliable as an indicator of the total body iron burden or as a parameter for the monitoring of chelator efficacy, and does not in any way inform of the differential iron loading that may exist between the liver and the heart.

Without the wide availability of noninvasive measures of hepatic and cardiac iron, there is still reliance on the serum ferritin level as a means of monitoring the iron burden and the efficacy of chelation. However, it may actually be misleading in individual patients, remaining stable in the face of rising body iron burden and ongoing deposition in the heart and endocrine organs. Similarly, measurements of serum iron, transferrin or transferrin saturation, and urinary iron excretion do not provide a reliable indication of the level of body iron stores. Plasma nontransferrin-bound iron (NTBI) has been suggested to be a marker of the “toxic iron pool,” but its measurement is very complex and is currently still used largely for research purposes only.<sup>58,59</sup> These limitations in serum measurements of iron-related moieties underscore the need for assessment of iron in specific tissues. While not optimal, it may be used to follow trends, and when there is a consistent trend, an MRI could be performed to assist with decisions related to the transfusion regimen.

As discussed in this chapter, there is variability in iron deposition between the heart and the liver, as a result of the changing balance between transfusional iron loading and chelation.<sup>23,24</sup> Thus, optimal monitoring of iron burden should include assessment of both the hepatic iron concentration by biopsy, magnetic resonance, or susceptometry as well as myocardial iron using the surrogate T2\* estimate. These noninvasive monitoring methods are not yet widely available, but special effort should be devoted to securing such testing for patients in order to chelate them effectively and prevent the development of complications.

## Management

The primary goal of chelation therapy is to prevent tissue deposition of excess iron, thereby preventing organ damage and resulting morbidity and mortality. Maintaining safe levels of tissue iron requires achieving a balance between the amount of iron entering the body and that being removed by chelation. Unlike in patients with hereditary hemochromatosis, phlebotomy to remove excess iron is not an option for those with transfusion dependence, although it may become an option after the patient has successfully undergone stem cell transplantation or once therapy has been completed in case of patients treated with intensive chemotherapy regimens. If transfusion therapy is ongoing, iron-overloaded patients must be treated with a chelating agent capable of sequestering iron and permitting its excretion from the body. As discussed previously, a minimum chelator-induced excretion of 0.25–0.40 mg Fe/kg/day

is necessary to maintain iron balance in regularly transfused individuals. In less regularly transfused individuals, such as those on intensive chemotherapy regimens or those with thalassemia intermedia or sickle cell syndromes, a lower daily iron excretion rate may be tolerated. Monitoring the rate of iron loading by keeping a record of units transfused, as well as periodic assessments of tissue iron levels, is extremely helpful in tailoring chelation therapy. The ideal chelator should form a high-affinity 1:1 uncharged complex with iron; be able to chelate intracellular iron; be orally effective, with a long half-life, high chelator efficiency, and low toxicity profile; and be effective in removing iron from, and preventing deposition in, all organs that may be affected by long-term usage. Such a chelator is not yet available. Chelators in current use are described in brief in the “Chelation therapy” section; more detailed reviews of chelation are available elsewhere.<sup>60</sup>

## Chelation therapy

### Chelating agents

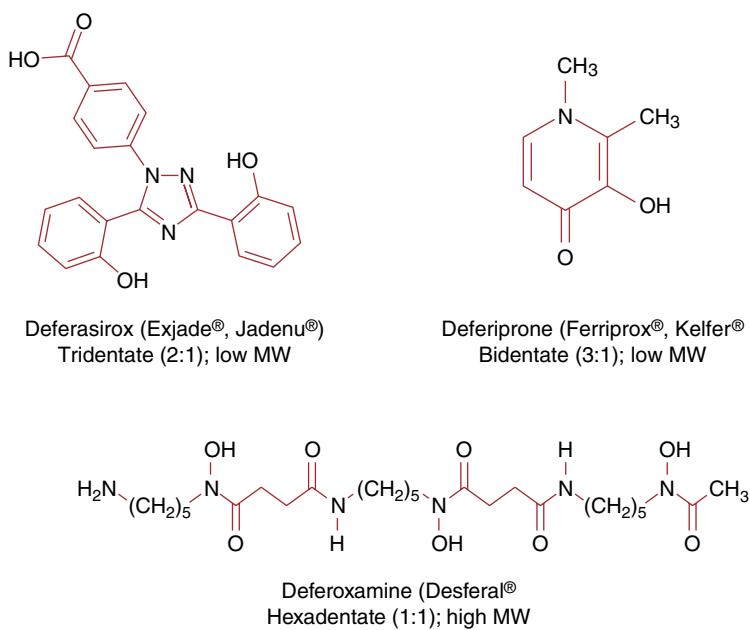

Three iron chelators are in clinical use currently. One of these, deferoxamine, has been the mainstay for approximately four decades; and the other two, deferiprone and deferasirox, have been approved for clinical use in the past 10 years. Table 51.1 shows a comparative evaluation of these agents.

### Deferoxamine B mesylate (DFO, Desferal<sup>®</sup>)

Deferoxamine B mesylate (DFO, Desferal; Figure 51.2), a naturally occurring trihydroxamic acid produced by *Streptomyces pilosus*, was first introduced almost 40 years ago and has been found to be a generally safe and effective means of managing iron overload, ameliorating or preventing iron-induced organ damage, and reducing morbidity and mortality. In fact, patients with TM who were effectively chelated survived significantly longer than those whose chelation was ineffective.<sup>61</sup> Deferoxamine is a hexadentate chelator that forms a charged 1:1 complex with iron that does not readily enter or leave cells and is excreted almost equally by the liver in bile and by the kidneys. Unfortunately, deferoxamine is not absorbed intact when taken orally and has a very short half-life (approximately 15 minutes); it must be administered by subcutaneous infusion using a portable syringe pump over 8–12 hours daily for maximal chelation efficiency.<sup>62</sup> It has been shown that levels of NTBI (the form of iron that more easily enters parenchymal cells) rise in the plasma within 16 hours of the end of the infusion,<sup>62</sup> and maintaining chelator levels in the body is critical to prevent toxic effects of this iron. Patients who receive the drug in this

**Table 51.1** Chelators in Current Clinical Use

	Desferrioxamine	Deferasirox	Deferiprone
Structure, iron binding (chelator:iron)	Hexadentate (1:1)	Tridentate (2:1)	Bidentate (3:1)
Half-life			
Route of administration, frequency	20–30 minutes Parenteral IV or SQ, usually SQ over 8–12 hours, 5–7 nights per week	10–16 hours oral, once daily	1.5–2.5 hours oral, in three divided doses
Iron excretion	Urinary and fecal	Mostly fecal	Mostly urinary
Dose range	30–60 mg/kg	10–40 mg/kg	75–100 mg/kg
Usual chelation application	First or second choice as single agent, or in combination	Usual first choice now, and in combination	Usually second choice, and in combination
Reported efficacy	Efficient hepatic and cardiac iron removal	More efficient clearance of hepatic iron, also effective in cardiac iron removal	More efficient in removing cardiac iron, less so for hepatic iron clearance
Adverse events	Local and allergic reactions, optic neuritis, sensorineural hearing loss	Gastrointestinal upset, rash, hepatic and renal toxicity, proteinuria	Neutropenia/agranulocytosis, gastrointestinal upset, arthralgia/arthropathy, hepatotoxicity
Dose adjustment required if	Impaired renal function	Hepatic or renal toxicity	Hepatotoxicity or neutropenia

**Figure 51.2** Chemical structure of different chelator molecules.

manner often have pain, swelling, and redness at the site of infusion, and may develop injection abscesses. Rare toxicities occur when deferoxamine is present in excess of chelatable iron, including effects on hearing (usually high-frequency hearing loss) and vision (leading to blindness in severe instances).<sup>62,63</sup> For all of these reasons, compliance with this regimen is not very good, and morbidity from organ deposition and dysfunction is often the result. The dosage range for deferoxamine is between 30 and 50 mg/kg administered over 8–12 hours by subcutaneous infusion 5–7 times a week.<sup>63</sup> In severely loaded individuals, such as those with iron-induced cardiac disease,<sup>29</sup> it may be administered by continuous intravenous infusion, although dosing above 50 mg/kg/day does not increase iron excretion further<sup>62</sup> and may result in toxicity. Although cardiac function may improve relatively quickly (2–3 months), such continuous therapy may have to be continued for many months or even years before there is a substantial decline in the liver iron concentration or improvement in the myocardial T2\*.<sup>30</sup> Though a review by the Cochrane Collaboration concluded that deferoxamine is still the recommended first-line agent for chelation in patients with thalassemia,<sup>64</sup> given the cumbersome nature of its administration, this agent is now mostly used in combination with one of the oral agents.

#### **Deferiprone (1,2-dimethyl-3-hydroxypyridin-4-one, DFP, L1)**

Deferiprone (Figure 51.2) is a bidentate chelator that forms an uncharged 3:1 complex with iron, enabling it to easily cross membranes and remove toxic iron from cells. It is effective orally, but has a short half-life (<2 hours) and must be taken 3–4 times a day. Most of the chelated iron is excreted in the urine. It is less effective than deferoxamine in reducing the liver iron concentration, but it has been suggested to have greater effectiveness in removing myocardial iron.<sup>65</sup> A retrospective study comparing TM patients who had been treated with deferiprone long term showed that there were significantly fewer cardiac events as compared with patients who had been treated with deferoxamine alone.<sup>34</sup> Serious idiosyncratic complications have been reported with its use, including neutropenia (up to 5%) and agranulocytosis (up to 0.5%), the development

of an erosive arthropathy (from 5 to >20%), and the development of a neurologic syndrome of cerebellar and psychomotor retardation.<sup>66</sup> In spite of adherence to the suggested weekly monitoring of blood counts, one death from agranulocytosis has been reported.<sup>67</sup> Although a Canadian study described progression of hepatic fibrosis in several patients who were on this drug long term,<sup>68</sup> a subsequent study did not confirm this finding.<sup>69</sup> Deferiprone is prescribed at 75–100 mg/kg/day divided into three doses, with careful monitoring of blood counts every week. The ability of this drug to move across the cell membrane led to the idea of using it in combination with deferoxamine, with deferiprone acting as a siphon to bind iron and transport it extracellularly. Although one study showed that patients treated with combination deferoxamine and deferiprone showed significantly greater improvements in T2\* than those on deferoxamine alone,<sup>70</sup> the significance of this finding is limited by the small number of subjects and the short duration of evaluation. Although approved for use as an iron chelator, a recent independent review by the Cochrane Collaboration<sup>71</sup> concluded that deferiprone is a second-line agent for iron chelation in thalassemia. The disadvantage of this agent in that it had to be given three times a day resulting in some reduced compliance has now been ameliorated to some extent, with a twice daily preparation now being available.

#### **Deferasirox (ICL 670Q, Exjade®, DFX)**

Deferasirox (Figure 51.2) is a tridentate N-substituted bis-hydroxyphenyltriazole chelator that forms a 2:1 complex with iron that is primarily excreted in bile. With a plasma half-life of 12–16 hours, once-daily administration means the drug is present in the circulation throughout the day, enabling constant effective scavenging of iron. There are three preparations available, a dispersible tablet (Exjade®), a film coated tablet (Jadenu®), and sprinkles for children (also Jadenu®). At the suggested starting dose of 20 mg/kg (Exjade®) or 14 mg/kg (Jadenu®), most patients are not able to achieve negative iron balance, although this dose appears adequate to maintain iron balance in well-chelated individuals.<sup>72</sup> At higher doses, it is able to cause negative iron balance (reduction in liver iron concentration) but may result in a higher incidence of hepatic

and/or renal toxicity. Other side effects include gastrointestinal upset, rash, and, rarely, neutropenia.<sup>72</sup> Patients who are on this agent should have careful monitoring of hepatic and renal function, and appropriate dose adjustments should be made. Studies have shown that deferasirox is able to consistently remove myocardial iron as well as deferoxamine, and higher doses of 30–40 mg/kg/day (Exjade<sup>®</sup>) or 21–28 mg/kg/day (Jadenu<sup>®</sup>) may be an effective way of reducing the cardiac iron burden and improving function.<sup>73</sup> Because it is the most conveniently administered iron chelator, with once-daily dosing, it has become the first choice of many hematologists for initiating chelation. However, a recent Cochrane Collaboration review<sup>74</sup> concluded that there was not enough evidence to support this in thalassemia, and stated “If a strong preference for deferasirox is expressed, it could be offered as first-line option to individual patients after a detailed discussion of the potential benefits and risks.” Deferasirox has been used with good efficacy in patients with SCD,<sup>75</sup> but there are as yet no long-term studies of this agent in patients with MDS and transfusional iron overload. In clinical practice, given the once a day administration, wide therapeutic index, and good safety profile, this has become the first-line therapy for most patients with transfusional iron overload.

Newer agents in the desferrithiocin family<sup>76,77</sup> have shown promise in the animal model. These are tridentate chelators that initially showed significant nephrotoxicity in the rodent and primate models, but, with structural modifications, these have not been an issue. Phase I/II human trials have been initiated, with little human data available to date.

### Initiation of chelation

Without data to support a lower range, the optimal range recommended for maintaining the liver iron concentration is 3–7 mg Fe/g dw,<sup>78</sup> as discussed previously. When this range is reached after regular transfusion, chelation therapy should be initiated. There are no immediate clinically apparent consequences of not instituting chelation when the patient reaches this range, or even higher levels of iron overload, because such complications usually result at higher levels and after more prolonged loading. The goal of therapy is to prevent these complications, and chelation should be instituted well before they occur. Based on calculations in the “Transfusional iron burden” section, the range for initiation of chelation is usually reached after approximately 15 transfusions (or a total of ~180 mL/kg of packed RBCs). If records of transfused volumes are not available, the liver iron concentration, as measured by biopsy or noninvasive methods such as MRI or SQUID, should be used in making the decision. Usually in children in whom iron is required for growth, aggressive chelation could potentially reduce the amount of available iron, and a conservative liver iron concentration of 4–5 mg/g dw is usually used as the threshold for initiating chelation (Table 51.2). In the past, a serum ferritin level of 1000 ng/mL was used as the threshold for initiation of chelation, and some models have been proposed more recently<sup>79</sup> to suggest that 800 ng/mL should be the threshold in nontransfusion-dependent thalassemia patients. However, the correlation between the liver iron concentration and serum ferritin was not strong. An MRI assessment of LIC is strongly recommended if possible so as to provide a baseline to which subsequent measures could be compared to evaluate efficacy of the chelation regimen. Cardiac and endocrine organ iron deposition occurs late, and initial measurements are not indicated. Although an oral chelating agent would be much preferred by patients compared to a parenterally administered one, as discussed previously, there is still not enough experience or data with regard

**Table 51.2** Guidelines for Chelation Therapy

Current Guidelines For Chelation	
Initiation of chelation	LIC 3–7 mg Fe/g dry weight, or total transfusion volume ~180 mL/kg packed red cells, or ~15 transfusions
When to begin	Deferoxamine (Desferal <sup>®</sup> ) 35–40 mg/kg by subcutaneous infusion over 8–12 hours 5–7 times/week Deferasirox (Exjade <sup>®</sup> ) 20–30 mg/kg/day on empty stomach, daily
Choice of chelator	<b>Intensification (in conjunction with expert consultation and advice)</b>
Indication	1. LIC >15 mg Fe/g dry weight, with T2* >20 milliseconds, no clinical cardiac disease 2. LIC 3–15 mg Fe/g dry weight, with T2* 10–20 milliseconds, no clinical cardiac disease 3. LIC >15 mg Fe/g dry weight, with T2* 10–20 milliseconds 4. LIC 3–15 mg Fe/g dry weight, with T2* <10 milliseconds Deferoxamine 50 mg/kg/day For 1 and 2: by subcutaneous infusion over 8–12 hours daily For 3 and 4: by continuous infusion via central venous catheter Deferasirox For 1 and 2: 30–40 mg/kg/day For 3 and 4: 40 mg/kg/day Combination therapy (see Table 51.3) Multiple combinations are in use; usually deferasirox or deferiprone added to a lower dose/less frequent base deferoxamine regimen
Regimen	

LIC: liver iron concentration.

to the long-term use of deferasirox or deferiprone as a first-line agent, and these agents are only recommended if deferoxamine is contraindicated. However, given the complexity of parenteral administration of deferoxamine and the ease of administration and proven efficacy of deferasirox, an increasing number of hematologists are initiating chelation with the latter. Deferiprone remains the choice for patients who have tried one of the others and have had to discontinue because of toxicity.

There is much controversy as to when patients with MDS should begin chelation, or if they even need chelation.<sup>3,80,81</sup> Several centers have reported their experience,<sup>82–84</sup> but good data to inform the development of a guideline are lacking. Some studies are underway to gather such information, and there are likely to be some clearer directions in the future. With preexisting bone marrow disease, deferoxamine or deferasirox may be the safer options, but some centers have used deferiprone<sup>85</sup> with success.

### Compliance

Compliance with chelation therapy is the primary determinant of morbidity and survival in such patients, and the responsibility of the medical team caring for such patients in reinforcing this cannot be emphasized enough. If compliance with chelation is poor, iron loading exceeds removal and iron accumulates first in the liver and then in the other parenchymal tissues, including the heart. A meta-analysis of 18 studies of patients with thalassemia confirmed that noncompliance results in significant cardiac and endocrine morbidity, and increased risk of death from heart disease.<sup>86</sup> When transfusion and chelation are begun in early childhood, it is usually the responsibility of the parent to ensure that the chelation regimen is followed. In adolescence and young adulthood, when this responsibility shifts to the patient, various distractions and life-changing

**Table 51.3** Combination Chelation Therapy

Combination	Deferasirox (DFX) and add desferrioxamine (DFO)	Desferrioxamine (DFO) and add deferiprone (DFP) OR deferiprone and add desferrioxamine	Deferasirox (DFX) and add deferiprone (DFP)
Documented efficacy	Improvement in both LIC and cardiac T2*	Improvement in cardiac T2*, cardiac function (LVEF), and decrease in LIC	Case series with improvement in both LIC and cardiac T2*
Synergy Indication	Unknown Rising LIC despite DFX at max dose, or DFX dose limited by toxicity	Yes Worsening cardiac T2* despite DFO/DFP at maximum dose or to reduce DFO infusions per week	Unknown For worsening cardiac T2* despite DFX at max dose or DFX dose limited by toxicity
Regimens described	DFX 20–30 mg/kg with DFO 30–40 mg/kg, simultaneously or sequentially	DFO 30–40 mg/kg with DFP 75–100 mg/kg, in a variety of combinations	DFX 20–40 mg/kg with DFP 75–100 mg/kg, concomitantly or alternating

events may result in poor compliance. Often, a lack of physical symptoms in spite of significant iron overload lulls such individuals into a false sense of wellness and invulnerability. This is a particularly critical time for all caregivers to monitor these patients very carefully. Similarly, older individuals who have begun regular transfusion later in life may feel that it is unnecessary to chelate because the onset of symptoms may be several years later. Education and constant reinforcement are necessary to ensure compliance and reduce morbidity and mortality. Providing patients with accurate estimates of their tissue iron levels may be a powerful motivator, especially when achievable targets for LIC and cardiac T2\* are set.

Patients on chelation should be vigilant for symptoms and signs of infection, particularly if they have undergone splenectomy. Because almost all microorganisms require iron to thrive, the mobilization of iron sequestered in stores could allow such microbes to run rampant. Therefore, chelation should be temporarily suspended if there is any suspicion of a bacterial or fungal illness, until this is appropriately managed.

### Intensification of chelation

Noncompliance resulting in a positive iron balance and a rise in the liver iron concentration, or shortening of the T2\*, would necessitate changes in the chelation regimen to prevent progression of organ damage. The compliance record should be closely examined, and consultation with an expert in the management of iron overload should be obtained, before intensification of chelation is undertaken. Dosage of deferoxamine may be increased to a maximum of 50 mg/kg/day, beyond which there seems to be no additional increment in urinary iron excretion.<sup>62</sup> Higher doses have also been associated with the development of a pulmonary syndrome.<sup>87</sup> Increasing the frequency of subcutaneous administration to seven days per week is a more effective strategy (Table 51.2). For patients with symptomatic heart disease, continuous intravenous chelation with deferoxamine at 50 mg/kg/day has been shown to be effective in reversing heart failure, improving cardiac function, and reducing the liver iron concentration more effectively<sup>18</sup> (Table 51.2). Generally, an indwelling catheter is required because deferoxamine may cause sclerosis of peripheral veins. Close monitoring for toxicity and efficacy is necessary. Because noncompliance is the primary cause of severe loading, this regimen may not be acceptable to the patient. Studies using 40 mg/kg of deferasirox have shown some efficacy. Various combinations of chelators have been used with reported efficacy in the thalassemias,<sup>29,49,70,88,89</sup> but there are little data in other conditions. However, these reports have not consistently shown efficacy or benefit of a single combination. Some recommendations are made in Tables 51.2 and 51.3. Longer prospective studies with larger numbers of patients are required before a spe-

cific combination therapy can be recommended. Intravenous deferoxamine as described above should be considered the base of the regimen for any patient with a severe iron burden, corresponding to a liver iron concentration above 15 mg Fe/g dw even in the absence of clinical cardiac deposition, and for those with myocardial T2\* values below 10 milliseconds.

### Monitoring while on chelation

Once chelation is begun, regular noninvasive assessment of iron deposition in the heart (MRI T2\*) and liver (MRI R2 or SQUID) every 12–18 months is recommended (Table 51.4) to ensure the efficacy of chelation and give warning of rising levels, which may be associated with significant iron toxicity. When chelation is being initiated, an MR-determined LIC is helpful to establish a baseline, which would help evaluate the success of ongoing chelation. A cardiac T2\* is usually not necessary for a few years after chelation has been initiated if compliance is good and the LIC remains in the desired range. If, however, the LIC rises due to ineffective chelation and intensification of the regimen is being considered, a cardiac T2\* should be obtained. Given the discordance between LIC and cardiac iron loading while on transfusion and chelation,<sup>24</sup> cardiac T2\* should be obtained regularly for monitoring. As previously discussed, higher LIC values predispose to progression of fibrosis,<sup>44</sup> and keeping the LIC in the ideal range of 3–7 mg Fe/g dw is important to prevent this from occurring. A liver biopsy may be indicated if there is coexisting hepatitis, or liver dysfunction suggestive of fibrosis or progression to cirrhosis. Adjustments in the chelation regimen should preferably be based on changes in the LIC or the cardiac T2\*. More frequent measurements may be indicated after such changes have been made to ensure optimal efficacy of the regimen.

In addition to monitoring iron burden and adherence to chelation therapy, organ function must also be monitored for the development of abnormalities related to the transfusion and chelation regimen (Table 51.4). The ideal method for assessing cardiac function is magnetic resonance assessment of chamber dimensions, ventricular filling, and ejection fractions. This would provide indicators of systolic as well as diastolic function. Conventional echocardiography does not provide adequate assessment of diastolic function, and it is suboptimal because cardiac dysfunction in iron-induced cardiac disease is mainly diastolic and systolic function is preserved until late in the course of the iron-induced restrictive cardiomyopathy. Normal results often lead to a false sense of well-being and noncompliance with chelation. Serial measurements may provide useful information on trends and may signal the need for closer evaluation by MRI.<sup>90</sup> Despite preserved global function, tissue Doppler echocardiography-detected regional wall motion

**Table 51.4** Recommended Comprehensive Evaluation of Regularly Transfused and Chelated Individuals

System	Test	Frequency
Monitoring of iron load	LIC by biopsy, MRI, or SQUID Cardiac T2*	Every 12–18 months; more frequently if high iron burden and on intensive chelation; cardiac T2* may be less frequent if stable values and no upward trend in LIC
Cardiovascular	MRI for assessment of function (echocardiography with tissue Doppler if MRI not possible)	MRI as above, echocardiography annually when MRI is not done, especially if some residual cardiac dysfunction
Hepatobiliary	Holter monitoring	Annually
	Bilirubin levels and AST/ALT monitoring HBV, HCV serology	Every transfusion visit if on deferasirox or if active HBV or HCV infection; less frequent if on deferoxamine Annually
Hematologic	CBC with differential	Weekly if on deferiprone
Renal	BUN and serum creatinine	Every transfusion visit if on deferoxamine or deferasirox
Endocrine	Thyroid and parathyroid function	Annually
	Bone Density	Annually
	Glucose tolerance	Annually
	hGH, testicular and ovarian function	Based on age and clinical indications
Other	HIV serology	Annually
	Vision and hearing	Annually if on deferoxamine
	Pulmonary function	Every two years

LIC: liver iron concentration; SQUID: magnetic susceptometry.

abnormalities may represent an early sign of cardiac disease.<sup>91</sup> These special echocardiographic techniques may be of limited use, but annual magnetic-resonance-based cardiac function assessment, performed at the same time as T2\* measurement, is the ideal method of monitoring. Holter monitoring for the development of arrhythmias is also recommended annually. Regular assessment of hepatic and renal function should also be part of comprehensive care. In addition to screening for transfusion-associated viral infections, frequent assessment is also indicated to monitor for chelator toxicity. Comprehensive annual endocrine evaluations, including thyroid and parathyroid function, bone density assessment, glucose tolerance, and gonadal function testing, are recommended, especially for growing children and adolescents. Vision and hearing should be evaluated annually in patients on deferoxamine. Testing of pulmonary function is also recommended, although not as frequently. Monitoring for chelator toxicity should also be followed, as shown in Table 51.4. Guidelines for monitoring of iron overload and its management in patients with thalassemia have been developed and may be referenced at <https://www.thalassemia.org/thalassemia-management-checklists-now-available-download>.

### Novel Approaches to reduce transfusion burden in transfusion-dependent individuals

Novel agents targeting various pathways in erythropoiesis and iron regulation have been developed in recent years, with the goal of ameliorating IE and reducing the toxicity of iron in transfusion-dependent patients. Several approaches have been used:

#### 1 Erythroid maturation agents

Luspatercept (ACE-536) is a recombinant fusion protein comprising a modified extracellular domain of the human activin receptor type IIB fused to the Fc domain of human IgG1. The molecule acts as a trap binding select transforming growth factor (TGF) β superfamily ligands, resulting in a block of SMAD2/3 signaling, thus enhancing erythroid maturation. Randomized double blinded placebo controlled phase 3 clinical trials were conducted in transfusion-dependent thalassemia patients (BELIEVE trial),<sup>93</sup> and transfusion-dependent patients with very low, low, or intermediate risk MDS (MEDALIST trial).<sup>94</sup> Both trials had positive outcomes with a statistically significant reduction in transfusion requirement. In a proportion of TDT patients,

there was a reduction of 33% in transfusion requirement and a proportion of MDS patients were able to remain transfusion free for periods of eight weeks or longer. Based on these data, the drug has been approved for use in these specific populations.

#### 2 Pyruvate kinase (PK) activators

Inducers of PK may increase red cell ATP levels and increase survival. In addition, increased PK in the red cell precursors in the bone marrow may enable them to manage the oxidative stress better, improving the IE that is seen in thalassemia and PK deficiency. Phase 2 studies in PK deficiency have shown increased hemoglobin levels in nontransfusion-dependent patients<sup>95</sup> and a reduction in transfusion requirements (presented in abstract form only) in regularly transfused patients. Clinical trials are planned in TDT and NTDT patients as well with the goal of reducing transfusion needs in TDT patients and increasing hemoglobin levels in the latter group.

#### 3 Inducers of fetal hemoglobin (HbF)

IMR-687, a potent, specific, and highly selective small molecule, inhibits phosphodiesterase (PDE) 9, thereby increasing cyclic guanosine monophosphate (cGMP), leading to increased fetal hemoglobin production in preclinical models of sickle cell disease.<sup>96</sup> Clinical trials are underway in TDT patients with the goal of reducing transfusion requirements. Benserazide is a peripheral decarboxylase inhibitor shown to increase HbF levels in animal models.<sup>97</sup> An early phase trial is investigating safety and efficacy in NTDT patients.

#### 4 Agents affecting the hepcidin pathway

In animal models, hepcidin mimetics have been shown to improve the efficacy of erythropoiesis and increase levels of hemoglobin. Clinical trials of two such agents were undertaken.<sup>98</sup> The trial of LPJ401 in TDT (NCT03381833) assessed the efficacy of the agent in reducing cardiac iron and was terminated early for futility. A trial of PTG-300 (NCT03802201) to reduce transfusion burden in TDT is ongoing, but little data have been shared publicly. Antisense oligonucleotides (ASO) and small interfering RNA (siRNA) targeting TMPRSS6 have been shown to increase hepcidin, reduce iron, and thus improve ineffective erythropoiesis and RBC survival in mouse models of β-thalassemia.<sup>99,100</sup> Both approaches are now progressing to clinical trials in thalassemia.

## Summary

Iron overload is a significant cause of transfusion-related morbidity and mortality. With improved survival of patients with inherited or childhood transfusion-dependent anemias, older individuals with marrow failure, and cancer patients who have undergone intensive chemotherapeutic treatments or stem cell transplantation, the prevalence of this entity is likely to continue to grow. There is evidence to suggest that the reduction of iron burden in individuals with MDS and patients undergoing stem cell transplantation may be beneficial and result in better outcomes. More research is underway in those fields. Newer technologies are now available for the noninvasive assessment of the body iron burden, making it easier to quantify the amount of excess storage iron in different tissues and to monitor the efficacy of chelation regimens. New oral drugs have made it easier for patients to be compliant with the chelation therapy that must be instituted in order to prevent tissue iron deposition and ameliorate the toxicity that would result from such deposition. As more information becomes available on the long-term use of deferasirox and deferiprone, combination therapy with deferoxamine may change the way chelation is prescribed. Research continues on the development of

newer oral chelators. In addition, various strategies to reduce transfusion burden have been employed, some with success already, and others in clinical trials. These developments hold promise for a new era of effective diagnosis, monitoring, and treatment of transfusional iron overload.

## CHAPTER 52

# Hematopoietic growth factors

David J. Kuter

Hematology Division, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA

## Introduction

Over the past several decades, the major hematopoietic growth factors have been identified, purified, and therapeutic products made. These hematopoietic growth factors affect the growth and differentiation of stem cells and later progenitor cells of all lineages. Several of these molecules play important roles in patient care and are widely used. After a brief review of general principles of hematopoietic growth factor function, this chapter focuses on the clinically relevant hematopoietic growth factors that affect erythroid, myeloid, and megakaryocyte differentiation, specifically erythropoietin (epoetin alfa, epoetin beta, darbepoetin alfa, and methoxy polyethylene glycol-epoetin beta), G-CSF (filgrastim, tbo-filgrastim, pegfilgrastim, and their biosimilars), GM-CSF (sargramostim), and thrombopoietin (romiplostim, eltrombopag, avatrombopag, lusutrombopag, and hetrombopag). The general biology and clinical use of each in adults are described as well as their role in transfusion medicine. With the large proliferation of biosimilar versions of initial products, focus is devoted to the studies with the initial molecules with the reader being asked to recall that the regulatory approval for each biosimilar brings with it the indications of the initial product. It is beyond the scope of this review to address each individual study for each molecule currently approved. Furthermore, discussion is limited to products available in North America.

## General principles of hematopoietic growth factors

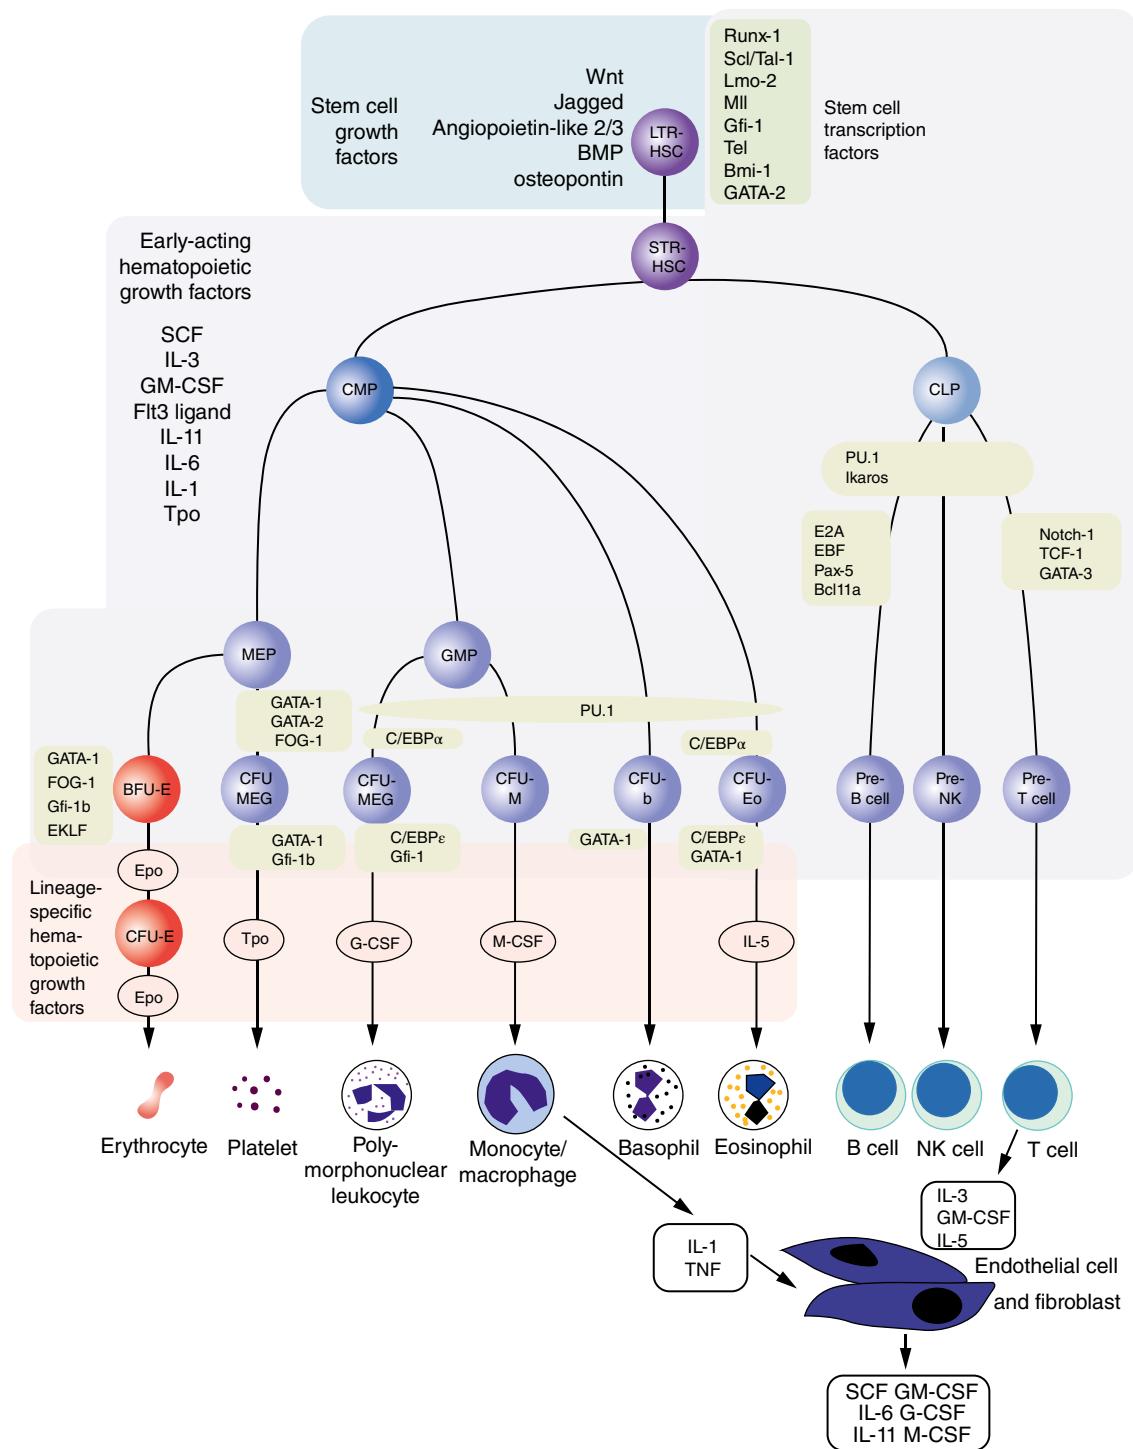

Pluripotential stem cells give rise to all of the final differentiated blood cells (Figure 52.1). The molecular differentiation steps for some of these precursor cells have been described and in general involve a random (“stochastic”) process in which lineage-specific differentiation occurs at multiple stages. For example, a micro-RNA (miR-150) binds to and downregulates c-Myb which causes the common erythroid–megakaryocyte precursor to undergo megakaryocytic, not erythroid, differentiation.<sup>1</sup> But the subsequent survival of cells at each differentiation stage is determined by the presence of specific hematopoietic growth factors; if the stage- or lineage-specific hematopoietic growth factor is absent, the cells undergo programmed cell death. For example, erythroid burst-forming cells

(BFU-E) will continue their divisions as long as erythropoietin is present; if absent, BFU-E cells undergo programmed cell death.

In this complicated hierarchy of cell division, differentiation, and apoptosis, the hematopoietic growth factors can be generally grouped into those that are early acting, whose circulating levels are not altered and affect multiple lineages (interleukin [IL] 3, IL-6, IL-11, GM-CSF, and stem cell factor), versus those that are late acting, whose levels are modulated and affect single lineages (erythropoietin, G-CSF, and M-CSF). Thrombopoietin (TPO) is somewhat of an exception in that it is necessary for the viability of multiple lineages but specifically amplifies megakaryocyte progenitors. All of these hematopoietic growth factors are active at very low concentrations and work via specific cell surface receptors thereby promoting the viability of the target cells.

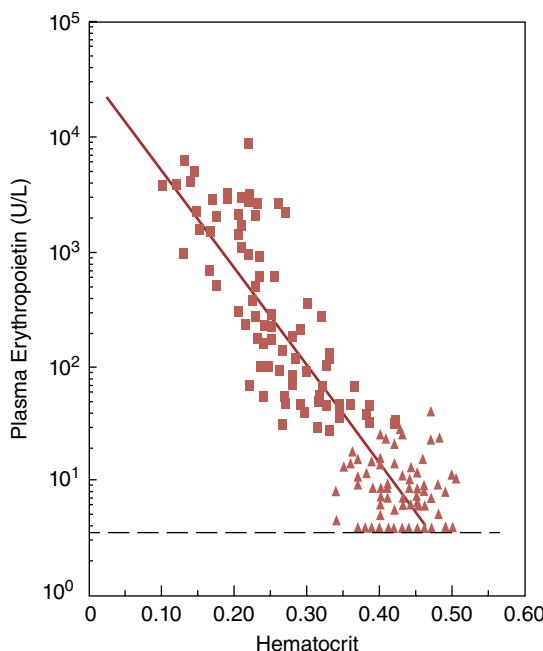

For the clinically relevant hematopoietic growth factors, G-CSF, erythropoietin, M-CSF, and thrombopoietin, a number of general physiological principles should be noted:

- The circulating level of each factor in normal physiology is inversely proportional to the mass of the differentiated cell it regulates, e.g., as the hemoglobin, absolute neutrophil count (ANC), monocyte count, and platelet count fall, the respective levels of erythropoietin, G-CSF, M-CSF, and TPO rise.<sup>2–4</sup>
- The normal physiologic response is usually “log-linear,” i.e., erythropoietin levels increase exponentially as the hemoglobin declines on a linear scale (Figure 52.2).<sup>2,5</sup>
- Circulating levels of each factor are determined by the relative rates of its production and metabolism. For erythropoietin, there is a precise mechanism that regulates its production with a rather fixed rate of renal clearance. For thrombopoietin and M-CSF, levels are primarily regulated through clearance by the platelet<sup>6</sup> or macrophage,<sup>7</sup> respectively. These cells have very high affinity receptors for their regulatory factor, and bind, internalize and degrade it.<sup>8</sup> There is little effect on the rate of production. Finally, G-CSF is regulated by both production and clearance. Mature neutrophils bind and clear G-CSF,<sup>9</sup> but many cells can increase G-CSF production when stimulated.<sup>10</sup> In normal basal physiology, G-CSF production is relatively constant.
- This normal physiologic response may be altered in pathologic states.

**Figure 52.1** Scheme of normal hematopoiesis. The many different stages of differentiation of the myeloid, erythroid, and megakaryocyte lines are illustrated along with their relevant early and late acting hematopoietic growth factors. BFU: blast-forming unit; CFU: colony-forming unit; CLP: common lymphoid progenitor; CMP: common myeloid progenitor; EPO: erythropoietin; G-CSF: granulocyte colony-stimulating factor; GM-CSF: granulocyte-macrophage colony-stimulating factor; GMP: granulocyte-myeloid progenitor; IL: interleukin; LTR-HSC: long-term repopulating hematopoietic stem cell; M-CSF: monocyte/macrophage colony-stimulating factor; MEP: megakaryocyte-erythroid progenitor; SCF: stem cell factor; STR-HSC: short-term repopulating hematopoietic stem cell; TNF: tumor necrosis factor; TPO: thrombopoietin. From Sieff and Zon.<sup>183</sup> Reproduced with permission of Elsevier Inc.

- In anemia of chronic disease, renal erythropoietin production is decreased.<sup>2</sup>
- In acute infection, there is a marked increase in G-CSF production.
- In liver failure, thrombopoietin production is markedly decreased.<sup>11</sup>
- The clinical effect of pharmacologic administration of a hematopoietic growth factor also operates on an exponential dose-response curve. In a healthy subject, linear increases in any blood cell require an exponentially greater dose of the specific hematopoietic growth factor.<sup>12,13</sup>

**Figure 52.2** Log-linear relation between erythropoietin (EPO) level and hematocrit. EPO levels were determined for normal blood donors (triangles) and patients with anemia (squares; those with renal disease, rheumatoid arthritis, or solid tumors were excluded). Dashed line denotes limits of detection for this assay. Note that EPO does not begin to rise until hematocrit falls below ~36, suggesting that other factors (i.e., androgens) account for the higher values. Reprinted from Erslev<sup>2</sup> with permission of Elsevier Inc.

### Erythroid growth factors

Ever since the initial studies by Paul Carnot in 1906, it has been known that blood contained a “hémopoïétine” that had the ability to stimulate red cell production.<sup>14,15</sup> Decades after identifying a factor in the urine that stimulated red cell production,<sup>16</sup> erythropoietin (EPO) was finally purified and a recombinant form FDA approved in 1989.<sup>17,18</sup> EPO was the first hematopoietic growth factor available for clinical use and paved the way for the development of many other hematopoietic growth factors.

### Structure, function, and physiology

Erythropoietin is made as a 193 amino acid precursor, of which 27 amino acids are cleaved off to produce a 166 amino acid form that loses a terminal arg166 to give the final 165 amino acid (MW = 30,400 Da) heavily glycosylated (30% carbohydrate) protein. It is made by a single gene (7q22.1) and produced by interstitial peritubular fibroblasts in the kidney with maybe a small amount being made by the liver. Using an efficient renal sensor of hypoxia (hypoxia inducible factor [HIF]), circulating EPO levels are primarily determined by its rate of transcription. HIF is a dimeric protein made of  $\alpha$  and  $\beta$  subunits that binds to a promoter region of the EPO gene and increases its rate of transcription. However, the HIF $\alpha$  subunit undergoes proline hydroxylation in the presence of oxygen and is degraded by the proteasome. So, with normoxia, HIF $\alpha$  is rapidly degraded and transcription of the EPO gene reduced; with hypoxia, HIF $\alpha$  survives and increases transcription. EPO has no storage form and once made is immediately secreted into the circulation and cleared by the kidney.

EPO binds to and activates preformed, inactive, dimeric EPO receptors (Figure 52.3) that are present on pronormoblasts,

basophilic normoblasts, polychromatophilic, and orthochromatophilic normoblasts, but not on reticulocytes or mature red cells. When EPO is present, these precursor cells do not undergo apoptosis but survive and produce mature red cells.

The usual log-linear relationship between the EPO level and the hematocrit (Figure 52.2) seen in disorders such as iron deficiency is blunted in conditions historically referred to as “anemia of chronic disease” (e.g., diabetes, cancer, renal failure, and inflammation).

### Clinically available erythroid growth factors

#### Epoetin alfa (Epogen, Procrit); biosimilar epoetin alfa-epbx (Retacrit)

This 165 amino acid (MW = 30,400 Da) glycosylated protein (Figure 52.3) is made in CHO cells and is available in vials and pre-filled syringes in a wide variety of doses. Epoetin alfa is FDA approved for:

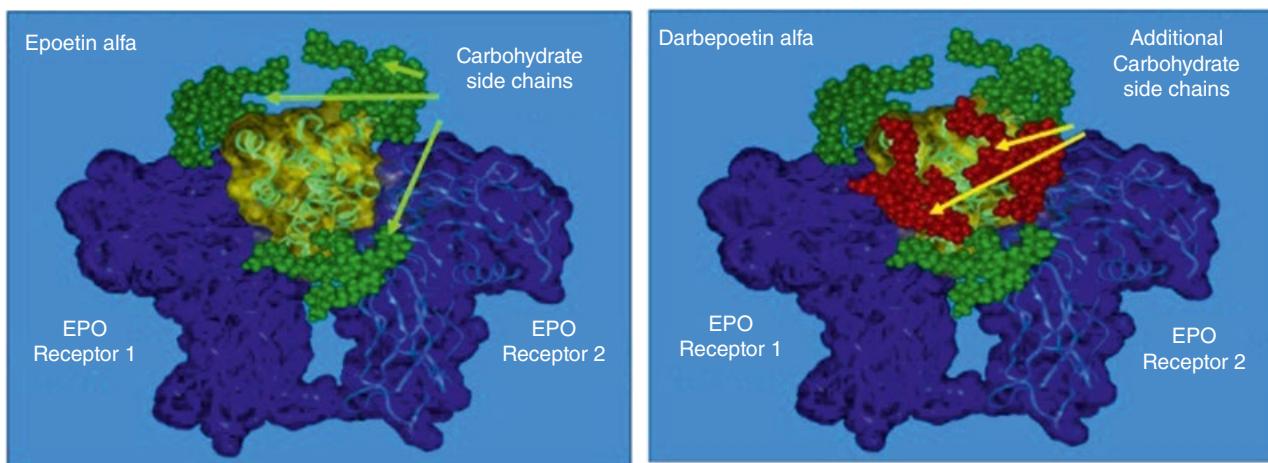

- The treatment of anemia due to chronic kidney disease (CKD) in patients on dialysis and not on dialysis.
- The treatment of anemia due to the effects of concomitant myelosuppressive chemotherapy, and upon initiation, there is a minimum of two additional months of planned chemotherapy.
- The treatment of anemia due to zidovudine in patients with HIV infection.
- Reduction of allogeneic RBC transfusions in patients undergoing elective, noncardiac, and nonvascular surgery.

The starting dose of epoetin alfa is usually 50–100 U/kg tiw for renal failure patients, 100 U/kg tiw for HIV patients, 40,000 units weekly or 150 U/kg tiw for chemotherapy patients (40,000 units per week has become a standard for oncology patients),<sup>19</sup> and either 300 U/kg daily for 15 days or 600 U/kg weekly for preoperative surgery patients with anemia. The intravenous route is recommended for patients on hemodialysis. Subsequent doses are adjusted every three to four weeks based upon response. Despite the recommendation above for patients on hemodialysis, this drug is more effective when given subcutaneously than IV.<sup>20</sup> Drug levels after subcutaneous administration rise at 2 hours, peak at 18 hours, with a T1/2 of 8 hours. All patients should be evaluated for iron status before and during treatment to maintain adequate iron repletion.

#### Darbepoetin alfa (Aranesp)

Darbepoetin alfa was designed from understanding how epoetin alfa is cleared from the circulation. Epoetin alfa has many isoforms due to variations in the number of sialic acids present (Figure 52.3).<sup>21,22</sup> Isoforms with the maximum 14 sialic acids have a prolonged half-life whereas those with 8 sialic acids have almost no biologic effect. This led to the hypothesis that if the number of sialic acids on epoetin alfa was increased, its T1/2 would be even longer. By creating two additional N-linked glycosylation sites on epoetin alfa, darbepoetin alfa was created and contains a maximum of 22 sialic acids versus the 14 sialic acids on epoetin alfa (Figure 52.3). Adding these sialic acids minimally reduced binding to the EPO receptor, but markedly increased the T1/2 from 8.5 to 25.3 hours, thereby increasing the biologic effect. Darbepoetin alfa (MW = 39,000 Da) is made in CHO cells and is 51% carbohydrate. It comes in vials and pre-filled syringes with various doses. It is FDA approved for:

- The treatment of anemia due to chronic kidney disease (CKD) in patients on dialysis and patients not on dialysis.
- The treatment of anemia due to the effects of concomitant myelosuppressive chemotherapy, and upon initiation there is a minimum of two additional months of planned chemotherapy.

**Figure 52.3** Binding of epoetin alfa and darbepoetin alfa to the erythropoietin (EPO) receptor. Epoetin alfa has three N-linked carbohydrate chains with a maximum of 14 sialic acids. It has a MW of 30,400 Da and is 40% carbohydrate. Darbepoetin alfa has five N-linked carbohydrate chains with a maximum of 22 sialic acids. It has a MW of 39,000 Da and is 51% carbohydrate. Both bind to and activate the preformed dimeric EPO receptor. Figure courtesy of Prof. David Kuter.

The starting dose for patients with CKD on dialysis is 0.45 mcg/kg intravenously or subcutaneously weekly, or 0.75 mcg/kg intravenously or subcutaneously every two weeks; for patients with CKD not on dialysis 0.45 mcg/kg intravenously or subcutaneously every four weeks; and for oncology patients 2.25 mcg/kg subcutaneous weekly or 500 mcg subcutaneously every three weeks. Doses are subsequently adjusted every four weeks according to response. The intravenous route is preferred for patients on hemodialysis.

#### Methoxy polyethylene glycol-epoetin beta (Micera)

Endogenous erythropoietin as discussed above is highly glycosylated and exists in several forms with identical amino acid sequence but different glycosylation patterns.<sup>23</sup> Epoetin alfa and epoetin beta have exactly the same amino acid sequence, but the latter has a higher molecular weight and lower number of sialic acid residues. Epoetin beta is commonly used outside the United States. Methoxy polyethylene glycol-epoetin beta was created by coupling polyethylene glycol to the N-terminal amino acid of epoetin beta thereby creating a molecule with a much longer circulating half-life, comparable to that of darbepoetin alfa. This 60 kD protein has a reduced affinity for the erythropoietin receptor, but given its long half-life of 130 hours (darbepoetin has a half-life of 20–70 hours and epoetin alfa has a half-life of about 8 hours) it has a prolonged biological effect.<sup>24,25</sup> In multiple studies compared with epoetin alfa, epoetin beta or darbepoetin alfa, methoxy polyethylene glycol-epoetin beta demonstrated response rates of up to 97.5% when given intravenously or subcutaneously every two weeks with the comparator response rates up to 96.3%.<sup>25,26</sup> In patients being switched from other erythropoiesis-stimulating agents (ESA), stable hemoglobin levels were maintained with administration every 2–4 weeks. The drug was well tolerated with side effects comparable to those of other ESAs. Note that pure red cell aplasia has been reported with this drug but is rare.

Methoxy polyethylene glycol-epoetin beta is supplied as a solution of 30–360 mcg in prefilled syringes for intravenous or subcutaneous administration. It is not a treatment for anemia due to cancer chemotherapy. It is only FDA approved for:

- The treatment of anemia associated with chronic kidney disease (CKD) in adult patients on dialysis

The initial dose of 0.6 mcg/kg body weight is administered every two weeks by subcutaneous or intravenous injection. Subsequent doses are based upon the hematocrit response. It is important to maintain adequate iron stores.

#### Effects and adverse effects of erythropoietin administration

After the administration of epoetin alfa, epoetin beta, methoxy polyethylene glycol-epoetin beta, or darbepoetin alfa to healthy individuals, the reticulocyte count starts to rise on Day 3 and peaks on Day 10 while the hematocrit starts to rise on Day 8 and peaks at Days 20–25.<sup>27</sup> Importantly, the iron saturation and transferrin begin to fall by Day 4 and drop 74% by Day 16.<sup>27</sup>

The major effect of treatment with any of these ESAs is to increase the basal hemoglobin and reduce the need for transfusions in the disorders for which they are indicated. In most disease states, response rates and hemoglobin rises occur in well over 90% as long as adequate iron stores are provided. Although none of the FDA approvals for oncology patients supported an improvement in quality of life, multiple studies dispute that statement.<sup>28–30</sup> The quality of life benefits of erythropoietin administration for CKD patients have been amply documented in many studies.<sup>31</sup>

The major side effects of erythropoietin administration are listed in Table 52.1. Of these, thrombosis and potential adverse outcomes of cancer patients deserve further detail.

**Table 52.1** Adverse Effects of Erythroid Growth Factors

Hypertension—renal failure patients
Seizures—renal failure patients
Allergic reactions—rare
Antibody formation leading to pure red cell aplasia—European formulation; very rare USA
Thrombosis—twofold increase in all patients
Increased cardiovascular complications and death at Hgb >11—renal failure patients
Decreased survival if target Hgb >12—cancer patients (breast, head-neck, cervical, and lymphoma) on chemotherapy; not indicated for cancer chemotherapy patients when anticipated outcome is cure
Decreased survival—cancer patients not receiving chemotherapy

## Thrombosis

There is an approximate twofold increased rate of thromboembolism in renal failure and cancer patients receiving these agents. A meta-analysis of 91 trials with 20,102 cancer patients showed that the risk ratio (RR) of thromboembolic complications was increased in patients receiving these drugs compared to controls (RR 1.52; 95% CI, 1.34–1.74; 57 trials, N = 15,498).<sup>32</sup> In a meta-analysis of 27 trials (10,452 patients), chronic kidney disease patients at a higher hemoglobin target (median 13.0 g/dL, IQR, 12.0–14.0 g/dL) had higher risks for stroke (RR 1.51; 95% CI, 1.03–2.21), hypertension (RR 1.67; 95% CI, 1.31–2.12), and vascular access thrombosis (RR 1.33; 95% CI, 1.16–1.53) compared with those at a lower hemoglobin target (median 10.1 g/dL, IQR, 9.2–11.0 g/dL). However, there were no statistically significant differences in the risks for mortality (RR 1.09; 95% CI, 0.99–1.20), serious cardiovascular events (RR 1.15; 95% CI, 0.98–1.33), or end-stage kidney disease (RR 1.08; 95% CI, 0.97–1.20).<sup>33</sup>

## Tumor progression/cancer mortality

The second major concern with the erythroid growth factors is that they may increase tumor progression and mortality in some cancer patients. In one study, head and neck cancer patients treated with erythropoietin to a target hemoglobin of 14–15 had worse progression-free survival (RR 1.62; 95% CI, 1.22–2.14; p = 0.0008), loco-regional control (RR 1.69; 95% CI, 1.16–2.47; p = 0.007), and overall survival (RR 1.39; 95% CI, 1.05–1.84; p = 0.02) than placebo.<sup>34</sup> However, this study and others reporting similar worsened outcomes<sup>35</sup> were not sufficiently structured or powered to assess cancer progression or survival. In the absence of adequate prospective clinical trials, a massive meta-analysis has been conducted of 21,102 cancer patients in 91 trials treated with epoetin alfa or darbepoetin alfa.<sup>32</sup> These erythroid growth factors significantly reduced the relative risk of red cell transfusions (RR 0.65; 95% CI, 0.62–0.68; 70 trials, N = 16,093). On average, patients in the erythropoietin arms received one unit less blood than the control group with a suggestion of increased quality of life. However, erythroid growth factors increased mortality during active study (HR 1.17; 95% CI, 1.06–1.29; 70 trials, N = 15,935) and might have decreased overall survival (HR 1.05; 95% CI, 1.00–1.11; 78 trials, N = 19,003). There was no evidence that ESAs affected tumor response (RR 1.02; 95% CI, 0.98–1.06; 15 trials, N = 5012).

## Clinical use of erythroid growth factors

The erythroid growth factors have been used in a wide range of medical conditions ranging from renal failure to hemochromatosis (Table 52.2).

### Chronic renal failure

In patients with chronic renal failure, the use of erythroid growth factors has been shown to increase hematocrit, decrease transfusion needs, and increase quality of life. For most such patients, the hemoglobin target is no higher than 11.5 g/dL.<sup>36</sup> This is based upon clinical studies that showed that patients experienced greater risk for death and serious cardiovascular events with a target hemoglobin of >13 g/dL; those with a target of 11.5–13 g/dL had no better or worse outcomes, but possibly improved quality of life compared to those with a lower hemoglobin level.<sup>33,36</sup>

### Cancer patients

The use of erythroid growth factors has been shown to decrease the need for red cell transfusions in most populations studied;<sup>19</sup> the exceptions being anemic cancer patients who are not receiving chemotherapy<sup>37</sup> and those with EPO levels >500 IU.<sup>38</sup> Given the concerns over

**Table 52.2** Clinical Uses of Erythroid Growth Factors

Chronic renal failure in patients on dialysis or not on dialysis
HIV infection being treated with zidovudine
Cancer chemotherapy
Preoperative anemia (hemoglobin 10–13) for elective, noncardiac, and nonvascular surgery
(Myelodysplastic syndromes, primary myelofibrosis, postpolycythemia myelofibrosis, and postessential thrombocythemia myelofibrosis)
(Anemia in rheumatoid arthritis)
(Anemia of chronic disease)
(Anemia in congestive heart failure)
(Anemia in epidermolysis bullosa)
(Anemia due to porphyria cutanea tarda)
( $\beta$ thalassemia)
(Treatment of anemia in patients whose religious beliefs forbid transfusion)
(Anemia due to hepatitis C treatment)
(Mobilization of iron in hemochromatosis)
(Improved harvesting of autologous blood)
(Mobilize peripheral blood progenitor cells)
(Neuroprotection—studies in progress)

Uses in parentheses denote lack of FDA approval but for which compendial data exist. See prescribing information for each individual erythroid growth factor.

tumor progression and survival, current guidelines<sup>39–41</sup> encourage a thorough discussion of the risks and benefits of these agents before their use in all patients receiving myelosuppressive chemotherapy. Furthermore, these agents are not to be used in cancer patients not receiving myelosuppressive chemotherapy or in those for whom cancer treatment is not expected to be curative, and when the hemoglobin is <10 g/dL with only the lowest dose being used to avoid transfusions; treatment is discontinued when chemotherapy ends. It should be remembered that improvement in quality of life reaches a plateau once the hemoglobin rises above 11 g/dL (range, 11–13 g/dL).<sup>28,29,42,43</sup>

### HIV infection

Clinical benefit has been demonstrated in anemic (Hct <30) HIV-infected patients with endogenous EPO levels ≤500 IU/mL undergoing treatment with zidovudine at doses ≤4200 mg/week. In a pooled analysis of four trials,<sup>44</sup> 297 AIDS patients treated with zidovudine received either epoetin alfa or placebo for 12 weeks. No benefit was seen in those with EPO levels >500 IU, but in those with lower levels epoetin alfa therapy decreased the mean number of units of blood transfused per patient compared with placebo (3.2 units vs. 5.3 units, respectively; p = 0.003) and increased the mean hematocrit from the baseline level (4.6 vs. 0.5 percentage points, respectively; p <0.001). Overall quality of life improved in patients on epoetin alfa but was not statistically significant (p = 0.13).

### Preoperative anemia

In patients who are not candidates for autologous blood transfusion, epoetin alfa has been shown to increase the hemoglobin and decrease the need for subsequent allogeneic transfusions when given to patients with hemoglobin between 10 and 13 prior to therapy. In two studies of 461 patients undergoing major orthopedic surgery, 358 received epoetin alfa (100–300 IU/kg sq daily for 15 days [10 days preoperative] or 600 IU/kg weekly for four weeks). The use of ESAs significantly reduced (p < 0.001) the need for allogeneic transfusions.<sup>45</sup>

### An important issue associated with the use of erythroid growth factors

The response to erythroid growth factors depends on the availability of adequate reserves of bone marrow and iron. Since the ferritin

falls dramatically after administration of EPO,<sup>27,46,47</sup> iron supplementation has been shown to be critical in amplifying the hemoglobin response to erythroid growth factors in chronic kidney disease patients<sup>48</sup> and in cancer chemotherapy patients.<sup>49</sup> In most studies, intravenous iron was superior to oral iron repletion.

### Implications for transfusion medicine

The impact of the erythroid growth factors on blood resource utilization has received little attention. With the recognition of adverse events especially thrombosis and possibly cancer progression, their use in oncology has dropped dramatically<sup>50</sup> with a prediction that RBC transfusions would increase 1% nationally.<sup>51</sup> However, the decreased use in cancer seems to have resulted in the acceptance of a lower hemoglobin target in this patient population.<sup>52</sup> Similar regulatory changes have also reduced the use of these agents in chronic kidney disease and have been accompanied by slightly increased rates of transfusion.<sup>53</sup> These changes have minimally impacted the use of red cell transfusions, although exact numbers are difficult to obtain.<sup>54</sup>

The erythroid growth factors remain the only option for many patients who cannot receive RBC transfusions for religious or medical reasons. Administration of 140 IU/kg epoetin alfa three times a week for three weeks along with oral iron three times a day to 45 Jehovah's Witness patients increased the hemoglobin and allowed all patients to undergo major cardiac procedures without blood transfusion.<sup>55</sup>

Finally, the use of erythroid growth factors has been demonstrated to increase the preoperative collection of RBCs, a practice that is falling out of favor currently. In a randomized study of 47 patients scheduled for orthopedic surgery, patients received 600 IU/kg or placebo twice a week for 21 days (along with oral iron) during which time up to six units of RBC were scheduled to be collected. Epoetin alfa treated patients collected a mean ( $\pm$ SD) of  $5.4 \pm 0.2$  units compared with  $4.1 \pm 0.2$  for the placebo group.<sup>56</sup>

Overall, it is hard to find any major impact of the use of erythroid growth factors on demand for red blood cell transfusions. Rather recent clinical studies have eschewed the prior acceptance of the need for higher hemoglobin in many clinical situations

### Novel erythropoiesis-stimulating agents

Increased understanding of erythropoiesis has led to the development of a number of novel stimulators of red cell production. These include agents that affect the HIF pathway and molecules that shorten the time to produce a red cell.

### Modulators of the HIF pathway

As described previously, HIF affects erythropoietin production. The HIF $\alpha$  subunit is inactivated by prolyl hydroxylase in normoxia, and this prevents transcription of the erythropoietin gene. Inhibitors of prolyl hydroxylase have been generated to maintain full HIF activity and thereby allow continued erythropoietin production unregulated by the "oxygen sensor." One of these, vadadustat, an oral prolyl hydroxylase inhibitor, has undergone extensive evaluation in anemic CKD patients on dialysis and prior to dialysis.<sup>57</sup> In two phase III, noninferiority studies in CKD patients not on dialysis (one in patients with no prior exposure to ESA and the second in patients with ongoing ESA treatment) and a hemoglobin less than 10 g/dL, vadadustat was compared with darbepoetin. While there was no difference in hemoglobin response between the two drugs, vadadustat did not meet the prespecified noninferiority margin for cardiovascular safety.<sup>58</sup> However, in CKD patients

who are on hemodialysis, two phase III, noninferiority studies of vadadustat were conducted (one in patients with minimal prior ESA exposure and one in patients previously on ESA), and there was no difference in the incidence of cardiovascular events and no difference in the hemoglobin responses.<sup>59</sup>

### Activin receptor ligand traps

Although no ESA acts sufficiently rapidly to replace RBC transfusions in acute settings, a newly described family of novel recombinant proteins comprising the modified extracellular domain of the human activin type II receptor linked to the Fc region of human IgG1 might accelerate erythropoiesis. It appears that late stage erythropoiesis is normally highly damped down by a number of members of the transforming growth factor beta (TGF- $\beta$ ) family, particularly growth differential factor (GDF)11, which are produced by nonerythroid cells.<sup>60</sup> These new activin receptor molecules act as "ligand traps" for these TGF- $\beta$  superfamily (including activin) negative regulators of late-stage erythropoiesis, and thereby accelerate late-stage erythropoiesis and rapidly increase the hemoglobin. One of these, sotatercept (ACE-011), is a recombinant human fusion protein containing the extracellular domain of the human activin receptor IIa that binds to and inhibits activin, growth differentiation factor (GDF11), and other members of the TGF- $\beta$  superfamily.<sup>61</sup> Administration of sotatercept to healthy volunteers led to a rapid and sustained increase in hematocrit in phase I clinical trials; at the highest dose tested, a mean (range) increase of 1.21 g/dL (0.4–2.0) after eight days and an increase of 1.75 g/dL (0.9–3.1) after 15 days were observed.<sup>62,63</sup>

Luspatercept (ACE-536) is the second novel activin receptor ligand trap and contains a modified extracellular domain of the human activin type IIb receptor and binds with high affinity to select TGF- $\beta$  family ligands such as GDF11 and GDF8. It is distinct from sotatercept in that it binds minimally to activin A and does not increase bone density. In healthy volunteers, a dose-dependent increase in hemoglobin was observed after one week with over 80% eventually achieving a 1.0 g/dL increase.<sup>64</sup> Luspatercept-aamt (Reblozyl) is currently FDA approved for the treatment of anemia:

- In adult patients with beta thalassemia who require regular RBC transfusions.
- In adult patients with very low- to intermediate-risk myelodysplastic syndromes with ring sideroblasts (MDS-RS) or with myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T) failing an erythropoiesis-stimulating agent and requiring two or more RBC units over eight weeks.

However, given the current cost for luspatercept, some have felt it is not cost effective when compared to transfusion.<sup>65</sup>

### Myeloid growth factors

While deficiencies in RBCs and platelets can be readily treated with transfusion, neutropenia may be a severe, life-threatening disorder that is not readily amenable to transfusion. Although neutrophil transfusions may be arranged, they are neither readily available nor have they demonstrated benefit.<sup>66</sup> With the FDA approval of both G-CSF (filgrastim) and GM-CSF (sargramostim) in early 1991, treatment and prevention of neutropenia became a reality.

### Structure, function, and physiology

Granulocyte colony-stimulating factor (G-CSF) is a 174 amino acid glycosylated protein (MW = 25,000 Da) and is encoded by a single

gene (17q21.1). G-CSF is synthesized by macrophages, monocytes, endothelial cells, and fibroblasts, and its production can be vastly increased by other inflammatory molecules (TNF $\alpha$ , IL-1, IL-3, interferon  $\gamma$ , IL-4). It is made without a storage form and immediately released into the circulation where it is cleared by neutrophils via their G-CSF receptor ( $K_d = 65 \text{ pM}$ ) and less so by the kidney. In the noninfected individual, production is constant and circulating levels are inversely proportional to the absolute neutrophil count (ANC) by way of neutrophil clearance.<sup>9,67</sup> With infection, production is stimulated by inflammatory cytokines.<sup>10</sup> Normal G-CSF levels are  $<39 \text{ ng/L}$ , but rise to a different extent depending on the type of infection: bacterial,  $799 \pm 1501 \text{ ng/L}$ ; viral,  $58 \pm 34 \text{ ng/L}$ ; mycoplasma,  $60 \pm 33 \text{ ng/L}$ .

G-CSF has many biological effects (Table 52.3). For existing neutrophils, it promotes demargination and release from bone marrow reserves as well as increases neutrophil survival. Neutrophil production is markedly increased with the maturation time reduced from six days to three days, an increase in “left shift,” and often the appearance of Dohle bodies and toxic granulation. Neutrophil motility is altered. Neutrophil function (phagocytosis, O $_2^-$  generation, endomitosis, ADCC, and Fc $\gamma$ RI receptors) is increased, an underappreciated effect. Finally, G-CSF mobilizes peripheral progenitor cells. In animals lacking G-CSF,<sup>68</sup> neutrophils are 20–30% of normal, neutrophil precursors 50% of normal, and there is decreased neutrophil mobilization into the circulation.

Although G-CSF is necessary for the normal production and maturation of myeloid precursors into neutrophils, GM-CSF has no physiologic importance for hematopoiesis. In GM-CSF-deficient mice, the number of neutrophils, macrophages, and their precursors are normal but the mice develop pulmonary problems.<sup>69</sup>

GM-CSF is a 127 amino acid (23,000 Da) glycosylated protein made from a single gene (5q31.1). It is made by T cells, macrophages, monocytes, endothelial cells, and fibroblasts. Significant levels are not detected in the circulation, and amounts of this protein do not vary inversely to the absolute neutrophil count. GM-CSF does not increase in amount during infection, but its production by bone marrow stromal cells maybe decreased by interferon 1 $\beta$ . It is normally cleared by the GM-CSF receptor on neutrophils and monocytes with less than 40% being renally cleared.

The biologic effects of GM-CSF on neutrophil survival, production, and mobility are comparable to those of G-CSF but are extended to eosinophils and monocytes (Table 52.3). In addition to increasing neutrophil function like G-CSF, it also increases the destruction of *T. cruzi*, *mycobacterium avium*, *influenza A*, and *candida*. Unlike G-CSF, GM-CSF can increase the production of TNF $\alpha$  and IL-1, which may explain some of its clinical side effects.

### Clinically relevant myeloid growth factors

#### Filgrastim (Neupogen)

Filgrastim is a 175 amino acid protein (MW = 18,800 Da) identical to the native molecule except for an added N-terminal methionine (r-met huG-CSF) and a lack of glycosylation since it is made in *E. coli*. Vials and prefilled syringes of filgrastim are available in doses of 300 and 480 mcg. For most uses, the dose is 5 mcg/kg/day (~230 mcg/m $^2$ /day). Remembering the log-linear dose-response curve for hematopoietic growth factors, one rounds down to the nearest vial or syringe size. While doses for stem cell mobilization are usually higher, much lower doses (0.4 mcg/kg/day) are often adequate in neutropenic patients with HIV, idiopathic neutropenia, or drug-induced neutropenia. Filgrastim has a T $1/2$  of 3.5 hours

**Table 52.3** Biological Effects of G-CSF and GM-CSF

↑ Demargination of neutrophils
↑ Release of neutrophils, monocytes, and eosinophils from marrow reserves
↑ Neutrophil, monocyte, and eosinophil survival
↑ Production of neutrophils, monocytes, and eosinophils
↓ Motility of phagocytes, ↓ skin window migration
↑ Neutrophil function (↑ of both normal and abnormal neutrophils)
↑ phagocytosis
↑ endocytosis
↑ destruction of <i>T. cruzi</i> , <i>Mycobacterium avium</i> , <i>Influenza A</i> , <i>Candida</i>
↑ O $_2^-$ -generation
↑ Mobilization of peripheral blood progenitor cells

Italics denote effects seen only with GM-CSF.

and is metabolized mostly by mature neutrophils and less so by the kidney. Like most hematopoietic growth factors, subcutaneous administration gives a better response than intravenous administration. In chemotherapy patients, filgrastim is usually started 24 hours after the end of chemotherapy and stopped at least 24 hours before the next chemotherapy dose. In chemotherapy patients, prescribing information suggests stopping once the ANC is  $>10,000$ , but it is often stopped once the ANC is  $>2000$ .

Filgrastim is FDA approved to:

- Decrease the incidence of infection, as manifested by febrile neutropenia, in patients with nonmyeloid malignancies receiving myelosuppressive anticancer drugs associated with a significant incidence of severe neutropenia with fever.
- Reduce the time to neutrophil recovery and the duration of fever, following induction or consolidation chemotherapy treatment of patients with acute myeloid leukemia (AML).
- Reduce the duration of neutropenia and neutropenia-related clinical sequelae, e.g., febrile neutropenia, in patients with nonmyeloid malignancies undergoing myeloablative chemotherapy followed by bone marrow transplantation (BMT).
- Mobilize autologous hematopoietic progenitor cells into the peripheral blood for collection by leukapheresis.
- Reduce the incidence and duration of sequelae of severe neutropenia (e.g., fever, infections, and oropharyngeal ulcers) in symptomatic patients with congenital neutropenia, cyclic neutropenia, or idiopathic neutropenia.
- Increase survival in patients acutely exposed to myelosuppressive doses of radiation (Hematopoietic Subsyndrome of Acute Radiation Syndrome).

#### Filgrastim biosimilars (filgrastim-sndz [Zarxio] and filgrastim-aafi [Nivestym])

Since the expiration of the patent on Neupogen on December 2013, at least 25 biosimilar filgrastims have been evaluated by regulatory agencies around the world. As of writing this chapter, three have been approved by the FDA and several are under consideration. All of these molecules have the same protein structure as filgrastim and have gone through the rigorous biosimilar development process wherein their structural identity, pharmacokinetics, and pharmacodynamics are compared with filgrastim. All of these biosimilars have been tested in some but not all of the clinical settings in which the initial filgrastim is approved, but with approval all biosimilars receive the same regulatory approval for all the uses in which the original filgrastim is indicated.

It is beyond the scope of this review to describe the development of each filgrastim biosimilar but an example is provided for one. Filgrastim-sndz has exactly the same peptide structure on HPLC as filgrastim.<sup>70</sup> In healthy humans, it displays identical pharmacokinetic properties and elevates the neutrophil count to exactly same degree as filgrastim.<sup>70</sup> In breast cancer patients undergoing TAC chemotherapy, the neutrophil response over several chemotherapy cycles was identical for filgrastim-sndz compared with filgrastim.<sup>71</sup>

The biosimilar filgrastims described above are available in the same doses as filgrastim and are used in identical fashion. The current FDA labeling for their use is the same as for filgrastim except for their lack of approval for use in Acute Radiation Syndrome.

### Tbo-filgrastim (Granix)

Tbo-filgrastim is a protein identical to filgrastim, but with slightly different concentrations of excipients. Its pharmacokinetics and neutrophil response are identical to filgrastim in clinical trials in chemotherapy, stem cell mobilization, and stem cell transplantation. Although it has been regarded as a “biosimilar,”<sup>72</sup> it has gone through the full FDA approval process just like filgrastim. It is available as 300 and 480 mcg prefilled syringes and used just like filgrastim. It is FDA approved:

- In adult and pediatric patients one month and older for reduction in the duration of severe neutropenia in patients with nonmyeloid malignancies receiving myelosuppressive anticancer drugs associated with a clinically significant incidence of febrile neutropenia.

### Pegfilgrastim (Neulasta)

Pegfilgrastim is a longer acting form of filgrastim produced by adding a 20,000 Da polyethylene glycol (PEG) moiety to the amino terminus of the filgrastim protein. It has a MW of 39,000 Da and is available as a 6 mg prefilled syringe that is usually administered every two weeks. Its action is prolonged because it is cleared mostly by neutrophils, not the kidney. Its T<sub>1/2</sub> of 33 hours (varies from 15 to 80 hours depending upon the ANC) is at least 10 times longer than filgrastim. It is usually given one day after the end of the chemotherapy cycle and is not to be given in the period 14 days before to 24 hours after chemotherapy. It may be administered as a manual injection or used with an on-body injection system (Onpro®). Its major attribute is that of convenience; one 6 mg pegfilgrastim dose every two weeks is equivalent to 10–14 daily doses of filgrastim.<sup>73</sup> For the treatment of Acute Radiation Syndrome, it is given as soon as possible after myelosuppressive doses of radiation and the second dose given one week later. It is FDA approved to:

- Decrease the incidence of infection, as manifested by febrile neutropenia, in patients with nonmyeloid malignancies receiving myelosuppressive anticancer drugs associated with a clinically significant incidence of febrile neutropenia.
- Increase survival in patients acutely exposed to myelosuppressive doses of radiation (Hematopoietic Subsyndrome of Acute Radiation Syndrome).

### Pegfilgrastim biosimilars (pegfilgratim-jmdb [Fulphilia], pegfilgrastim-cbqv [Udenyca], pegfilgrastim-apgf [Nyvepria], and pegfilgrastim-bmez [Ziectenzo])

With the expiration of the patent for PEG filgrastim in the United States in October 2015, 19 biosimilar pegfilgrastims have undergone development and 4 are available in the United States. They have undergone the same biosimilar development process as described briefly above for the filgrastim biosimilars. They all have the same FDA labeling indications except the lack the indication for

the treatment of Acute Radiation Syndrome. They are available at the same dosing sizes as pegfilgrastim with the same dosing instructions. However, none has an on-body injection system to allow delayed automated drug administration.

### Sargramostim (Leukine)

Sargramostim has a structure identical to native GM-CSF except that it has a leucine at amino acid 123. This glycosylated protein is prepared in yeast and has three different molecular forms of 19,500, 16,800, and 15,500 Da. It is available as a solution in multidose vials of 500 mcg/mL and as individual vials containing 250 mcg of lyophilized drug. Doses of 250 mcg/m<sup>2</sup>/day are given intravenously or subcutaneously over different periods of time (2–24 h) for the various indications; for the treatment of Acute Radiation Syndrome, the adult subcutaneous dose is 7 mcg/kg. It is more effective when given subcutaneously than intravenously and its major use has been in the treatment of patients undergoing induction chemotherapy for acute myeloid leukemia and stem cell transplantation. It is FDA approved:

- To shorten time to neutrophil recovery and to reduce the incidence of severe and life-threatening infections and infections resulting in death following induction chemotherapy in adult patients 55 years and older with acute myeloid leukemia (AML).
- For the mobilization of hematopoietic progenitor cells into peripheral blood for collection by leukapheresis and autologous transplantation in adult patients.
- For the acceleration of myeloid reconstitution following autologous bone marrow or peripheral blood progenitor cell transplantation in adult and pediatric patients two years of age and older.
- For the acceleration of myeloid reconstitution following allogeneic bone marrow transplantation in adult and pediatric patients two years of age and older.
- For the treatment of delayed neutrophil recovery or graft failure after autologous or allogeneic bone marrow transplantation in adult and pediatric patients two years of age and older.
- To increase survival in adult and pediatric patients from birth to 17 years of age acutely exposed to myelosuppressive doses of radiation (Hematopoietic Subsyndrome of Acute Radiation Syndrome).

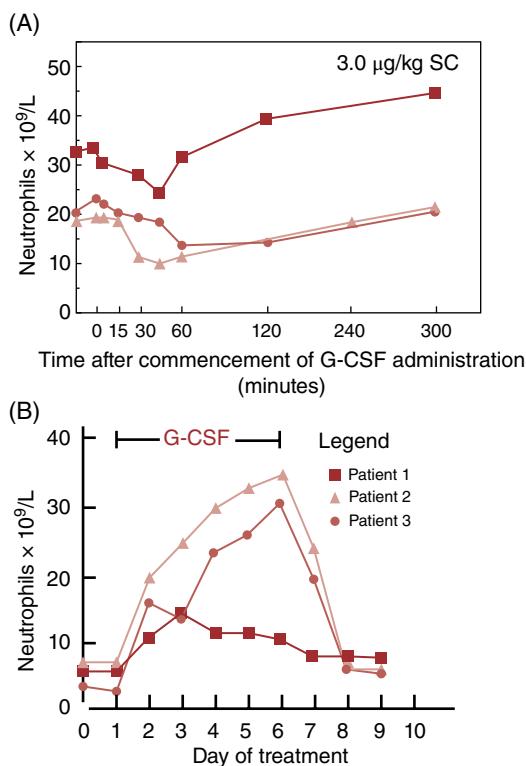

### Effects and adverse effects of G-CSF and GM-CSF administration

The neutrophil response to the filgrastims, pegfilgrastims, and sargramostim in healthy volunteers after a single injection is comparable in some ways (Figure 52.4):

- 15–30 minutes—neutrophils decrease modestly and then return to baseline, probably due to transient sequestration/margination.
- 1–36 hours—the neutrophils gradually rise due to demargination and release from bone marrow stores.
- 36 hours—increased production of neutrophils.

But in other ways, the filgrastims/pegfilgrastims and sargramostim differ greatly with much of the WBC response of the latter coming from increases in eosinophils. Most of the GM-CSF effect on neutrophils is to increase their survival<sup>74</sup> not their production (Table 52.4).

The side effects of the myeloid growth factors are listed in Table 52.5. The filgrastims/pegfilgrastims are comparable in terms of their side effects, but GM-CSF has a somewhat expanded repertoire. These commonly include myalgias, but capillary leak syndrome and a “first dose” phenomenon of hypotension, tachycardia, and dyspnea may be seen at high doses in the transplant setting. If myeloid growth

**Figure 52.4** Time course of the effect of G-CSF on neutrophil counts in human subjects. (A) G-CSF was administered subcutaneously to three subjects at a dose of 3 mcg/kg and the neutrophil count assessed over the next 300 minutes. (B) G-CSF was administered to three human subjects by continuous subcutaneous infusion at 10 mcg/kg/day for five days and the neutrophil response assessed. Figure modified and redrawn from data in Morstyn.<sup>13</sup>

**Table 52.4** Effects of G-CSF and GM-CSF on Neutrophil Kinetics

Neutrophil production	Normal	GM-CSF	G-CSF
Maximum count ( $\times 10^9/\mu\text{L}$ )	5.2	17.0	35.0
Appearance in peripheral blood (days)	4–7	4.5–6.5	1–2
Peripheral T1/2 (hours)	8	48	7.6
Amplification factor	1	1.5	9.4
Extra divisions	0	0.6	3.2

Adapted from data in Lord *et al.* (1992).<sup>74</sup>

factors are administered concurrent with chemotherapy or radiation therapy, subsequent neutropenia may be worsened.

The use of myeloid growth factors in chemotherapy patients may be associated with a small increased risk of treatment-related acute myeloid leukemia or myelodysplasia.<sup>75,76</sup>

### Clinical uses of myeloid growth factors

Table 52.6 lists the uses of myeloid growth factors. Most of these have been studied only with filgrastim and pegfilgrastim.<sup>77</sup>

### Chemotherapy-induced neutropenia

The filgrastims, tbo-filgrastim, and pegfilgrastims have all shown marked ability to stimulate neutrophil production and to mitigate chemotherapy-induced neutropenia. In small cell lung cancer patients undergoing chemotherapy,<sup>78</sup> neutropenic fever for all chemotherapy cycles was decreased from 77% with placebo to 40%

**Table 52.5** Adverse Effects of Myeloid Growth Factors

Bone pain (15–39% on filgrastim vs. 0–21% on placebo)
Exacerbation of preexisting inflammatory conditions (eczema, psoriasis, and vasculitis)
Allergic reactions at injection sites (rare)
Sweet's syndrome (acute and febrile neutrophilic dermatosis)
Antibody formation (none are neutralizing)
Splenic rupture (rare)
Adult respiratory distress syndrome (rare)
Precipitate sickle cell crisis (rare)
↑ Risk MDS and AML in patients receiving chemotherapy or with congenital neutropenia
↑ LDH, uric acid, and LAP; ↓ cholesterol
<i>Myalgias and fever</i>
<i>"First dose phenomenon"—rare; hypotension, tachycardia, and dyspnea due to transient pulmonary leukocyte sequestration (very high doses)</i>

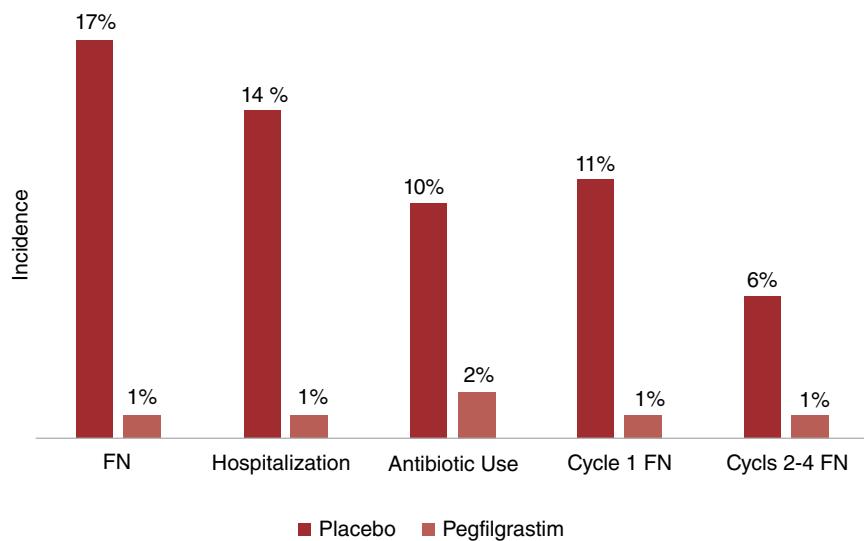

Italics denote effects seen only with GM-CSF.

**Table 52.6** Clinical Uses of Myeloid Growth Factors

Primary prophylaxis of FN if incidence >20%
Primary prophylaxis considered if FN incidence >10–20% (usually "high-risk" patients)
Primary prophylaxis if FN incidence <10% (rarely)
Secondary prophylaxis of FN to keep dose intensity
All high-risk chemotherapy patients admitted with FN
After allogeneic or autologous stem cell transplantation
Peripheral blood progenitor cell mobilization
AML induction/consolidation chemotherapy
Severe chronic neutropenia
Hematopoietic Subsyndrome of Acute Radiation Syndrome (MDS patients with neutropenia and recurrent infection)
(MDS patients with symptomatic anemia)
(Drug-induced neutropenia—low dose [0.4–5 mcg/kg])
(Aplastic anemia)
(HIV neutropenia)
(Neutropenia due to renal transplantation)
(Hairy cell leukemia)
(Acute lymphoblastic leukemia chemotherapy)
(Agranulocytosis)

FN: febrile neutropenia; MDS: myelodysplastic syndrome; AML: acute myeloid leukemia. Uses in parentheses denote lack of FDA approval but for which compendial data exist. See prescribing information for each individual myeloid growth factor.

( $p < 0.001$ ) with filgrastim; hospital days were shortened from 4.2 to 2.3 for all cycles. Antibiotic use and days with an ANC <500 were also markedly decreased. In breast cancer patients undergoing chemotherapy with docetaxel, pegfilgrastim markedly decreased the incidence of febrile neutropenia, hospitalization, and antibiotic use.<sup>79</sup> (Figure 52.5). NCCN guidelines<sup>77</sup> suggest using myeloid growth factors for primary prophylaxis of febrile neutropenia when the expected incidence of such is greater than 20%. Routine chemotherapy regimens for breast cancer, non-small cell lung cancer, ovarian cancer, and non-Hodgkin's lymphoma have respective rates of febrile neutropenia of 15%, 28%, 24%, and 20%.<sup>77</sup> Additionally, myeloid growth factors can be considered for primary prophylaxis for patients receiving chemotherapy where febrile neutropenia risk is 10–20% if patients have one or more risk factors (age  $> 65$ , prior chemotherapy or radiation therapy, recent surgery and/or open wounds, renal dysfunction [creatinine clearance  $< 50$ ], or liver dysfunction [bilirubin  $> 2.0$ ]). Prophylactic myeloid growth factors are rarely considered for chemotherapy patients where the rate of febrile neutropenia is expected to be <10%.

**Figure 52.5** The effect of pegfilgrastim or placebo in breast cancer patients receiving docetaxel every three weeks. Figure prepared from data in Vogel.<sup>79</sup>

In chemotherapy patients experiencing febrile neutropenia in a chemotherapy cycle not supported by myeloid growth factor, subsequent use of myeloid growth factor (secondary prophylaxis) is recommended to maintain dose intensity.

Unless considered high risk, myeloid growth factor treatment is not indicated for chemotherapy patients (not on myeloid growth factor therapy) at the time they develop severe neutropenia without fever or are currently hospitalized with febrile neutropenia.

### Neutropenia due to induction/consolidation therapy for acute myeloid leukemia

Myelosuppression and neutropenia with consequent infection are major complications of the induction and consolidation treatment for acute myeloid leukemia (AML). In a study of 521 AML patients undergoing induction and consolidation chemotherapy, patients were randomized to filgrastim (5 mcg/kg daily) or placebo. There was no effect upon remission rate or survival but patients receiving filgrastim during induction had a five-day earlier neutrophil recovery ( $p < 0.0001$ ), fewer days of fever (7 days vs. 8.5 days;  $p = 0.009$ ), less parenteral antibiotic use (15 days vs. 18.5 days;  $p = 0.0001$ ), and shorter hospitalization (20 days vs. 25 days;  $p = 0.0001$ ) than those receiving placebo.<sup>80</sup> Subsequent follow-up of these patients showed no long-term detriment from exposure to filgrastim.<sup>81</sup> In another study of patients with AML receiving diaziquone and mitoxantrone, those receiving 5 mcg/kg daily filgrastim had no greater response or survival than prior cohorts not so treated, but the duration of neutropenia was markedly reduced.<sup>82</sup> While there has been considerable discussion whether this form of therapy is cost effective, a recent analysis showed a reduction in total costs of around \$5000 for those receiving filgrastim after induction chemotherapy, driven primarily by a shorter median hospital stay (24 days vs. 26 days,  $p < 0.01$ ), faster median neutrophil count recovery (23 days vs. 25 days,  $p = 0.03$ ), and fewer mean days of antibiotics (18.5 days vs. 21.4 days,  $p = 0.01$ ).<sup>83</sup>

### Neutropenia with stem cell transplantation

As with other myelosuppressive therapies, neutropenia and infection are a common complication of stem cell transplantation. In a randomized study of patients with lymphoma undergoing autologous stem cell transplantation receiving either filgrastim or placebo,

filgrastim reduced the time to obtain an absolute neutrophil count (ANC) over 500 (12 days vs. 20 days,  $p = 0.0004$ ), the duration (11 days vs. 27 days,  $p = 0.0001$ ) of neutropenia (ANC < 500), and the number of febrile neutropenic days (5 days vs. 10 days,  $p = 0.036$ ).<sup>84</sup> In a phase III randomized study of filgrastim versus placebo in patients undergoing autologous bone marrow transplantation for hematological malignancy, filgrastim significantly shortened the median (range) time to neutrophil engraftment (ANC > 500) from 19.0 days (15.0–28.0) to 15.0 days (1.0–22.0) ( $p < 0.0001$ ).<sup>85</sup> There was no effect on the rate of survival or GVHD. In general, filgrastims and pegfilgrastins decrease the time to ANC recover, reduce febrile neutropenic days, reduce hospital days, and may reduce overall costs. In a retrospective analysis of autologous stem cell transplantation patients receiving pegfilgrastim or filgrastim, there was an improved reduction in time to neutrophil engraftment (9.6 days vs. 10.9 days,  $p < 0.001$ ), lower incidence of febrile neutropenia (59% vs. 78%,  $p = 0.015$ ), shorter hospital stay, fewer days on antibiotics (6.3 days vs. 9.6 days,  $p = 0.006$ ), and fewer radiographic tests, decreasing costs by about \$8000.<sup>86</sup> The biosimilar filgrastims have shown identical effects on neutrophil engraftment and febrile days but were not associated with reduced overall transplant costs.<sup>87</sup>

### Mobilization of peripheral blood progenitor cells

Four to six days after administration of a myeloid growth factor, peripheral blood progenitor cells increase as much as 100-fold. This has allowed for the marked improvement of collection of such cells in patients or donors for stem cell transplant. The basic physiologic principles governing mobilization of PBSC probably involve breakage of molecular bonds between the adhesive marrow elements, i.e., CXCR-4 on the progenitors and stromal-cell-derived factor 1 (SDF-1) on the marrow stromal cells.<sup>88</sup> Administration of G-CSF expands myeloid and progenitor mass, and there is good evidence that the proteases released from neutrophils disrupt key adhesive bonds holding the progenitors in the marrow and allow their mobilization from marrow spaces.<sup>89</sup>

### Severe chronic neutropenia

The clinical benefit of long-term myeloid growth factor administration for patients with severe congenital neutropenia (including Kostmann syndrome), severe idiopathic neutropenia, or cyclic

neutropenia has been well established.<sup>90–92</sup> In a large randomized clinical trial of patients with severe chronic neutropenia, the occurrence of fever, oropharyngeal ulcers, infections, hospitalizations, and antibiotic use were all significantly reduced with filgrastim treatment. The quality of life and activity profiles of patients also improved. The only complication of therapy was the increased risk of developing myelodysplasia and acute leukemia in patients with severe congenital neutropenia.<sup>93,94</sup> This risk appears to be disease specific with substantially lower or no risk for patients with cyclic or idiopathic neutropenia. Those with severe congenital neutropenia need to be monitored with regular white counts, clinical observation, and possibly bone marrow examination.

### Treatment of Hematopoietic Subsyndrome of Acute Radiation Syndrome

Acute exposure to high levels of radiation leads to significant myelosuppression for which there is no standard current therapy. Studies in mice and nonhuman primates have shown that filgrastim can reduce the extensive myelosuppression and improve survival.<sup>95–99</sup> Given the ethical constraints of doing such studies in humans, approval for the use of filgrastim and pegfilgrastim (but not their biosimilar variants) was granted based upon nonhuman primate studies and bioequivalence modeling studies in humans.<sup>100</sup> These studies showed that for adult and pediatric populations exposed to a wide range of radiation doses, 10 mcg/kg filgrastim initiated 1–10 days after exposure and given daily for up to three weeks provided a 50% increase in survival.

### Implications for transfusion medicine

The use of myeloid growth factors to mobilize peripheral blood progenitor cells is a standard transfusion medicine practice. They can also be used to ameliorate drug-induced neutropenia such as that occurring after the administration of IVIG. Widespread use of myeloid growth factors in oncology may reduce the need for hospitalization and antibiotics. Unfortunately, their use to provide neutrophils for transfusion has not met with much success. Indeed, a recent heroic effort was unable to show a significant effect of neutrophil transfusion on the outcomes of infected, neutropenic patients.<sup>66</sup>

### Thrombopoietic growth factors

Although James Homer Wright described how bone marrow megakaryocytes produced platelets in 1902,<sup>101</sup> it was not until 1958 that Kelemen proposed that a “thrombopoietin” regulated this process.<sup>102</sup> This last of the major hematopoietic growth factors was not purified until 1994.<sup>103</sup> Initial clinical studies with two types of recombinant thrombopoietin (recombinant human TPO [rhTPO] and pegylated human megakaryocyte growth and development factor [PEG-rhMGDF]) showed they were quite effective in raising the platelet count in healthy subjects<sup>104</sup> and increasing platelet apheresis yields.<sup>105,106</sup> They raised the platelet count nadirs and decreased platelet transfusions after nonmyeloablative chemotherapy, but had minimal effect on the recovery of platelets to 20,000 or need for platelet transfusions in patients undergoing leukemia induction chemotherapy or stem cell transplantation.<sup>104</sup> There was a modest platelet count increase when given to MDS patients. Unfortunately, these studies were terminated in most countries when antibodies developed against one of these recombinant molecules (PEG-rhMGDF) that crossreacted with native thrombopoietin and produced thrombocytopenia.<sup>107,108</sup> rhTPO has been developed and is approved in China for the treatment of ITP and chemotherapy-induced thrombocytopenia.

Subsequently, a number of thrombopoietin growth factors, now referred to as thrombopoietin receptor agonists (TPO-RA), have been developed that are nonantigenic, strongly stimulate platelet production, and some are orally active.<sup>109</sup> Romiplostim is a recombinant protein TPO-RA while eltrombopag, avatrombopag, lusutrombopag, and hetrombopag are all orally available small molecule TPO-RA.

### Thrombopoietin structure, function, and physiology

Thrombopoietin (TPO) is encoded by a single gene (3q27.1) that produces a 332 amino acid (MW = 95,000 Da) glycoprotein of which the first 153 amino acids are 23% homologous with EPO, and probably 50% similar if conservative amino acid substitutions are considered.<sup>110</sup> This region also contains four cysteine residues like those in EPO and is responsible for binding to the TPO receptor. But despite these similarities, TPO does not bind the EPO receptor and EPO does not bind the TPO receptor. The rest of the molecule is rich in carbohydrates which increase its half-life

Thrombopoietin is the key regulator of platelet production. In mice deficient in both genes for either TPO or the TPO receptor, the platelet count, bone marrow megakaryocytes, and megakaryocyte precursors are 10–15% of normal.<sup>111</sup> These animals also have reduced levels of erythroid and myeloid precursors but with no anemia or neutropenia.<sup>112</sup>

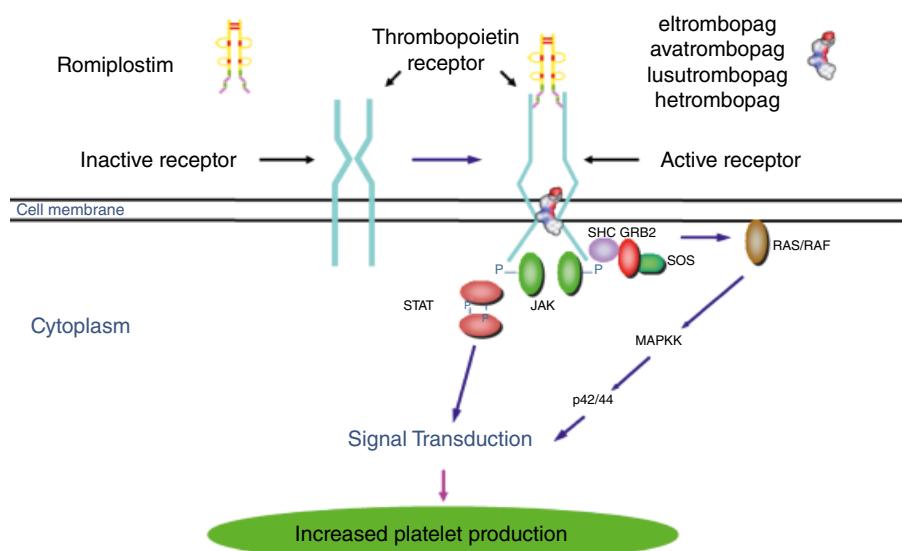

Thrombopoietin is primarily produced in the liver at a constant basal rate. Multiple studies of thrombocytopenic animals with ITP or after chemotherapy have shown no increase in the hepatic TPO mRNA levels.<sup>113</sup> Thrombopoietin levels decrease in liver disease and return to normal upon liver transplantation.<sup>11</sup> Only interleukin-6 (IL-6) seems capable of increasing basal thrombopoietin production.<sup>114</sup>

Thrombopoietin levels are inversely related to the rate of platelet production. Once in the circulation, TPO is bound to and cleared by high affinity platelet TPO receptors leaving a small basal amount of TPO.<sup>8</sup> This primitive normal feedback loop is shared with other hematopoietic growth factors such as M-CSF<sup>7</sup> and G-CSF;<sup>9</sup> there appears to be no specific sensor of the platelet count in the body. In aplastic anemia patients, TPO levels are >2000 pg/mL (normal: 7–99 pg/mL).<sup>115</sup> In animals or humans transfused to platelet counts above normal, TPO is suppressed below basal levels. In patients with chronic liver disease (CLD), TPO production is reduced.<sup>116</sup>

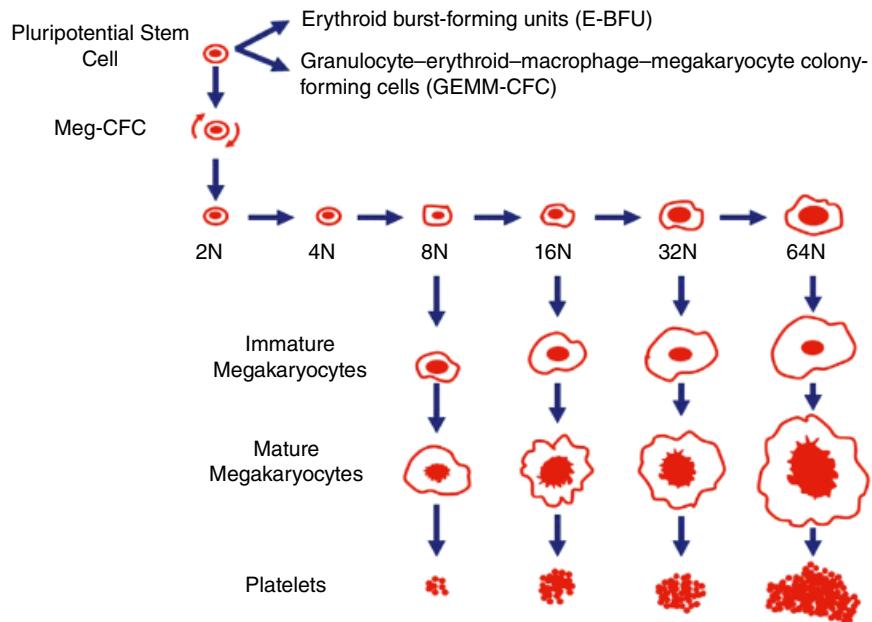

TPO has no carrier molecule and works by binding to TPO receptors on target hematopoietic cells leading to a number of downstream signal transduction events (Figure 52.6). TPO is necessary for the viability of stem cells; humans born without it are thrombocytopenic at birth and eventually become pancytopenic. TPO is necessary for the viability of precursors of all lineages (Figure 52.1) but only amplifies the megakaryocyte lineage by promoting the mitosis of megakaryocyte colony-forming cells, increasing the rate of megakaryocyte endomitosis and maturation, thereby increasing platelet production (Figure 52.7).

### Clinically available thrombopoietin receptor agonists Romiplostim (Nplate)

Romiplostim is a TPO receptor agonist composed of an IgG1 heavy chain carrier molecule into which four identical 14 amino acid peptides have been inserted which activate the TPO receptor.<sup>117</sup> This peptide (IEGPTLRLRWLAARA) has no sequence homology with TPO but was found to bind and activate the TPO receptor. If dimerized, it was as potent as thrombopoietin in vitro but given its short half-life had minimal activity in vivo. By inserting this peptide into

**Figure 52.6** Mechanism of action of the various TPO-RA on the thrombopoietin (TPO) receptor. The TPO-RA bind the TPO receptor and initiate a number of signal transduction pathways that stimulate megakaryocyte growth and increase platelet production. STAT: signal transducer and activator of transcription; JAK: Janus kinase; GRB2: growth factor receptor bound protein 2; SHC: Src homology 2 domain containing; SOS: Son of Sevenless kinase; RAF: rapidly accelerated fibrosarcoma kinase; RAS: rat sarcoma kinase; MAPK: mitogen-activated protein kinase. Figure courtesy of Prof. David Kuter.

**Figure 52.7** Scheme of megakaryocyte maturation from stem cell to mature platelet. Stem cells and megakaryocyte colony-forming cells (M-CFC) undergo mitosis, but at some stage they stop mitosis and undergo endomitosis during which nuclear and cytoplasmic division do not occur giving rise to polyploid early megakaryocytes that contain 2–8 times the normal diploid (2N) amount of DNA. The early megakaryocytes then stop endomitosis and mature into morphologically identifiable megakaryocytes and then shed platelets. TPO plays a major role in all but the last process. Figure courtesy of Prof. David Kuter.

the IgG carrier construct, romiplostim has a T<sub>1/2</sub> of ~120 h, three times longer than native TPO.<sup>118</sup> Although romiplostim binds to the TPO receptor with an affinity 25% of that of TPO, it is a very potent activator of platelet production. Romiplostim is available in vials containing 125, 250, or 500 mcg of lyophilized drug. It is administered as a subcutaneous injection of 1–10 mcg/kg once a week for the treatment of ITP. There is no effect upon white cell or red cell

production. Romiplostim is currently FDA approved for the treatment of thrombocytopenia in:

- Adult patients with ITP who have had an insufficient response to corticosteroids, immunoglobulins, or splenectomy.
- Pediatric patients one year of age and older with ITP for at least six months who have had an insufficient response to corticosteroids, immunoglobulins, or splenectomy.

In Japan, romiplostim is also approved for the treatment of aplastic anemia.<sup>119,120</sup>

### Eltrombopag (Promacta, Revolade)

Efforts to identify small molecules that bound and activated the TPO receptor successfully identified a number of compounds. Eltrombopag was the first of these compounds identified and subsequently modified to enhance its pharmacological and biological properties.<sup>121</sup> Eltrombopag binds the TPO receptor at a transmembrane site distant from where TPO binds (Figure 52.6). It thereby activates the TPO receptor differently than TPO or romiplostim: there is less phosphorylation of JAK and STAT and no effect upon the AKT pathway.<sup>122</sup> Nonetheless, eltrombopag increases megakaryocyte growth and maturation to increase platelet production.

Eltrombopag is available as 12.5, 25, 50, or 75 mg tablets and an oral suspension of 12.5 and 25 mg. Eltrombopag is primarily metabolized by the liver, and dose adjustments are necessary for patients with reduced metabolism of this drug due to East Asian ancestry or liver dysfunction. It is usually taken orally once a day and distant from calcium-containing compounds or food stuffs that would neutralize its activity if coadministered. Eltrombopag is currently FDA approved for:

- The treatment of thrombocytopenia in adult and pediatric patients one year and older with persistent or chronic ITP who have had an insufficient response to corticosteroids, immunoglobulins, or splenectomy. Eltrombopag should be used only in patients with ITP whose degree of thrombocytopenia and clinical condition increase the risk for bleeding.
- The treatment of thrombocytopenia in patients with chronic hepatitis C to allow the initiation and maintenance of interferon-based therapy. Eltrombopag should be used only in patients with chronic hepatitis C whose degree of thrombocytopenia prevents the initiation of interferon-based therapy or limits the ability to maintain interferon-based therapy.
- In combination with standard immunosuppressive therapy for the first-line treatment of adult and pediatric patients two years and older with severe aplastic anemia.
- For the treatment of patients with severe aplastic anemia who have had an insufficient response to immunosuppressive therapy.

### Avatrombopag (Doptelet)

Avatrombopag is structurally different from eltrombopag but also binds to the transmembrane region of the thrombopoietin receptor (Figure 52.6) which it activates in a similar manner. Like eltrombopag, it is orally available but differs in that it is better absorbed when administered with food, lacks any adverse effects on liver function tests, and does not chelate iron.<sup>123</sup> It is available in 20 mg tablets. For ITP, daily dosing starts at 20 mg/day and is subsequently altered based on platelet count with dosing ranging from 20 mg weekly to 40 mg daily. For CLD patients needing procedures the daily dose is based upon platelet count prior to procedure, given for 5 days beginning 10–13 days before procedure. For platelet count less than 40,000, the dose is 60 mg (three tablets) once daily; for platelet counts 40,000–<50,000 the dose is 40 mg (two tablets) once daily.

Avatrombopag is FDA approved for the treatment of:

- Thrombocytopenia in adult patients with chronic liver disease who are scheduled to undergo a procedure.
- Thrombocytopenia in adult patients with chronic immune thrombocytopenia who have had an insufficient response to a previous treatment.

### Lusutrombopag (Mulpleta)

Lusutrombopag is another orally available small molecule TPO-RA that binds the transmembrane region of the TPO receptor (Figure 52.6). It is available as a 3 mg tablet. For the treatment of CLD patients, a dose of 3 mg orally (with or without food) is administered daily for 7 days in a period 8–14 days prior to a scheduled procedure. It is currently FDA approved for:

- The treatment of thrombocytopenia in adult patients with chronic liver disease who are scheduled to undergo a procedure.

### Effects and adverse effects thrombopoietin administration

After giving a single dose of romiplostim<sup>118</sup> or avatrombopag<sup>123</sup> or 10 daily doses of eltrombopag<sup>124</sup> to healthy volunteers, platelet counts begin to rise by Day 5, peak at Days 10–15, and return to baseline by Day 28. These three TPO RA differ in their relative potency in healthy volunteers when tested at their maximal FDA-approved doses for ITP.<sup>125</sup> At 75 mg/d for 10 days, eltrombopag increased the platelet count by about 119,000 (1.4-fold) above baseline;<sup>126</sup> after a single 10 mcg/kg dose of romiplostim, the platelet count increased 1,300,000 (6-fold) over baseline;<sup>118</sup> and after 10–14 days of 20 mg avatrombopag, the platelet count rose by 372,000 (~3-fold) over baseline.<sup>123</sup> Nonetheless, these differences in potency have not translated into any different response rate for these agents in ITP clinical trials. With continued administration of either molecule, peak platelet counts can be maintained indefinitely with no effect on the RBC or WBC. The platelets so produced have normal function.

The TPO receptor agonists have not demonstrated any tachyphylaxis or significant long-term complications.<sup>127,128</sup> The potential and real adverse effects are listed in Table 52.7. A few deserve additional comment.

### Thrombosis

Although the TPO-RA can significantly increase the platelet count, thrombosis has not been clearly associated with TPO-RA in placebo-controlled ITP studies. Rather, what has been uncovered is that ITP itself is a prothrombotic disorder<sup>129</sup> whose rate of thrombosis does not appear to be exacerbated by TPO-RA. Compared with placebo treatment, thrombosis was not increased by recombinant TPO treatment in earlier trials in cancer patients. Platelet function studies have shown no increase in platelet activation with any TPO-RA<sup>130</sup> despite the finding that romiplostim (but not the small molecule TPO-RAs) reduces the activation threshold for other agonists by about 50%.

### Tumor progression/cancer mortality

Unlike the controversy over erythroid growth factors, solid tumor cells lack the TPO receptor.<sup>131</sup> Furthermore, in cancer chemotherapy studies with recombinant thrombopoietins in the 1990s, there was no effect on progression or survival for patients with myeloid leukemia, MDS, or solid tumors.<sup>104</sup> In the oncology studies so far completed

**Table 52.7** Adverse Effects of Thrombopoietic Growth Factors

Thrombocytosis	Autoantibody formation (romiplostim only)
Thrombosis	Liver function abnormalities (eltrombopag only)
Increased bone marrow reticulin	Reduction in threshold for platelet activation (romiplostim only)
Stimulation of leukemic blasts	Rebound worsening of thrombocytopenia upon discontinuation

with TPO-RAs, there was no apparent increased rate of progression of myeloid or nonmyeloid malignancies.<sup>132</sup> The one early exception was in one romiplostim clinical trial with MDS patients that was stopped due to monitoring committee concern about progression to leukemia; upon final analysis this had not occurred.<sup>133</sup>

### Antibody formation

Although antibody formation ended the development of PEG-rhMGDF,<sup>134</sup> no clinically relevant antibodies have developed against the TPO-RA. There have been no reports of any antibody formation against the small molecule TPO-RA. Antibody formation against romiplostim has been extensively analyzed.<sup>135</sup> Out of 961 patients in 13 clinical trials, 60 patients developed antibodies against romiplostim of which only four were neutralizing; none of these four patients lost their therapeutic effect and none cross-reacted with endogenous TPO.

### Hepatic toxicity

Eltrombopag is metabolized by the liver and in one ITP study 11% of patients developed abnormal liver function tests.<sup>136</sup> In general, these were mild, reversible, and did not often require cessation of medication. Intermittent monitoring of liver function tests is recommended for eltrombopag.

### Rebound thrombocytopenia

The major concern with TPO receptor agonists occurs in ITP patients in whom the drug is abruptly stopped. Current prescribing information is unhelpful and states that TPO-RA be stopped when the platelet count exceeds 400,000. Unfortunately in 10–20% of such situations, stopping the drug results in a rebound thrombocytopenia with the platelet count rapidly dropping below prior baseline values 7–10 days later and a markedly increased bleeding risk.<sup>109</sup> Such patients are better treated by a gradual dose reduction over several weeks.<sup>137–139</sup>

### Bone marrow reticulin and collagen fibrosis

Reticulin is a normal component of the bone marrow and may increase in patients with ITP<sup>140</sup> and in those receiving TPO receptor agonists.<sup>141</sup> This reticulin deposition is generally mild, reversible, clinically silent, and does not portend progression to the disease myelofibrosis. Prospective bone marrow studies of ITP patients receiving TPO receptor agonists have been performed. In one study, romiplostim-treated patients showed an ~5% incidence of increased bone marrow reticulin (reticulin stain) that was reversible upon discontinuation of the drug, was not associated with abnormal blood counts, and often did not require drug cessation.<sup>142</sup> Only two patients demonstrated increased collagen fibrosis (trichrome stain) that was reversible. In another two-year study with eltrombopag, normal (MF-0) reticulin staining was seen in 94% at baseline and 89% after two years. None had MF-2 or MF3. Collagen staining was rare, and none of the patients had blood count abnormalities.<sup>143</sup> Routine bone marrow assessment is not required for patients on TPO-RA.

### Clinical use of thrombopoietin receptor agonists

Table 52.8 provides a complete list of conditions that have been treated with TPO-RA.

### Immune thrombocytopenia (ITP)

ITP is a disease of increased platelet destruction and inappropriately low platelet production.<sup>144</sup> Although standard therapies such as immunosuppression, rituximab, and splenectomy decrease platelet destruction, TPO-RA increase platelet production thereby miti-

**Table 52.8** Clinical Uses of Thrombopoietic Growth Factors

Immune thrombocytopenia (ITP)—all stages	(Liver failure)
Hepatitis C-related thrombocytopenia being treated with interferon	(Myosin heavy chain 9-related disease)
Aplastic anemia	(Peripheral blood progenitor cell mobilization)

(Chemotherapy-induced thrombocytopenia)	(Acute leukemia)
(Presurgical thrombocytopenia)	(Platelet apheresis)
	(Myelodysplastic syndromes)

Uses in parentheses denote lack of FDA approval but for which compendial data exist. See prescribing information for each individual thrombopoietic growth factor.

gating thrombocytopenia. All approved TPO-RA increase the platelet count >50,000 in more than 85% of patients accompanied by reduced bleeding and need for other therapies.<sup>136,145,146</sup> Long-term use of TPO-RA is successful<sup>127,128</sup> and may be associated with increased numbers of T regulatory lymphocytes with increased disease remission.<sup>147,148</sup> The TPO-RA have now been incorporated into most ITP guidelines as the major second-line therapy.<sup>149–152</sup> They are as effective in early ITP (months 0–12) as they are in chronic ITP (over 12 months).<sup>137,153</sup>

### Hepatitis C-related thrombocytopenia

Hepatitis C is associated with two forms of thrombocytopenia that may be difficult to distinguish in any one patient. One is an ITP-like condition that responds to ITP therapies; the second is TPO deficiency due to hepatic injury. Consequently, in patients with platelet counts <70,000, older forms of antiviral therapy with ribavirin and interferon may be contraindicated. When such patients with a mean baseline platelet count of 55,000 were treated with eltrombopag 75 mg/day for four weeks, the mean platelet count rose to 209,000 compared with 54,000 in those receiving placebo.<sup>154</sup> With continued eltrombopag support, 65% of patients could finish antiviral treatment compared with 6% receiving placebo. In a large phase III study of such hepatitis C patients with platelet counts under 100,000, 95% increased their platelet count to over 100,000 by week 9 and were then randomized to receive eltrombopag or placebo during the next 24–48 weeks of antiviral treatment.<sup>155</sup> Sustained virologic response was seen in 19–23% of eltrombopag patients compared with 13–15% on placebo ( $p < 0.02$ ) with more patients maintaining a platelet count >50,000 (69–81% vs. 15–23%, respectively). However, the newer treatments for hepatitis C have markedly reduced the need for this form of supportive care.

### Aplastic anemia

Although TPO levels are markedly elevated (>2000 pg/mL) in most aplastic anemia patients, eltrombopag produced a platelet count raise in 9/25 patients with a trilineage response in 6/25 patients.<sup>156</sup> In responders, marrow cellularity increased and response was maintained for long term with some coming off treatment.<sup>157</sup> Subsequent studies assessed the addition of various regimens of eltrombopag to antithymocyte globulin in the initial treatment of patients with severe aplastic anemia.<sup>158</sup> At six months, 26–50% of the different eltrombopag groups had a complete response compared with a historical cohort in which the rate was 10%; overall response rates at six months ranged from 80% to 94% compared to 66% in historical cohorts. The rate of clonal evolution was similar to

the historical cohort. These striking results were not seen in prior studies with recombinant TPO<sup>104</sup> but studies with romiplostim reported comparable outcomes.<sup>159</sup> One mechanism for the success of eltrombopag might be that its binding to the TPO receptor may not be impaired by the high levels of interferon present in patients with aplastic anemia; it has been suggested that interferon- $\gamma$  forms a heterodimer with TPO and prevents it from binding to the receptor. Since eltrombopag binds to a different location on the TPO receptor and is not bound by interferon- $\gamma$ , it bypasses this inhibitory mechanism.<sup>160</sup>

### Presurgical treatment of thrombocytopenic patients

Thrombocytopenia complicates many illnesses, and such patients are often given aggressive platelet transfusions or even refused needed surgical procedures. Several studies have shown that romiplostim and eltrombopag can increase platelet counts in such patients, reduce bleeding, and allow procedures to be performed. In one study of 51 thrombocytopenic patients treated with romiplostim, all were able to raise their platelet count (from a median of  $47 \times 10^9/L$  at baseline to  $164 \times 10^9/L$  at the time of surgery) and undergo surgery with no excessive bleeding and minimal need for transfusion.<sup>161,162</sup> In a second study of thrombocytopenic cirrhotic patients being prepped for liver biopsy, platelet transfusion was avoided in 72% of patients receiving eltrombopag compared with 19% of those receiving placebo ( $p < 0.001$ ); there was no difference in bleeding (17% vs. 19%, respectively).<sup>163</sup> However, this study was terminated early because 6/145 eltrombopag patients developed portal vein thrombosis versus 1/147 on placebo. The study was weakened by the absence of standardized assessment for portal vein clot. In the only randomized, prospective study of TPO-RA in the treatment of thrombocytopenic ITP patients undergoing surgery, eltrombopag was felt to be comparable to IVIG.<sup>164,165</sup>

### Chemotherapy-induced thrombocytopenia

Chemotherapy-induced thrombocytopenia (CIT) remains a major challenge in identifying a strategy for both studying this patient population and crafting an effective therapy. Early studies in patients receiving nonmyeloablative chemotherapy for ovarian cancer<sup>166</sup> or lung cancer<sup>167</sup> showed that treatment with the first generation of thrombopoietin growth factors, rhTPO and PEG-rhMGDF, increased the nadir platelet count, decreased the need for platelet transfusions, and allowed for chemotherapy to be given on time.<sup>104</sup> However, neither recombinant TPO showed benefit in patients receiving myeloablative chemotherapy for acute leukemia induction or for stem cell transplantation.

In a very large retrospective study of 173 patients receiving chemotherapy for solid tumors ( $n = 153$ ) and lymphoma/myeloma ( $n = 20$ ), romiplostim was highly effective: 71% had a response, 79% avoid chemotherapy dose reduction/treatment delays, and 89% avoided platelet transfusions. Median platelet counts rose from  $60 \times 10^9/L$  to  $116 \times 10^9/L$ , and treatment was most effective in those who lacked bone marrow tumor invasion, prior pelvic radiation, prior temozolamide, or hematologic malignancy.<sup>168</sup> In a small randomized, prospective trial of chemotherapy patients with platelet counts under 100,000 for at least four weeks, 93% of patients received romiplostim but only 12.5% of control patients restored their platelet count to over 100,000 within three weeks. Continuation of romiplostim allowed maintenance of adequate dose intensity with subsequent chemotherapy.<sup>132</sup> Current NCCN guidelines for hematopoietic growth factors list TPO-RA as alternatives to platelet transfusions during the COVID-19 pandemic.<sup>169</sup>

### Myelodysplastic syndrome (MDS)

Thrombocytopenia commonly complicates the care of patients with MDS. In a study of thrombocytopenic (<20,000 or history of bleeding and platelets  $\geq 20,000$ ) low-risk/intermediate-1-risk MDS patients, romiplostim or placebo were administered for 58 weeks.<sup>133</sup> Overall, clinically important bleeding events were not significantly reduced with romiplostim (HR 0.83; 95% CI, 0.66–1.05;  $p = 0.13$ ), but in those with platelet counts  $\geq 20,000$  significant reductions were seen (HR, 0.34; 95% CI, 0.20–0.58;  $p < 0.0001$ ). Romiplostim reduced bleeding events (RR, 0.92) and platelet transfusions (RR, 0.77) and increased platelet response (OR, 15.6). This study was stopped at an interim analysis because of a perceived increase in the AML rate (HR, 2.51) with romiplostim, but final analysis showed AML rates of 6% with romiplostim and 4.9% placebo (HR, 1.20; 95% CI, 0.38–3.84) and similar survival rates. Current clinical practice is supportive of using TPO-RA to treat thrombocytopenia and bleeding in MDS patients who are not adequately controlled by platelet transfusions.

### Implications for transfusion medicine

Since 2008, the TPO-RA have played an increasing role in the treatment of a number of thrombocytopenic disorders. TPO receptor agonists clearly decrease the use of IVIG and platelet transfusions in ITP patients.<sup>145</sup> They can also reduce or eliminate the need for transfusions in thrombocytopenic patients undergoing major surgery. They have helped a number of Jehovah's Witness patients or those with severe platelet alloimmunization to undergo surgery without platelet transfusion.<sup>161,162</sup>

The bigger issue is whether TPO-RA can decrease the thrombocytopenia associated with nonmyeloablative chemotherapy and reduce the need for platelet transfusions. Early data showed that rhTPO reduced the rate of platelet transfusion from 75% to 25% in women being treated for ovarian cancer.<sup>166</sup> It is possible that studies with the current TPO-RA will show similar benefit in nonmyeloablative chemotherapy.<sup>170</sup> A number of CIT studies are currently underway and may clarify the benefit of TPO-RA treatment.

Patients undergoing myeloablative chemotherapy for the treatment of leukemia or for stem cell transplantation often require extensive platelet transfusion support. Early studies with recombinant thrombopoietin agents showed no significant reduction in platelet transfusions or time to platelet recovery. The underlying biology of bone marrow recovery may limit the potential benefit of TPO-RA in this patient population.<sup>171,172</sup>

Whether TPO receptor agonists will ever play a role in enhancing platelet apheresis yields remains unclear. Prior studies showed that PEG-rhMGDF increased the median platelet count from 248,000 to 602,000 with an increase in median (range) apheresis yield from  $3.8 \times 10^{11}$  ( $1.3 \times 10^{11}$  to  $7.9 \times 10^{11}$ ) to  $11.0 \times 10^{11}$  ( $7.1 \times 10^{11}$  to  $18.3 \times 10^{11}$ ) platelets.<sup>105</sup> Once transfused, these products were hemostatically active and provided a dose-dependent rise in platelet count and increased transfusion-free interval.<sup>173</sup> rhTPO-mobilized platelets have also been frozen and later transfused with benefit into alloimmunized chemotherapy patients.<sup>106</sup>

TPO may be helpful in improving hematopoietic recovery after radiation injury.<sup>174–177</sup> Early intervention mitigates multilineage suppression and improves survival after radiation of nonhuman primates;<sup>178</sup> cross-species modeling studies might suggest human benefit as was done for filgrastim and pegfilgrastim in this setting.<sup>100</sup>

### Development of newer TPO receptor agonists

Hetrombopag (5-[2-hydroxy-3-[[5-methyl-3-oxo-2-(5,6,7,8-tetrahydronaphthalen-2-yl)-1H-pyrazol-4-yl]diazenyl]phenyl]furan-2-

carboxylic acid) is another oral TPO-RA small molecule (580.6 Da) that is being developed in China for ITP and chemotherapy-induced thrombocytopenia. Like the other small molecule TPO-RAs, it too binds to the transmembrane region of the TPO receptor (Figure 52.6). In some in vitro experiments, it has been shown to be 10-fold more potent than eltrombopag.<sup>179–181</sup> In a large phase III trial, 424 ITP patients (with platelet counts <30,000) were randomized to two different doses of hetrombopag or placebo for 10 weeks.<sup>182</sup> After eight weeks, platelet counts >50,000 were seen in 58.9% and 64.3% of those receiving either 2.5 or 5.0 mg daily, respectively, versus 5.9% in the placebo group. Bleeding and rescue medication use was reduced in those on hetrombopag. No new safety signals were observed. There were no adverse effects on liver function tests.

## General conclusions

The hematopoietic growth factors have markedly impacted the practice of medicine over the past 30 years. Beginning with erythropoietin and then extended with myeloid growth factors and now with thrombopoietic growth factors, there is an ability to increase specific blood cell production in patients who have anemia, neutropenia, or thrombocytopenia. These molecules are generally safe, effective, and with adequate time will raise the blood count. Unfortunately, none is immediately active and most take days for the onset of activity. None of these will replace the need for transfusion in acute situations of anemia or thrombocytopenia. However, all three offer the opportunity to prevent subsequent RBC transfusion, infection, or bleeding. Although expensive, in some settings they have been demonstrated to reduce medical care costs.

## Acknowledgments

I am grateful to Dr. Drew Provan for his help with many of the figures.

## CHAPTER 53

# Hematopoietic stems cells and transplantation

Garrett S. Booth

Department of Pathology, Microbiology, and Immunology, Vanderbilt University Medical Center, Nashville, TN, USA

### Stem cells

The human being is composed of trillions of native cells, the majority of which resides in the vascular space.<sup>1</sup> Despite stem cells representing just 1 in every 10–20,000 cells in the bone marrow (Figure 53.1), they possess a remarkable ability to both differentiate into the varying cellular components of blood, but also self-replicate to sustain a lifetime of hematopoiesis (Table 53.1).

Hematopoietic stem cells (HSCs) and hematopoietic progenitor cells (HPCs) have been utilized in the treatment of a range of diseases, both for neoplastic conditions, as well as non-neoplastic disorders, with a diverse set of reported outcomes. Since the 1950s, with the initial successful transplantation of bone marrow,<sup>4</sup> health-care providers have expanded the use of HSCs for the treatment of three broad categories.

Allogeneic stem cell transplant allows for reconstitution of hematopoiesis in patients with either a genetic disorder affecting blood production/function or for the treatment of a bone marrow failure syndromes. Additionally, allogeneic or autologous stem cell products can be used following irradiation and/or systemic chemotherapy to afford the patient the opportunity for bone marrow reconstitution following eradication of the malignant process. Lastly, genetic manipulation of HSCs can be undertaken to insert normal genomic material into defective stem cells with a primary goal of establishing sufficient levels of the gene product to result in clinical improvement.

### Hematopoietic stem cells

For clinical use, there are three primary sources of hematopoietic stem cells (HSCs): bone marrow harvested by aspiration from the cavity of the ilium (pelvis), peripheral blood obtained through leukapheresis, and umbilical cord blood (UCB) collected from the placenta after childbirth (Table 53.2).<sup>5</sup>

Transplant providers must balance the allogeneic risk of graft-versus-host disease (GVHD) and graft-versus-tumor effect that can impact both patient satisfaction and clinical outcome.<sup>6–8</sup> Transplant providers seek to control the progression of the malignancy early following stem cell transplant while preventing GVHD. If no viable donor can be identified for either marrow harvest or peripheral

blood stem cell collection, providers may also be confronted with the prospect of utilizing umbilical cord blood (UCB) as a stem cell source.<sup>9</sup>

Umbilical cord blood (UCB) stem cells have been successfully used for hematopoietic cell transplant (HCT) since the first report in 1989 and to date have been successfully utilized in over 40,000 transplants worldwide.<sup>10–12</sup> The biologic properties of UCB units can be safely cryopreserved for more than 20 years under appropriate conditions, with efficient recovery of functional HSCs and HPCs.<sup>13</sup>

### Hematopoietic microenvironment

The bone marrow microenvironment is composed of adipose, hematopoietic cells, and vascular sinuses.

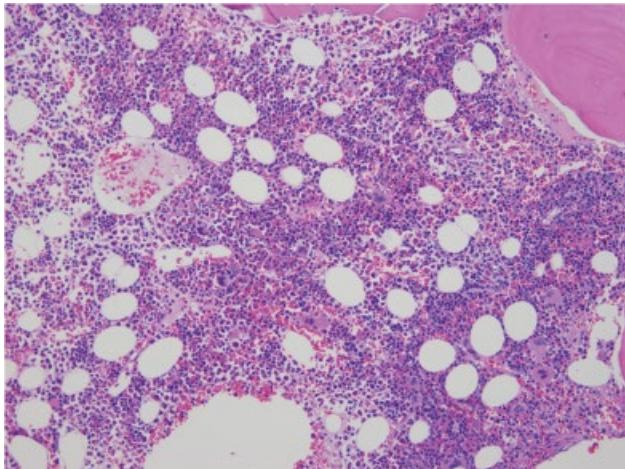

Bones such as vertebrae, sternum, pelvic bones, and metaphyses of long bones remain active sites of hematopoiesis throughout life, but longer weight bearing bones, facial bones, and distal upper extremity bones are slowly switched off and the marrow cavity is replaced by fat.<sup>14,15</sup> The central cavity of the active hematopoietic sites consists of hematopoietic tissue islands and adipose cells surrounded by vascular sinuses interspersed within a meshwork of trabecular bone, collectively forming the bone marrow niche.<sup>16</sup>

The bone marrow niche is not singular in nature as various microenvironments rely on differing endocrine, paracrine, and direct cell-to-cell interactions for progression of maturation. The arrangement of HSCs is in a nonrandom nature, locating close to endosteal bone allowing for differentiated cells to slowly migrate to central bone marrow regions around the perivascular compartment.<sup>17,18</sup> The current understanding of early multipotent stem cells indicates that in the steady state, stem cells are found as single cells adjacent to perivascular cells and within 30 µm from sinusoids.<sup>19</sup> The primary contributor of the endosteal niche is the osteoblast, which secretes multiple cytokines and growth factors that directly regulate HSCs.

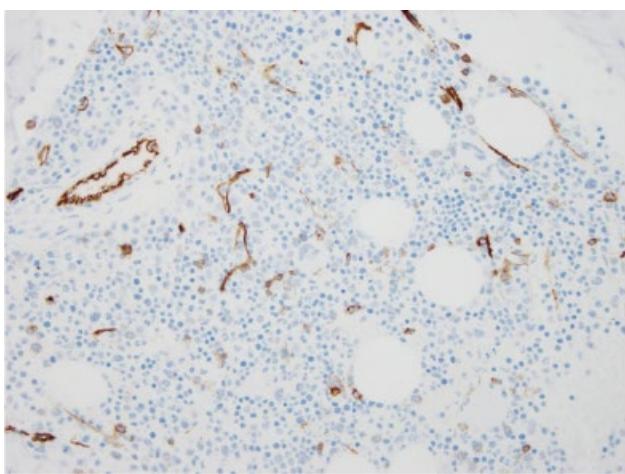

Osteoblast production of CXC-chemokine ligand 12 (CXCL12), stem-cell factor (SCF), osteopontin (OPN), granulocyte colony-stimulating factor (G-CSF), annexin 2 (ANXA2), angiopoietin 1 (ANG1), or thrombopoietin (TPO) allow for the control of homing, mobilization, and quiescence of HSCs.<sup>20–23</sup>

In contrast to the bone forming osteoblasts, osteoclasts are responsible for bone digestion. Mouse models lacking osteoclasts

	Bone Marrow	Peripheral Blood	Umbilical Cord Blood
Stem cell content	Adequate	Good	Low
Progenitor cell content	Adequate	High	Low
T-cell content	Low	High	Low
GVHD	Low	Moderate–high	Low

show reduced bone marrow activity,<sup>24,25</sup> but the overall role in human bone marrow activity remains elusive. Observations of osteoclast poor bone marrow impairing adequate stem cell mobilization have been reported, but conflicting studies have shown the opposite.<sup>26,27</sup>

### Different cells in BM niche

Over decades in axial bones, hematopoietic sites are progressively replaced by fatty yellow marrow with reduced hematopoietic activity.<sup>28</sup> Mice with abundant fat stores within the bone marrow appear to contain fewer HSCs; however, newer medications that expand adipocyte stores within the marrow (triglitazone) demonstrate that adipose has virtually no impact in bone marrow regulation.<sup>29,30</sup>

The sympathetic nervous system regulates the daily circadian rhythm of HSC mobilization through the  $\beta 3$  adrenergic receptor, downregulating CXCL12 expression by stromal cells and assisting in hematopoiesis recovery following chemotherapy.<sup>31,32</sup> Adrenergic cellular signaling between neural cells can influence early progenitor cells with corresponding receptors, allowing for migration and engraftment.<sup>33</sup> Additionally, aberrations of the neural network within the bone marrow via intragenic ablation from chemotherapy or irradiation has also been shown to influence the bone marrow microenvironment by anomalous expansion of mesenchymal cells resulting in bone marrow interference.<sup>32,34</sup>

Megakaryocytes ensure hematopoietic regulation by secreting CXCL4, TGF Beta, and CLEC2.<sup>35–37</sup> These signals and their associated feedback loops have been shown to regulate bone marrow quiescence.<sup>35,37</sup>

Bone marrow CD169+ macrophages have been identified as a regulator of bone marrow HSC migration owing to modulation of osteoblast and osteoclast activity.<sup>38,39</sup> A small subset of bone marrow macrophages have been identified as expressing the Duffy antigen receptor for chemokines (DARC) that may also enable bone marrow quiescence regulation.<sup>40</sup>

The discovery and description of neutrophils dates back to the 1800s with the Nobel Prize winning work of Metchnikoff.<sup>41</sup> Although not thought to be the primary driver of maturation of immature HSCs to differentiated blood elements, the daily steady-state production of  $\sim 1 \times 10^{10}$  neutrophils suggests that the sheer mass of neutrophils could influence the background inflammatory state and circadian rhythm of the bone marrow microenvironment.<sup>42,43</sup> In emergency situations, the production of reactive oxygen species from neutrophils can stimulate hematopoiesis.<sup>44</sup> Bone marrow neutrophils can also assist in the regeneration of sinusoid following transplantation, enabling re-establishment of the vascular framework needed for the maintenance of marrow activities.<sup>45,46</sup>

### Circulation and vasculature

The bone marrow niche is enabled by the vast network of blood vessels and their endothelial cells. These cells serve to transfer oxygen, as well as cell-to-cell signaling for tissue maintenance and

maturity. The overall flow of blood inside the bone marrow is from a small artery entering from cortical bone to branching thin-walled arterioles traveling close to the endosteum, giving way to the venous sinusoidal network that ultimately drains into a central vein.<sup>47,48</sup> Both endothelial cells and perivascular stromal cells provide abundant cellular signaling within the bone marrow niche, including CXCL12 and SCF.<sup>49,50</sup>

The current model of definitive hematopoiesis relies on the idea of two functionally different HSC populations: the long-term HSCs that give rise to new or additional HSC and the short-term HSCs. Long-term HSCs have lifelong self-renewing potential, whereas the short-term HSCs—that show more restricted self-renewing capacity—producing common myeloid progenitors and common lymphoid progenitors.<sup>51</sup>

Successful hematopoietic recovery following stem cell transplantation depends on efficient homing and subsequent engraftment of HSCs into specific bone marrow niches. Various adhesion molecules, chemokines, glycoproteins, and integrins—present both on the surface of stem cells and sinusoidal endothelium—play critical roles in transvascular migration.<sup>52</sup>

Integrins are heterodimeric transmembrane molecules consisting of  $\alpha$  and  $\beta$  subunits that are expressed on the surface of HSCs.<sup>53</sup> Together with other intercellular adhesion molecule-1/leukocyte function-associated antigen-1, vascular cell adhesion molecule-1/very late antigen-4, and few junctional adhesion molecules, stem cells remain closely adherent to endosteal bone and perivascular regions.

### Mobilization of HSCs

G-CSF is a recombinant hematopoietic growth factor that is produced by multiple bone marrow cells resulting in decreases in SDF-1 production and degradation of the SDF-1 molecule.<sup>54</sup> G-CSF is a cytokine that promotes granulocyte proliferation and differentiation and enhances mobilization through direct and indirect protease activation.<sup>55</sup> Neutrophils releases cathepsin, elastase, and matrix metalloproteinases, and peptidases. These molecules enable cleavage of the adhesion molecules on HPCs; in addition, G-CSF indirectly inhibits osteoblast activity and reduces SDF-1 expression that enhances HPC mobilization.<sup>56</sup> Further mobilization pathways following G-CSF administration include disruption of VCAM-1/VLA-4 interaction and cleavage of CXCR4 and CD44 on HSCs. Following these changes, HSCs are more prone to release from the periosteum, and subsequent migration to the peripheral blood where they may be collected by apheresis.

Administration of G-CSF is utilized in both autologous and allogeneic mobilization, resulting in high cell doses collected enabling downstream increases in engraftment rates; however, the exact mobilization regimen for autologous and allogeneic donations are variable.

G-CSF-mobilized peripheral blood stem cells are the preferred graft source for virtually all autologous and an increasing majority of allogeneic HSCs owing to its generally higher stem cell content, reduced rates of graft failure, and better overall survival as compared to the BM.<sup>57,58</sup> After 4–6 days of subcutaneous administration of G-CSF, HSCs can increase nearly 100 fold,<sup>59</sup> allowing for safe mobilization schemes in both adult and pediatric patient populations.<sup>60,61</sup> Despite well-established safety guidelines for the use of G-CSF, several limitations due exist, namely, the slow onset of effect (generally 4–5 days of therapy are needed before a donor can proceed with collection), bone pain, and mobilization failure.<sup>62–64</sup> Adverse effects of G-CSF are generally well tolerated, but caution

should be exercised in donors with known coronary artery disease or sickle cell disease, given reports of ischemic complications or provocation of a sickle cell crisis, respectively.<sup>65–67</sup> Enlargement of the spleen by 10–15% has also been shown to occur with G-CSF injections with rare but potentially fatal splenic rupture occurring in a single case.<sup>68</sup>

Optimal dosing can be influenced by donor and recipient body weight, and does not appear to be influenced by location of administration.<sup>69,70</sup> Dose escalation alone cannot overcome poor mobilization. In healthy allogeneic donors, a typical five-day course of G-CSF raises the WBC count to about  $40 \times 10^9/L$ , although rare reports of WBC expansion to over  $100 \times 10^9/L$  have been reported.<sup>71</sup> The rise in WBC mirrors an increase in CD34+ expansion, with allogeneic donors typically showing a 50–100-fold increase.<sup>72</sup>

Recently, biosimilar versions of filgrastim have been approved by the US FDA as alternate versions of biologic products that have demonstrated the same clinical safety and efficacy.<sup>73</sup>

Donor characteristics, including advanced age, diabetes mellitus, history of radiotherapy, and multiple cycles of chemotherapy, have all been identified as increasing the risk of low CD34+ mobilization.<sup>74–76</sup> Chemotherapeutic agents that are directly toxic to the bone marrow niche, including melphalan, fludarabine, or intensive regimes like hyper CVAD, can result in significant HSC damage and mobilization failure. Furthermore, the review of premobilization laboratory testing results can aid in the identification of donors with a reduced or low steady state of bone marrow production, including a below normal preprocedure platelet count.<sup>64</sup> For patients that fail to mobilize with G-CSF alone, newer mobilizing agents like plerixafor can be used in combination or alone (Table 53.3).

Plerixafor (AMD3100; Mozobil; Sanofi-Aventis, Paris, France) is the antagonist of CXCR4, preventing CXCR4 on HSCs from interacting with SDF-1 on bone marrow stroma.<sup>77,78</sup> AMD3100 administration not only blocks CXCR4, but also induces activation of MMP-9 and serine protease urokinase-type plasminogen activator.<sup>79</sup> Since 2008, plerixafor has been clinically approved by the US FDA to use alone or in combination with G-CSF to mobilize HSPC in heavily pretreated lymphoma and myeloma patients.<sup>80</sup> Although plerixafor is successful in increasing optimal CD34+ yield, decreasing mobilization failure, and reducing the number of apheresis sessions, its universal use is limited by its substantial cost.<sup>81</sup> Plerixafor is usually given as a single subcutaneous dose as part of a combined regimen in which G-CSF is given for five days, with plerixafor added in the evening on Day 4 or the morning on Day 5, followed by the apheresis collection.<sup>82</sup>

GM-CSF (sargramostim, Leukine, Bayer Healthcare Pharmaceuticals, Seattle, WA, USA) plays a limited role in HSC mobilization today owing to significantly fewer CD34+ cells than

**Table 53.3** Comparison Between HPC Mobilizing Agents

Mobilizing Agent		
	G-CSF	Plerixafor
Mechanism of action	Cleavage of adhesion molecules	CXCR4 antagonist
Half-life	3–5 hours	3–5 hours
Time to maximum mobilization	4–6 days	6–9 hours
Common side effects	Bone pain and headache	Diarrhea and edema at injection site
Dosing	10–15 mcg/kg/day	0.24 mg/kg/day

G-CSF in healthy subjects.<sup>83</sup> Moreover, in patients with NHL, mobilization with GM-CSF resulted in a lower CD34+ cell yield than mobilization with G-CSF.<sup>84</sup>

Chemotherapy-induced stem cell mobilization most commonly occurs with cyclophosphamide (CY), which induces the release of stress signals that cause inflammation, thereby activating the host immune system increasing HSC mobilization. The balance between toxicity and cell dose yields, along with logistical challenges in determining the ideal mobilization and collection day, have resulted in shifting utilization patterns for CY in the treatment of adults.<sup>85-87</sup>

The current modeling of donor stem cell mobilization utilizes five general strategies: G-CSF alone, G-CSF plus plerixafor, plexafor alone, chemotherapy alone, or chemotherapy plus G-CSF. These varying mobilization strategies have differing success and debate related to the cost-effectiveness of using newer more expensive mobilizing agents remains.<sup>88,89</sup> Plerixafor has gained considerable attention as a rescue agent for donors with suboptimal mobilization following G-CSF alone, and off-label use of plerixafor as a single mobilizing agent in allogeneic donors continues to be explored, especially in situations when a full five days of G-CSF is not practical.<sup>90-94</sup>

## Collection of HSCs for transplantation

### Bone marrow

Bone marrow harvests are invasive medical procedures and are commonly performed in an operating room under general anesthesia.

Specialized stainless-steel beveled needles are used to gain access to the marrow cavity, wherein the product can be safely siphoned off in heparinized syringes into a disposable collection bag. Large filters within the tubing sets help to reduce unwanted bone chips, fat, clots, and fibrin stands. The product is then drained to a collection bag wherein anticoagulant solutions are available or can be safely supplemented.<sup>95,96</sup>

Special consideration should be given to pediatric bone marrow donors as these patients may often be siblings of the intended recipient and the collection process is not devoid of risk or ethical entanglements.<sup>97</sup>

### Peripheral blood/PBSC collection

The acquisition of stem cells via peripheral blood collection is highly disparate when compared to bone marrow harvesting. Aggregate data from Center for International Blood and Marrow Transplant Research (CIBMTR) showed that almost all (>99%) of autologous HCT and 69% of allogenic HCT were supported by peripheral blood progenitor cells (<https://www.cibmtr.org>).

Due to the high flow rates of blood utilized during an apheresis procedure (some centers use flow rates in excess of 100 mL/min), adequate venous access must be maintained; this can be achieved via two large bore needles in peripheral veins most commonly in the antecubital fossa or placement of a central venous catheter (CVC). Given documented adverse reactions to in well donors, the use of CVC should be utilized sparingly in well donors.<sup>71,98</sup> Throughout the 3–6 hour duration of the apheresis collection, an anticoagulant must be used to prevent clotting in the device; this is most frequently achieved with the use of citrate. Given the known complication of hypocalcemia during the collection process, some centers elect to concurrently administer oral or intravenous calcium supplementation to prevent citrate toxicity.<sup>99</sup>

The apheresis collection of stem cells is accomplished by separating cells via centrifugation; however, this separation technique is

not perfect and can result in significant platelet reductions. Among unrelated donors, the average peripheral platelet count decreased 30% following apheresis collection, but thankfully the bleeding risk remains very low.<sup>98</sup> Review of hematologic indices is advisable given the concurrent loss in platelets secondary to the CD34+ collection.

In unrelated allogeneic stem cell donors who have received five days of mobilization with G-CSF, the average apheresis yield is  $3.5 \times 10^{10}$  MNCs, of which approximately 1% are CD34+ cells.<sup>100</sup> Autologous collections are more likely to require either consecutive day apheresis collections or infrequently the use of several collection time periods.<sup>101</sup> In aggregate, the stem cell collection efficiency achieved via apheresis ranges from 40% to 60%.<sup>102,103</sup> Comparisons of the two primary apheresis devices available, Spectra Optia (Terumo BCT) and Amicus (Fresenius Kabi), illustrate comparable cell yields and collection efficiencies.<sup>104</sup>

Comparison of bone marrow and PBSC has demonstrated higher rates of serious adverse events in peripheral blood stem cell donors.<sup>105</sup> Both BM and PB donation procedures may be burdened by the same psychologic effects, such as fatigue and reduced energy, after the procedure. More severe pain at the donation site, greater incidence of hemorrhage, anemia, and hypotension, and a tendency to have more days of restricted activity and hospitalization may occur related to BM donation, but for patient-related outcomes of overall or disease-free survival there is no discernable difference.<sup>106,107</sup> Peripheral blood stem cell products do however appear to confer a faster engraftment of neutrophils and platelets in both autologous and allogeneic hematopoietic transplants.<sup>108</sup>

### ABO and HSCs and antibodies

HLA and ABO antigens are independently inherited; thus, allogeneic hematopoietic stem cell transplantation is routinely (up to 50%) performed across the ABO blood group barrier.<sup>109</sup> Three groups of ABO mismatch can be distinguished in the course of a stem cell transplant: minor, major, and bidirectional ABO incompatibility.<sup>110</sup>

The discrepancies between ABO and HLA typing call for a sequential intervention beginning at the time of pretransplant evaluation and extending through post-transplant transfusion support management (Table 53.4).

In clinical situations that necessitate the use of stem cell donor that has a major or bidirectional ABO mismatch, providers should be aware of pure red blood cell aplasia (PRCA), which can be seen in 10% of ABO-incompatible stem cell transplants.<sup>114</sup> This immunologic insult from residual recipient plasma cells secreting offending isoantibodies, anti-A or anti-B, does not significantly impact overall survival<sup>115,116</sup> but can prolong the period of transfusion dependence. Indeed, hemolysis can be impressive in some cases and may lead to prolonged red blood cell transfusion dependence in the post-transplant period. In these (relatively) rare cases, serial assessment of incompatible isoantibody titer (usually anti-A) can be informative. Emerging evidence supports the use of daratumumab as a favorable treatment option for PRCA<sup>117,118</sup> but requires close communication with the blood bank prior to initiation of therapy to ensure adequate serologic testing has been completed.<sup>119</sup>

### Cryopreservation

HSCs, once harvested, are only viable for several hours to a few days, limiting their geographical reach. Freshly frozen cells can be transported from the site of processing to a clinical site, extending both the geographical reach of viable cells and the genetic diversity

**Table 53.4** ABO-Incompatible Stem Cell Transplant Interventions\*

	Clinical Intervention	Apheresis	Stem Cell Laboratory
Pretransplant evaluation	-Two independent ABO/Rh typing and antibody screen	-Consideration for predonation plasma exchange**	-Confirmation of ABO incompatibility status
Stem cell acquisition	-Communication with blood bank regarding specialty blood products needed, including matching for minor RBC antigens as appropriate	-Minimize incompatible RBC collection, adjust cell collection dose given product modification consideration	-Major mismatch: RBC depletion/ sedimentation of product -Minor mismatch: plasma depletion of product
Peri-Transplant Management	-Selection of blood products to ensure transplant compatibility -Major mismatch: monitor for acute RBC hemolysis -Minor mismatch: monitor for acute/chronic hemolysis and PLS	-Optimization of stem cell mobilizing agent for donors with sickle cell disease†	-Slow rate of infusion with concurrent monitoring for signs of hemolysis

\* Booth *et al.* (2013).<sup>111</sup>\*\* Sheppard *et al.* (2013).<sup>112</sup>† Boulad *et al* (2018).<sup>113</sup>

of cells available to patients. Despite these benefits, the cryopreservation of HSCs poses several challenges, most notably a decline in cell viability after freeze/thaw cycling and adverse reactions in recipients during infusion due to cryoprotectants used.

The predominant cryoprotectant for HSCs is dimethyl sulfoxide (DMSO), but owing to the adverse event rate seen at time of infusion, the dominant line of research in HSC cryopreservation focuses on reducing or removing DMSO from cryoprotectant solutions to allow for a safer infusion.

Cryopreservation of HSCs is generally carried out using slow cooling rates in specialized controlled rate freezers (approx. 1 °C/min), yet comparisons between slow cooling (2 °C/min) and rapid cooling (vitrification) of human UCB cells found that cell viability and CD34+ enumeration after rapid cooling was significantly higher than that after slow cooling. These results suggest that rapid cooling is a promising cryopreservation method for UCB.<sup>120</sup>

Delays in cryopreservation after collection may adversely affect cell viability,<sup>121</sup> but may be unavoidable if the collection site and cell processing laboratory are significantly geographically separated or constrained by staffing issues or if a logistical problem or weather event prevents timely delivery of the product to the laboratory. Avoiding room temperature storage and delayed cryopreservation provide better post-thaw potency in hematopoietic progenitor cell grafts.<sup>122</sup> Cell doses that are very high can lead the collected product to clump after thawing or rarely seizures.<sup>123</sup>

### Cord blood

Since 1989, umbilical cord blood (UCB) stem cells have been successfully used for hematopoietic stem cell transplantation.<sup>10</sup> To date, more than 40,000 umbilical cord blood stem cell transplants have been performed with overall comparable clinical outcomes when compared to bone marrow or peripheral blood stem cell transplants.<sup>11,124,125</sup> UCB offers a multitude of pragmatic advantages over bone marrow or peripheral blood stem cells.

Two main types of UCB banks exist: public and private (Table 53.5).

Collectively, there are several hundred thousand UCB products available worldwide.<sup>126</sup> Some hospitals have in-house processing capabilities, whereas others rely on collection at site of delivery followed by shipment to a remote site for processing.<sup>127</sup> Several states, including California and Connecticut, have adopted an extensive public cord blood banking practice.<sup>12,28,129</sup>

The advantages of public cord blood banks over private cord blood banks include no financial burden to the donor, mandatory

**Table 53.5** Comparison of Public and Private Cord Blood Banks

Cord Blood Bank		
	Public	Private
Donor	Altruistic donor	Paying families
Ownership	General public	Paying families
Recipient	Unrelated persons requiring stem cell transplant	Member of paying family
Financial burden	Taxpayer	Paying families

international standards, searchable registries of products, broader availability to society, and higher probability of utilization.<sup>130–132</sup> The disadvantages of public cord blood banks over private cord blood banks are high discard rate of products that fail strict collection and storage criteria and reliance of governmental or grant funding that can shift abruptly. Given the inherent uncertainty of use of privately banked UCB products and their associated financial costs, hybrid models that employ cost sharing and transition opportunities for products to reach at need patients have evolved.

If a donor is deemed to be initially acceptable, a complete medical history and laboratory screening can be undertaken. Maternal infectious disease testing for hepatitis B, hepatitis C, HIV-1 and HIV-2, HIV, cytomegalovirus, syphilis, and in some programs human T-lymphotropic virus (HTLV)-I/II, malaria, Chagas disease, and West Nile virus needs to be performed.<sup>133,134</sup> In some regions, consent is obtained after successful collection of umbilical cord blood to ensure adequate collection has been achieved, reducing the burden and costs associated with screening in the prenatal or delivery time period.<sup>135</sup>

Especially given the relative scarcity of non-Caucasian donors for unmatched stem cell transplants, there remains an ever-present need to utilize UCB for transplants.<sup>136</sup> Notwithstanding the needs to maintain sufficient numbers of cord blood products, further outreach and funding are essential to recruit, optimize, and sustain an adequate umbilical cord blood inventory for diverse patient population such as the United States.<sup>137</sup>

### Stem cell thawing

Cryopreserved HPCs are less prone to injury if thawed expeditiously; however, just as with freezing, the thawing process has critical impact on sample quality and downstream utility. It is advisable to perform the thawing process at the bedside with close collaboration between the cell processing laboratory staff and the clinical

staff to ensure proper processing and handoff for a safe infusion. If excess DMSO is to be avoided or if overall volume reduction is required, washing of cryopreserved products can be undertaken, although this is rarely done.<sup>138,139</sup>

A warm water bath (37 °C) is used to thaw frozen products (vials, bags, or other products). The products themselves should have overlapping bags to ensure for visual checks of leaks or bag tears. Bags should be thawed one at a time and immediately administered via center venous catheter or intravenous access site once the product has reached 15 °C. High volumes of platelets and plasma proteins can lead to clumping of HPCs following the thaw processes.<sup>140</sup>

### Stem cell infusion

Whether a patient receives an autologous peripheral blood stem cell product, a matched unrelated allogeneic hematopoietic stem cell product, bone marrow, or umbilical cord blood product, there will always be clinical and product factors to consider at time of infusion.

Adverse reactions to HSC infusion are common and range in severity from mild to potentially life-threatening.<sup>141</sup> Common reactions include gastrointestinal manifestations such as nausea or vomiting, flushing, fever, malodor, hypertension and cough and more rarely respiratory compromise, seizures, or cardiac arrest.<sup>142–144</sup>

Frozen HSCs/HPCs must be suspended in a cryoprotective agent, typically dimethyl sulfoxide (DMSO), which can lead to histamine release, and nervous system abnormalities.<sup>145</sup> Though infused products generally contain less than 15% DMSO, further efforts have been made in certain conditions to remove DMSO prior to infusion, though this manipulation must be balanced against potential for cell loss.

Even in the absence of DMSO, preserved HSC infusion products can contain lysed cells, debris, metabolites, and electrolytes which may induce symptoms associated with infusion.<sup>146</sup> Symptoms associated with infusion are likely multifactorial and related not only to DMSO or substances within the product but clinical circumstances in individual patients as well.

Numerous steps are taken to ensure sterility of HSCs, and regulations, specifically by the US FDA, require microbiological cultures be performed on HSCs, despite this, contamination rates have been reported to occur between 0.2% and 26.3%.<sup>9–11</sup> The suspected etiology of this microbiologic contamination may be secondary to collection or transfer bag leaks or microfractures, inadvertent collection of skin plugs and associated skin commensal contaminants, subclinical donor bacteremia, or other etiologies.<sup>147,148</sup> Common organisms are Gram-positive skin commensal bacteria or rarely Gram-negative or fungal pathogens.

Infusion of products containing known infectious pathogens (usually bacteria) is occasionally necessitated due to clinical circumstance surrounding individual patients. Patients generally receive products with positive cultures under preparative regimen schedules and with appropriate antimicrobial therapy show no significant difference in outcomes.<sup>149</sup> Patients with viral illnesses such as hepatitis B or C and HIV require monitoring as well as prophylactic therapy for optimal outcomes, likewise special considerations must be undertaken for processing and storage of these products.<sup>110,111,150</sup>

### Stem cell collection and transfusion considerations in the COVID-19 pandemic

This ongoing catastrophic pandemic event has resulted in significant barriers to the collection and transport of donor cells. In an early report, case fatality rates in nonsevere and severe

COVID-19 infections were 0.1% and 8.1%, respectively.<sup>151</sup> Additionally, ongoing immunosuppression, mucositis, malnutrition, and/or graft-versus-host disease may increase the risk of complications in HCT patients with COVID-19. As such, a comprehensive high frequency inspection and evaluation for individual patients, donor, staff members, and programs remains essential in the pandemic era.

From a programmatic perspective, there are a number of expert consensus opinions related to stem cell transplant programs responsibilities in the COVID-19 era.<sup>152</sup> For low-risk patients with a confirmed COVID-19 diagnosis, these patients should be deferred for three months; however, for high-risk patients, serial weekly PCR testing resulting until negative times three and asymptomatic is believed to be sufficient. For patients without a known diagnosis of COVID-19 but have symptoms of an upper respiratory infection consider PCR testing and deferral, as well as adherence to local guidelines. Individuals with close contacts to a confirmed COVID-19 should also be tested and potentially deferred based on clinical status.

For stem cell donors in the COVID-19 era, any confirmed diagnosis of COVID-19 should almost always result in exclusion from donation. Additionally, recent travel to high-risk areas or close contacts with confirmed COVID-19 cases can result in donor deferral for at least 28 days with close monitoring.<sup>153</sup>

The American Society for Transplantation and Cellular Therapy (ASTCT) and the National Marrow Donor Program/Be The Match (NMDP) have also issued recommendations that unrelated donor products should be delivered and cryopreserved at transplantation centers before the initiation of patient conditioning. The NMDP now requires that grafts be delivered and cryopreserved at the transplantation center before the initiation of a transplantation conditioning regimen for any patient scheduled for unrelated donor hematopoietic cell transplantation (HCT) in the absence of unique considerations.<sup>154,155</sup> The balance for flexibility and patient/donor safety remains a challenge for transplant program. Clinical vigilance surveilling stem cell transplants for any increase in early graft failure or delays in platelet or neutrophil engraftment with newly found cryopreserved allogeneic donor products is essential.<sup>156</sup>

Further, the maintenance of the blood supply necessary for transplant patients has been under significant strain.<sup>157</sup> Clinical team members should remain vigilant in their blood use and continue to transfuse only when necessary. Evidence-based guidelines for transfusion practices in the stem cell transplant population include recommendations from the AABB to restrict red cell transfusion practice with a hemoglobin threshold of 7 g/dL in a majority of patients.<sup>158</sup> Randomized controlled trials in oncology patients comparing liberal versus restricted transfusion strategies have identified that lower hemoglobin thresholds of 7–9 g/dL are no worse than liberal transfusion triggers of 10 g/dL or higher.<sup>159</sup>

Prophylactic transfusion of platelets should occur at a threshold of 10,000/µL for all hospitalized patients. The TOPPS trial demonstrated reduced bleeding with prophylactic transfusion in patients below this level and similar trial compared prophylactic transfusion at 10,000/µL versus platelet transfusion for symptomatic bleeding among acute myeloid leukemia and autologous stem cell transplant patients.<sup>160,161</sup>

Joint statements from the AABB, America's Blood Centers, and the American Red Cross underscore the importance of judicious use of these limited biologic products for transfusion, as well as encouraging the donation of blood if individuals are willing and able.<sup>162</sup> One area of ongoing debate is whether outpatient stem cell

recipients should have the same transfusion triggers as inpatients. Theoretically, inpatients can be more conservatively managed, given that they remain at the hospital and can be transfused if the need arises. Further study is needed in this area to optimally manage scarce resources.

## Regulation

The US Food and Drug Administration's Center for Biologics Evaluation and Research (CBER) is responsible for the regulation of cellular and tissue-based therapies. Additionally, the Center for Devices and Radiological Health (CDRH) is tasked with regulatory oversight of medical devices and safe-radiation-emitting products.

For any product that does not meet the FDA standards set forth under 21 CFR 12710(a), these products are regulated under the Federal Food, Drug, and Cosmetic Act (FDCA) and Section 351 of the PHS Act.

To comply with the myriad of legal requirements set forth by the US FDA, several national and international nonprofit organizations and professional bodies have developed comprehensive programs for stem cell transplant clinical programs, apheresis/bone marrow

collection facilities, and cellular therapy laboratories. The overarching goals of these organizations are to ensure maintenance of current good tissue practice, donor screening, and donor testing throughout the life of a cellular product from initiation of donor selection, processing, storage, release, and administration to the end patient.

## CHAPTER 54

# HLA antigens, alleles, and antibodies

Scott M. Krummey<sup>1</sup>, Robert A. Bray<sup>2</sup>, Howard M. Gebel<sup>2</sup>, & H. Clifford Sullivan<sup>2</sup>

<sup>1</sup>Department of Pathology, Johns Hopkins Hospital, Baltimore, MD, USA

<sup>2</sup>Department of Pathology, Emory University Hospital, Atlanta, GA, USA

In 1958, Professors Jean Dausset, Jon van Rood, and Rose Payne detected and reported on what were the first HLA antibodies.<sup>1–3</sup> Dausset's discovery was with serum from a patient who had received multiple blood transfusions, while van Rood and Payne's observations were in sera obtained from multiparous women. Originally thought to be autoantibodies responsible for nonhemolytic transfusion reactions, subsequent studies determined them to be alloantibodies<sup>6</sup> with their target antigens expressed on the cells of most tissues.<sup>4</sup> Due to inconsistent results with the assay used to identify HLA antibodies (leukoagglutination), further advances were understandably limited. This changed with the introduction of the microlymphocytotoxicity assay (also known as the complement-dependent cytotoxicity [CDC] assay) developed by Terasaki and McClelland.<sup>5,6</sup> The CDC assay became the gold standard for both HLA antibody testing and HLA antigen testing, remaining so until the worldwide adoption of solid-phase antibody detection assays and nucleic-acid-based technology to HLA antigens/alleles.<sup>7,8</sup>

In 1964, Dr. Bernard Amos organized the first International Histocompatibility where 23 pioneering investigators participated in a “wet workshop” to study HLA antigens and antibodies.<sup>9</sup> There have since been 16 additional workshops (Table 54.1), all designed to (1) confirm scientific observations; (2) develop unifying concepts regarding the major histocompatibility complex (MHC), and (3) update HLA nomenclature. In the third workshop (1967), it was established that HLA antigens all belonged to the same genetic system.<sup>10</sup> The term HL-A (a combination of the Hu leukocyte system and the LA system named by Dausset *et al.*<sup>11</sup> and Payne *et al.*,<sup>12</sup> respectively) was assigned to identify this system. The “-” was dropped when it became apparent that there were at least two genes (HLA-A and HLA-B) that encoded the antigens.<sup>13</sup> HLA-C antigens and antibodies were then identified.<sup>14</sup> Skin grafting studies in human subjects involving HLA-identical siblings then helped determine that these antigens were important in organ transplantation.<sup>15</sup> An assay known as the mixed lymphocyte culture identified a fourth HLA region (HLA-D),<sup>16,17</sup> which is now known to be composed of three separate loci (HLA-DR, HLA-DQ, and HLA-DP).<sup>18</sup> Other aspects of the HLA system were also recognized. By 1973, the association between HLA and a variety of diseases was recognized.<sup>19,20</sup> Then, between 1980 and 1987, advances in biochemistry

and molecular biology plus the development of monoclonal antibodies to HLA antigens and understanding of the biology of the MHC dramatically expanded.

## Major histocompatibility complex

The Class I, II, and III genes of the MHC are distributed over a 4-megabase region on the short arm of chromosome 6.<sup>21</sup> The telomeric end of the MHC contains 2000 kb and >200 polymorphic genes, including those encoding the Class I antigens (Figure 54.1). The classical Class I HLA-A, HLA-B, and HLA-C genes reside there as do the nonclassical MHC-Ib genes HLA-E, HLA-F, and HLA-G. The MHC Class I chain-related genes MICA and MICB are located between the HLA-B locus and the tumor necrosis factor loci. These genes encode proteins that interact with the activating NKG2D receptor on T cells and NK cells.<sup>22</sup>

Centromeric to the HLA-B locus is the 1-megabase segment Class III region (Figure 54.1).<sup>21</sup> This region has a dense and diverse array of genes which encode proteins associated with innate immunity and inflammation such as complement components C2, C4, and Bf (factor B protein of the alternate pathway of complement activation).

Centromeric to the Class III region and containing ~1 megabase of DNA are the Class II gene loci (Figure 54.1).<sup>21,22</sup> Within this region there are at least 18 closely linked loci that encode the  $\alpha$  and  $\beta$  chains of the Class II antigenic proteins. Proceeding from the telomeric to the centromeric boundaries of the region, the first gene cluster is composed of several  $\beta$ -chain loci and one  $\alpha$ -chain locus that encode the HLA-DR antigens. The DRB1 locus encodes for the DR1 to DR18 specificities, while the DRB3, DRB4, and DRB5 loci encode for the DR52, DR53, and DR51 antigens, respectively. Centromeric to the DRB genes are the DQ (DQA and DQB) and DP (DPA and DPB) genes which encode for HLA-DQ and HLA-DP antigen specificities (Figure 54.1). Other genes with important accessory functions to Class I and II antigen presentation are contained in the Class II region and include LMP2 and LMP7 genes, TAP1 and TAP2 genes, and tapasin. These genes encode proteins that participate in protein degradation and peptide transport and loading in the Class I system.<sup>23</sup> HLA-DM and HLA-DO loci encode proteins involved in peptide loading in the Class II system.

## Class I and II antigens and their function

The structure, tissue distribution, and function of the expressed proteins of Class I and Class II genes differ considerably. Both Class I and Class II antigens are heterodimeric, having three to four extra-

cellular domains in addition to transmembrane and cytoplasmic regions (Figure 54.2).<sup>21</sup> Class I antigens are composed of a 45,000-D  $\alpha$  chain encoded by the HLA-A, HLA-B, and HLA-C gene loci. This heavy chain is noncovalently bound to a nonpolymorphic 12,000-D light chain,  $\beta_2$ -microglobulin, encoded on chromosome 15.  $\beta_2$ -Microglobulin stabilizes the Class I complex; however, studies have shown that  $\beta_2$ -microglobulin-free, Class I heavy chains can be expressed and may present peptides.<sup>24,25</sup> The  $\alpha_1$  and  $\alpha_2$  domains contain variable amino acid sequences and thus provide the antigenic polymorphisms that serologically define individual HLA antigens. The  $\alpha_3$  domain may also contain polymorphic residues, but it is believed that these do not contribute significantly to the antigenic nature of Class I molecules.

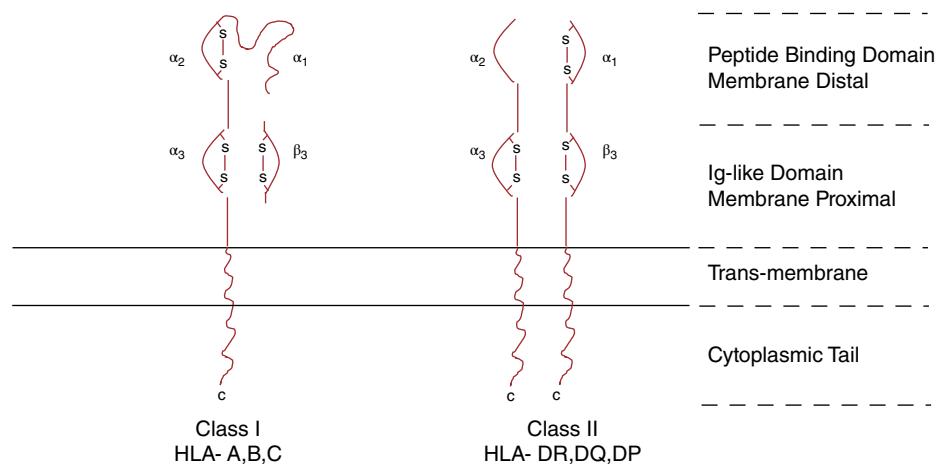

The  $\alpha_3$  domain of the heavy chain and  $\beta_2$ -microglobulin are noncovalently associated with each other near the cell membrane. The  $\alpha_1$  and  $\alpha_2$  domains sit on top of them and form a peptide-binding groove. This pocket has a floor of eight flat  $\beta$  sheets bounded by two long  $\alpha$  helices, as illustrated in Figure 54.3B. Most of the polymorphic amino acid changes of the Class I histocompatibility antigen differences are associated with the floor or sides of this pocket, although some map to other domains.<sup>26,27</sup>

Class II antigens are composed of a 33,000-D  $\alpha$  chain noncovalently associated with a 28,000-D  $\beta$  chain (Figure 54.2). The  $\alpha$  chain is encoded by the A gene loci and the  $\beta$  chain by the B gene loci in the HLA-D region of the MHC. For example, the DR antigen  $\alpha$  and  $\beta$  chains are encoded by the DRA1 and DRB1 genes, respectively. The  $\alpha_1$  and  $\beta_1$  domains form an antigen-binding groove similar to that described earlier.<sup>28</sup>

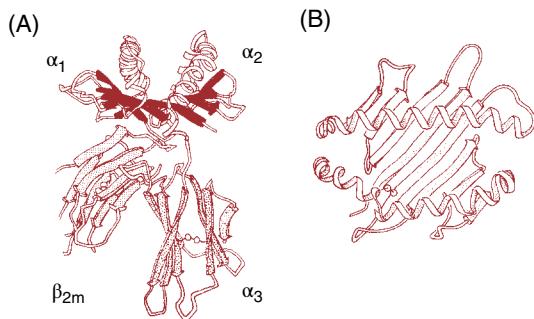

Class I antigens are expressed on the surface of all nucleated cells and platelets. Though some studies have demonstrated low expression of HLA-C antigens on platelets,<sup>29</sup> other studies suggest that this low expression is insufficient to clear platelets in the face of corresponding HLA-C locus antibodies.<sup>30</sup> Class II antigens have a limited tissue distribution primarily on antigen presenting cells, such as B lymphocytes, macrophages, and dendritic cells, although they can be induced in several cell types, including activated T cells and endothelial cells.

**Figure 54.1** Selected genes in the major histocompatibility region on human chromosome 6 in the Class I, II, and III regions. Distances between loci are not drawn to scale.

**Figure 54.2** Simplified illustration shows the biochemical structure of Class I and II antigens.

**Figure 54.3** (A) Side view of Class I antigen molecule. (B) View of the antigen-binding pocket looking down toward the cell membrane. Source: Adapted from Bjorkman *et al.* (1987).<sup>26</sup>

Class I and II molecules can acquire both self- and non-self-peptides in their binding cleft. This peptide-MHC complex is responsible for the presentation of peptides to T-cells via the T-cell antigen receptor.<sup>31</sup> During the selection process, T cells that bind with high affinity to self-peptides in the context of an individual's Class I and II molecules are either deleted or suppressed by a variety of mechanisms to prevent autoimmune disorders. However, peptides derived from viruses, bacteria, and some parasites that are presented by the individual's Class I and/or Class II molecules to T-cells can evoke an immune response. Class I molecules primarily present peptides of approximately 8–10 amino acids that have been generated via the degradation of cytoplas-

mic proteins in the proteasome system. Class I antigens function as MHC restriction elements in the destruction of virus-infected target cells and present peptides to CD8 cytotoxic T cells. Class II molecules bind peptides of approximately 13–25 amino-acids, derived from exogenous and endogenous origins, that have been degraded within the endosomal system. Class II antigens function as MHC restriction elements and present peptides to CD4 helper T cells. Activation of CD8 and CD4 T cells then results in the cellular expansion and differentiation into the cellular and humoral immune responses.<sup>31</sup>

### Nomenclature and polymorphism of the HLA system

Table 54.2 illustrates the HLA gene loci, the variable polypeptide chains, the number of related serologic specificities, and the number of alleles within each specificity. In the Class I region, the HLA-A, HLA-B, and HLA-C loci are all highly polymorphic with more than 20,000 known alleles.<sup>32,33</sup> Multiple alleles are present within most of the known serotypes. For example, the A2 serotype has more than 900 alleles. In the Class II region, the HLA-DRA locus is almost monomorphic, whereas DRB1 is highly polymorphic, with nearly 3000 known alleles and ~2000 expressed proteins. The DQA1 and DQB1 genes and the DPA1 and DPB1 loci demonstrate similar but less extensive polymorphism.

DPA1 and DPB1 allelic variation can be detected with DNA typing while a significantly lesser number can be distinguished with serologic testing.<sup>34</sup> It is important to note that the serological reactivity of many HLA alleles, not just DPB1, has not been tested. One

**Table 54.2** HLA Nomenclature

Genetic Locus	Encoded Polypeptide	Antigenic Specificity	Alleles	Number of Known Alleles/Proteins
HLA-A	α	A1 to A80	A*01:01 to *80:07	6425/3929
HLA-B	α	B5 to B82	B*07:02 to *83:01	7754/4885
HLA-C	α	Cw1 to Cw10	C*01:02 to *18:14	6329/3719

DRB1	β1	DR1 to DR18	DRB1* 01:01 to *16:68	3621/2504
DQA1	α		DQA1* 01:01 to *6:02	279/124
DQB1	β1	DQ1 to DQ9	DQB1* 02:01 to *06:385	1968/1288
DPA1	α1		DPA1*01:03 to *04:02	233/92
DPB1	β1	DPW1 to DPW6	DPB1*01:01 to *1167:01	1674/1081

The number of polypeptides known for each locus reflects unique amino acid sequences encoded by a larger number of alleles that may differ only by silent polymorphisms. Above data can be found at <https://www.ebi.ac.uk/ipd/>, release 3.43.0, January 2021.

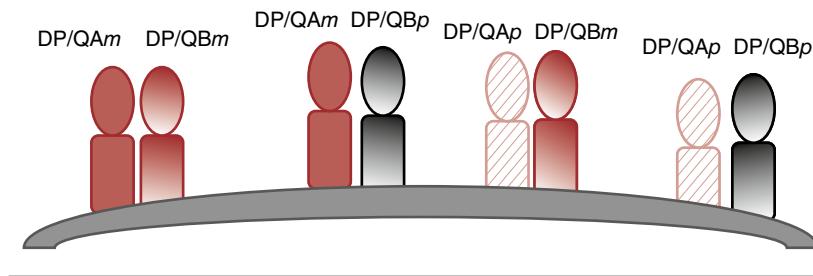

additional aspect that adds to the polymorphic diversity of both DP and DQ alleles is their ability to form heterodimeric isoforms. For certain DQA/DQB combinations, an individual heterozygous for both alpha and beta chains may produce surface heterodimers formed from both cis- and trans-linked alleles (Figure 54.4). Thus, rather than expressing two DQA/DQB heterodimers, one from each parental haplotype, a cell may express up to four different heterodimers. Note that not all DQA/DQB heterodimers are even possible as there are physical constraints as to which dimers can be formed.<sup>35</sup>

The HLA system is the most polymorphic genetic system known to exist in humans. The number of different phenotypes possible from all combinations of HLA alleles is greater than the global population. New alleles appear to emerge at a fairly constant rate and become fixed in populations. New alleles are generated by means of point mutation, recombination, and gene conversion-like events.<sup>34,36</sup> It is clear though that the HLA system is unique in that it appears to embrace or, at the very least, be tolerant of new mutations. When a new mutation does arise in an HLA gene, unless the mutation prevents transcription, translation, or expression, the new HLA molecule may merely bind a unique set of peptides. Whether these new alleles confer a survival advantage is unknown.

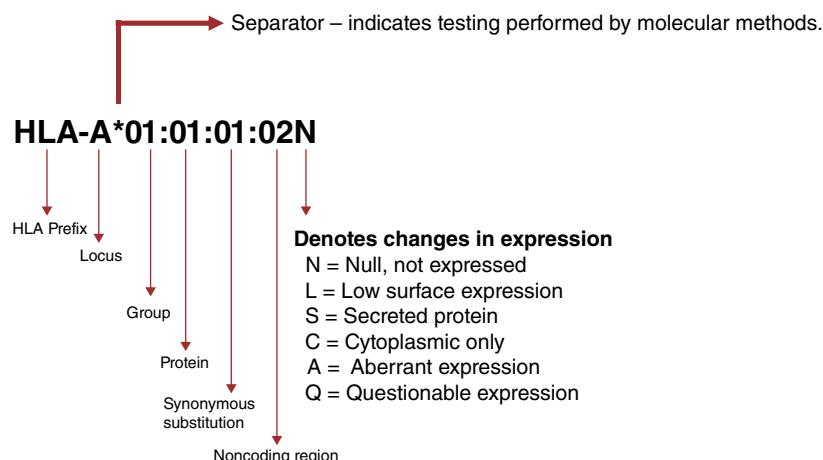

The nomenclature of the HLA system is established by an international committee sponsored by the World Health Organization and is updated frequently.<sup>37,38</sup> Figure 54.5 shows the general scheme for designating HLA antigens and alleles. Each serologic specificity is prefixed by the genetic system designation HLA-, followed by a

letter denoting the encoded antigen (e.g., A, B, C, DR, or DQ). This letter is followed by digits, arranged in distinct fields, indicating the exact allele specificity.<sup>37</sup>

The nomenclature of the HLA system was first established with serologic data. Molecular data were introduced later according to the precise DNA sequences of each allele. The existing nomenclature had to be modified to accommodate this information. For Class I alleles, because only the  $\alpha$  chain is variable, the molecular designation is the system (HLA-), the locus (A, B, or C), an asterisk (\*), followed by up to four fields of digits separated by colons. All alleles receive at least a four-digit name, which corresponds to the first two fields; longer names are assigned when necessary (see Figure 54.5). The first field corresponds to the serologic specificity while the second field denotes the expressed protein. For example, HLA-A\*03:01 is the first molecular allele of the HLA-A3 serologic specificity, and HLA-A\*03:02 is the second. In the Class II region, because both the  $\alpha$  and  $\beta$  chains can be variable, the locus designation must include the polypeptide chain responsible for the allele. For example, Class II, HLA-DRB1\*15:01 is interpreted as HLA system, DR locus,  $\beta 1$  polypeptide chain (B1), DR15 serologic specificity, first molecular allele (01). For molecular alleles that have no serologic equivalents, alleles are sequentially numbered, for example, HLA-DQA1\*01:01 is the first molecular allele of the  $\alpha_1$  polypeptide chain of DQ. The third and fourth fields are employed to designate alleles with silent polymorphisms and with variation occurring outside exons, respectively (Figure 54.5).

**Figure 54.4** Possible expression isoforms for DPB/A and DQB/A that could arise in a fully heterozygous individual. DP/Q = either DPB/A or DQB/A. *m*: maternal haplotypes; *p*: paternal haplotypes.

\* Historic, no longer commonly used in clinical practice

### Identification of HLA antigens and alleles

Three methods have been used for the detection of HLA antigens and alleles (Table 54.3). Serologic detection of HLA antigens by the microlymphocytotoxicity assay utilizes the addition of rabbit serum to HLA antibodies fixed to the membrane of peripheral blood lymphocytes to cause cell death. Vital dyes that enable identification of dead cells can then be used to deduce the presence of particular HLA antigens. Modifications of this test, primarily an increase in incubation time and isolation of B lymphocytes from peripheral blood, allowed for typing for the HLA-DR and -DQ antigens.<sup>39</sup> Variations of the mixed leukocyte reaction with homozygous testing cells, primed lymphocytes, or T-cell clones were historically used for detecting HLA-DR, HLA-DQ, and HLA-DP antigens.<sup>40–42</sup>

Over the last decade, serologic and cellular based approaches have been replaced by sequencing-based methods. The application of DNA-based techniques to the field of histocompatibility has led to an unprecedented expansion in knowledge of the MHC at the molecular level.<sup>37</sup> More specifically, sequence-based HLA typing methods have produced the following advances:

- They have revealed the underlying DNA sequence variations among individuals (and, therefore, amino acid variations) responsible for the antigenic differences in HLA molecules detectable with traditional serologic and cellular HLA testing.
- They have made apparent the fact that results of serologic HLA tests define only broad groups of Class I and Class II alleles. Numerous subgroups of alleles distinguishable by sequence differences are present within these broad serologic groups. The result is a very large number of known alleles.<sup>43</sup>
- Sequence data have allowed detailed definition of the genetic basis of the HLA-mediated disease associations described later in this chapter.

The success and precision of these methods have rendered serologic and cellular methods essentially obsolete for the purposes of clinical transplantation testing. Several sequenced-based methods have been developed and are in widespread use. Sequence-based genotyping methods focus on the antigen-binding regions of HLA Class I (exon 2 and exon 3) and Class II (exon 2), respectively, for the identification of HLA alleles (with the exception of NGS, as discussed below).

### Sequence-specific oligonucleotide probe hybridization (SSOP)

Relevant regions of the Class I and Class II genes are amplified from genomic DNA by means of the polymerase chain reaction (PCR) with two oligonucleotide primers that anneal to 5' and 3' flanking regions that are conserved (are identical) among individuals. These primers are locus-specific (e.g., amplify HLA-A but not the related HLA-B locus), can amplify all known alleles at a locus, and result in

roughly equal amplification of the two alleles in a heterozygous individual. After the PCR, the amplified DNA is denatured and labeled with biotin, and hybridized to a bead array containing a range of individual allele-specific DNA probes. Following the addition of streptavidin linked to a fluorescent probe, the identity of the HLA alleles can be deduced using the combination of positive and negative signals in the hybridized bead array.

### Sequence-specific primer polymerase chain reaction (SSP and real-time PCR)

Sequence-specific primer assays have been adapted to HLA genotyping in end-point PCR and real-time PCR formats. In both formats, multiple separate reactions are conducted for Class I and Class II genes in order to assess the HLA genotype at intermediate resolution. In endpoint analysis, PCR primers are designed with 5' ends that bind to conserved sequences and 3' ends that are complementary to HLA gene sequences of particular alleles.<sup>44</sup> Thus, only DNA sequences complementary to the allele-specific 3' end will result in DNA amplification, and other alleles will not amplify. Gel electrophoresis can then be used to detect the presence or absence of PCR products of the appropriate size, and hybridization assays are avoided. Sequence-specific PCR is most useful for intermediate-resolution HLA typing and for initial quick identification of broad antigen groups, such as DR52. Real-time PCR approaches utilize 100 or more combination of sequence-specific primers, and commonly used fluorescent real-time, such as Sybr Green. The combination of positive and negative reactions can quickly be interpreted by computer algorithms in order to provide HLA genotyping that is typically at the level of allele groups.

### Next-generation sequencing (NGS)

Next-generation sequencing has recently been adapted to HLA genotyping, and its use in clinical practice has grown exponentially in the last several years. The major advantage to NGS for HLA genotyping is the generation of full-length gene sequence data, which allows for unambiguous high-resolution HLA genotyping and phasing of HLA genotypes such that haplotypes can be determined. NGS also allows sequencing beyond the antigen-binding site, and thus has also led to the identification of many novel alleles. Limitations to NGS are the extensive hands-on time required to complete NGS assays, the length of time required to complete the genotyping and produce results, and the large amount of data generated.<sup>45</sup> However, all of these limitations are rapidly being addressed as NGS is adopted more widely. Currently, there are several vendors that offer NGS-based HLA genotyping platforms, and the methods and analysis software are updated frequently. HLA genotyping by NGS has been conducted using third-generation sequencing platforms with workflows that range from 2 to four days. However, newer methods in development, such as the Oxford Nanopore platform, offer the potential for NGS-based typing in only a few hours.<sup>46</sup>

### Choice of HLA typing method

Several factors influence the decision to use one HLA typing method over another, and often multiple methods are used in combination in a given laboratory. Sequence-specific real-time PCR can be performed in a relatively short time (3–5 hours) that accommodates clinical situations such HLA typing of deceased donors in the setting of solid organ transplantation. SSP, SSOP, and NGS are used in less time-sensitive situations, such as solid organ transplant

candidate genotyping and stem cell transplantation. In these cases, allele-level HLA matching of donors and recipients is desired and turnaround times of a few days to a week are acceptable. In regard to test volume, SSP platforms are generally optimized to run one patient sample at a time, whereas SSOP and NGS permit batching of patient samples to be run simultaneously.

### Genotypes, phenotypes, and haplotypes

The HLA locus has several defining molecular genetic features. First, HLA genes are expressed codominantly such that both copies of each HLA gene are expressed. This property is one that made antigen-level HLA typing important (and complicated) before the advent of sequencing-based techniques. Second, HLA genes are closely linked on chromosome 6, and they are inherited together as haplotypes. Thus, each child inherits two complete HLA haplotypes, one from each parent.

Figure 54.6 illustrates the segregation of haplotypes in a family of seven, focusing on the A, B, Cw, and DR serologic specificities. HLA genotyping of a single individual does not allow definitive assignment of the HLA haplotypes. For example, if sibling 3 was genotyped in isolation, one cannot be certain whether the DR7 is present on the chromosome carrying B8 or B13. However, the analysis of the typing data for the entire family and the transmission of specificities to the children make it possible to phase each of the pairs of parental chromosomes and to determine haplotypes. Each child in this family inherits a paternal [a] or [b] haplotype and a maternal [c] or [d] haplotype, and also differs from each parent by one HLA haplotype. Because there can be only four parental haplotypes, the chances are 1 in 4 that the siblings will have the same paternal–maternal haplotypes (i.e., HLA-identical), 1 in 2 that siblings will differ by one haplotype, and 1 in 4 that they will differ by two haplotypes. For example, siblings 4 and 5 are HLA-identical, and sibling 4 shares one haplotype with siblings 2 and 3 but no haplotypes with sibling 1. There are infrequent exceptions to haplotype inheritance due to recombination within the HLA locus during meiosis.

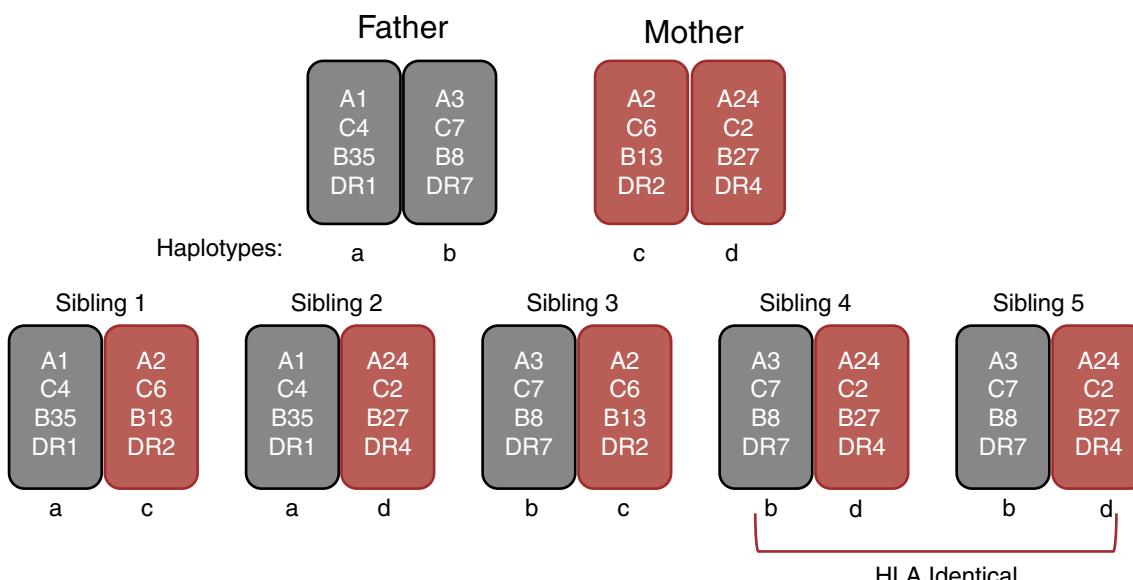

Finally, on a population level, there is strong linkage disequilibrium within the HLA loci such that certain populations have higher frequencies of particular HLA alleles based on geography and ethnicity. Linkage disequilibrium means that in randomly mating populations, the haplotype frequency for two or more linked gene loci is significantly higher than would be expected by chance alone. Some HLA alleles and haplotypes are widely distributed around the globe, and others are almost exclusively within a particular ethnic group. The expected frequency is obtained from the product of the gene frequencies of the involved genes. For example, among persons of European ancestry, the observed A1, B8 haplotype frequency (7.0%) is approximately 4.4 times greater than the expected haplotype frequency (1.6%). These excess haplotype frequencies may exist for a variety of reasons, including high prevalence in the founders of a population and selective pressure from infectious organisms.<sup>47</sup>

### Medical and biologic significance of HLA

The HLA system plays a role in several areas of biomedical significance, including the following:

- Antigen presentation
- Association with certain diseases
- Population genetics and anthropology
- Transfusion Medicine
  - Management of immune mediated platelet refractoriness (see Chapter 16)
  - Febrile nonhemolytic transfusion reactions (see Chapter 48)
  - Transfusion-related acute lung injury (see Chapter 49)
  - Transfusion-associated graft-versus-host disease (see Chapter 50)
- Solid organ and stem cell transplantation

For the purposes of this chapter, we focus on the role of HLA in transplantation and disease association, as the role of HLA in Transfusion Medicine is covered in more detail in the chapters noted above.

**Figure 54.6** HLA-A, HLA-B, HLA-C, and HLA-DR antigens segregating as haplotypes in a family. The data reflect the genotypes of each family member as well as the parental haplotypes.

## Transplantation

HLA and ABO are inherited independently from each other on different genes and separate chromosomes, and both need to be considered in the setting of transplantation. In regard to histocompatibility, the extreme polymorphism of the HLA loci makes it unlikely that an unrelated donor of cells, tissues, or organs will be matched at an allele level or at a serologic level with a recipient without a concerted effort to identify matched donors and recipients. One solution is to identify an HLA-identical sibling, but many potential transplant recipients do not have access to these donors. For solid organ transplantation, powerful immunosuppressant drugs have made transplantation feasible with mismatched living and cadaveric donors and recipients. However, better HLA-A, HLA-B, and HLA-DR matching at a serologic level generally increases the half-life of the transplanted organ and decreases overall morbidity.<sup>48</sup> Thus, zero HLA-A, HLA-B, and HLA-DR mismatched deceased donor kidney transplants are given high ranking priority in the kidney allocation scheme.<sup>49</sup>

Finding well-matched donors of hematopoietic stem cells if there are no HLA-identical siblings is facilitated by resources such as the National Marrow Donor Program, which has enrolled several million potential donors with known HLA types.<sup>50</sup> The goal for unrelated stem cell donation is increasingly allele-level matches for HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1, and HLA-DPB1, although the level of mismatching permissible is incompletely understood. Subtle allelic mismatches between stem cell donors and recipients appear to increase the risk of severe graft-versus-host disease and decrease overall survival.<sup>51,52</sup> The use of umbilical cord blood stem cells and the depletion of T cells from transplanted cells may allow greater donor-recipient mismatches.<sup>53,54</sup> Retrospective studies are continuing to assess in a definitive manner the level of matching necessary for successful stem cell transplantation.<sup>55</sup> Hematopoietic stem cell transplantation is discussed in Chapter 53.

Two major mechanisms by which Class I and II donor-recipient mismatches may adversely affect transplantation are cell-mediated rejection and production of HLA antibodies. Donor HLA antigens mismatched with recipient HLA antigens can elicit a strong cell-mediated immune response. Recipient T cells are able to recognize and respond to donor mismatched HLA antigen.<sup>56</sup> These responses contribute to acute rejection in organ transplantation and graft-versus-host disease in stem cell transplantation. HLA matching and immunosuppressive therapy help to mitigate this problem. Transplant recipients become sensitized or produce antibodies directed against Class I and Class II specificities through several routes.<sup>57</sup> Exposure to fetal HLA molecules encoded by paternal haplotypes during pregnancy, especially multiple pregnancies, can lead to the presence of long-lasting, high-titer HLA antibodies. Similarly, mismatched HLA antigens from previous organ donors and donors of transfused blood components can lead to sensitization. The presence of recipient preformed HLA antibodies may lead to hyperacute rejection of a donor organ bearing the relevant HLA specificities.<sup>58</sup> Therefore, laboratories maintain serum-screening programs to detect and identify HLA antibodies in waiting recipients so that inappropriate donors can be avoided. Some transplant centers have developed desensitization protocols that employ plasmapheresis and a variety of immunosuppressive/immunomodulatory agents in attempts to reduce and decrease production of HLA antibodies, respectively, thereby facilitating transplantation either by removing donor-specific HLA antibodies or widening the pool of compatible donors.<sup>59,60</sup>

## Identification of HLA antibodies

Detection of HLA-specific antibodies is critical in both solid organ and stem cell transplantation. Pretransplant, HLA antibodies can limit access to transplantation and may cause early allograft rejection or failed stem cell engraftment. Post-transplant, donor-specific HLA antibodies (DSAs) can lead to untoward consequences, such as antibody-mediated rejection and/or graft loss in renal, heart, lung, and liver transplants.<sup>61-65</sup> The clinical impact of HLA antibodies helped propel antibody testing forward from historical serologic tests to current solid-phase methods.<sup>66</sup> While the importance of HLA antibodies in solid organ transplant has been recognized for many years, the clinical relevance of HLA antibodies in hematopoietic stem cell transplantation has recently gained greater recognition with the increasing use of haploidentical transplantations.<sup>67</sup>

### Serological assays

Historically, HLA antibody testing was performed utilizing a complement-dependent cytotoxic assay (CDC) for both antibody identification and crossmatching. The panel-reactive antibody (PRA) test is another serological assay used to assess the breadth of HLA sensitization. The CDC assay is employed to test recipient serum against panel of cells from donors with varied HLA types. The number of positive reactions corresponds to the degree of HLA alloimmunization. For example, if 15 of 30 panel cells showed positive reactions, then the PRA would be 50%. However, these serological assays were complicated, required extensive quality control, and had a number of drawbacks.<sup>68</sup> More recently, the flow cytometric crossmatch was developed permitting direct identification of HLA antibody with fluorescently conjugated secondary antibodies independent of complement engagement. However, even with these advancements, there were drawbacks such as the need for viable cells and limited specificity. Such limitations could produce false-positive reactions precluding truly compatible transplantation.<sup>69</sup> Fortunately, the advent of solid-phase HLA antibody testing helped alleviate many such shortcomings.

### Solid-phase testing

Solid-phase testing further honed HLA antibody identification to the point where unique HLA antibody specificities could be determined. In lieu of viable cells, solid-phase testing utilized HLA antigens adhered to plastic matrices (e.g., microtiter plates or microparticle spheres). HLA proteins could be either purified native HLA antigens or single recombinant HLA Class I or II molecules.<sup>70</sup> Solid-phase platforms include ELISA, flow cytometry, and Luminex<sup>TM</sup> technologies. Currently, the Luminex platform is the most widely used technology in modern HLA laboratories. Recipient serum is incubated with hundreds of microparticle beads, each coated with a distinct HLA antigen.<sup>71</sup> Fluorescently labeled secondary antibody is then added prior to running the sample on a high throughput flow cytometer. This method permits the simultaneous detection of multiple HLA antibodies and their respective specificities, which is particularly useful in highly sensitized patients with complex antibody profiles, including allele-specific antibodies.<sup>72</sup> The HLA solid-phase Luminex assays used in most clinical laboratories report mean fluorescence intensity (MFI), which is at best a semiquantitative value that is not necessarily a reflection of the antibody titer and/or strength.

### The calculated PRA and virtual crossmatch

Solid-phase testing has led to the development of two major concepts in modern-day transplantation: the calculated PRA (CPRA)

and the virtual crossmatch (VXM). Whereas the aforementioned serologic PRA test relies on HLA types among a panel of cells, CPRA considers the antigen frequency in the general donor population.<sup>73</sup> Antigens to which recipients have corresponding antibody will be listed as unacceptable antigens. The CPRA is calculated as the collective frequency of the total number of these unacceptable antigens in a population. Therefore, the CPRA provides a more accurate assessment of the probability of finding a compatible donor compared to the conventional PRA.<sup>74</sup> For example, the overall frequency of HLA-A\*02 is approximately 48% in the US donor population; as such, a recipient with an A\*02 antibody would have a CPRA of 48%. Consequently, that individual would be expected to be compatible with approximately 52% of the donor population.

Akin to the electronic crossmatch in the blood bank, the VXM is an *in silico* assessment of recipient:donor histocompatibility. In lieu of performing a physical crossmatch, the VXM is performed by comparing the recipient's HLA antibodies to the donor's HLA antigens to determine the presence/absence of DSAs. If the donor expresses HLA-B\*27 and the recipient has B\*27 antibodies, then the VXM is considered positive. In this manner, the VXM has been shown to be effective in predicting the physical crossmatch.<sup>75</sup> Given that the VXM can be performed in a matter of minutes versus hours it takes to perform a physical crossmatch, the VXM can shorten time to transplant, decrease cold-ischemia time of allograft, and increase organ sharing between regions.<sup>76–78</sup> The VXM is becoming heavily relied upon as a predictor of compatibility pretransplantation.<sup>79–81</sup> Despite the advantages of the VXM, it is important to note that it is only as reliable as the quality of recipient antibody testing and accuracy of donor HLA typing upon which it is based. As with all assays, solid-phase antibody testing and molecular HLA typing have shortcomings that can preclude accurate VXM interpretation. Hence, there are still instances when the physical crossmatch has clinical utility.

### Epitopes

In recent years, focus in the field of histocompatibility has shifted from the antigens and alleles to epitopes and eplets (these terms are often used interchangeably although not exactly equivalent). If the antigen or allele was a puzzle, the epitopes would be the pieces that comprise the puzzle. Structurally, eplets are considered the antigenic components of the protein to which antibody can bind (i.e., "functional epitopes"). Eplets can be linear amino acid sequences or noncontiguous three-dimensional areas created as a result of protein folding. In solid organ transplant literature, eplet analysis has focused on quantifying donor-recipient pair eplet mismatches in relation to risk of poor transplant outcomes. Studies have shown that the number of eplet mismatches, particularly for HLA-DR and HLA-DQ loci, have correlated with de novo DSA formation and graft rejection.<sup>82,83</sup> Other studies have identified potential immunogenic eplets that may predispose to de novo DSA formation.<sup>84</sup> Lists of clinically relevant epitopes/eplets (i.e., antibody confirmed) and theoretical epitopes/eplets (i.e., antibody nonconfirmed) can be found at the HLA Epitope Registry website (<https://www.epregistry.com.br/>). In relation to transfusion medicine, recent publications have investigated the use of epitope matching using HLA Matchmaker software (<http://www.epitopes.net/>) for obtaining matched platelets in alloimmunized patients experiencing HLA-mediated platelet refractoriness.<sup>85</sup>

### Disease association

The association of certain HLA alleles and their encoded antigens with particular diseases, especially autoimmune disorders, has been

**Table 54.4** Selected Disease and Pharmacologic Associations with HLA Alleles

Disorder	HLA Linkage
Ankylosing spondylitis	B*27 alleles
Narcolepsy	DQB1*06:02
Celiac disease	DQ2.5, DQ2.2, and DQ8
Birdshot chorioretinopathy	A29
Behçet's disease	B51
Type 1 diabetes mellitus	DRB1*03/*04 (often inherited with DQB1*02 and *03 alleles)
Rheumatoid arthritis	DRB1*04
Abacavir hypersensitivity	B* 57:01
Allopurinol hypersensitivity	B*58:01
Carbamazepine hypersensitivity	B*15:02

known for some time. In more than 100 disorders, there is significant deviation in the frequency of HLA antigens from that of healthy controls (Table 54.4).<sup>86</sup> In general, HLA-associated diseases have certain common features. They are known or suspected to have an inherited component, usually have autoimmune features, and display a clinical course often featuring repeated acute relapses followed by remission. For most HLA-associated diseases, the etiologic factor and pathophysiological mechanism are incompletely understood. Possible mechanisms proposed include the following: presentation of pathogenic autoantigens or hybrid antigens (alternatively spliced self-peptides) to T-cell receptor, molecular mimicry whereby pathogenic peptides induce target T-cell reactivity with self-peptides, and linkage disequilibrium of HLA gene with the disease susceptibility gene.<sup>87</sup>

Two of the strongest HLA associations are the DQB1\*06:02 allele with narcolepsy<sup>88</sup> and B\*27 alleles with ankylosing spondylitis.<sup>89</sup> Almost all patients with narcolepsy have the associated alleles. Similarly, approximately 90% of patients with ankylosing spondylitis have the associated alleles. In populations without these disorders, the frequencies of DQB1\*06:02 (25–30%) and of the B\*27 group (5–10%) are substantial but do not approach the frequencies among persons with these disorders. Thus, the antigens involved are not unique to narcolepsy and ankylosing spondylitis but are over-represented among affected persons. Approximately 3% of persons with a B\*27 allele have ankylosing spondylitis, a risk approximately 100-fold greater than that among persons without B\*27. Results of HLA testing that show the absence of DQB1\*06:02 or B\*27 alleles are useful to help rule out a diagnosis of narcolepsy or ankylosing spondylitis for a patient. However, results that show the presence of these alleles are less useful because of the prevalence of these alleles in the general population.

Celiac disease<sup>90,91</sup> occurs almost exclusively in individuals that express HLA-DQ2.5 (encoded by DQA\*05:01 and DQB1\*02:01), HLA-DQ2.2 (encoded by DQA1\*02:01 and DQB1\*02:02), or HLA-DQ8 (encoded by DQA1\*03 and DQB1\*03:02). Ninety percent of the patients express the DQ2.5 heterodimer, 5% percent of the patients express DQ2.2, and 5% express DQ8. The  $\alpha$  and  $\beta$  chains of DQ2.5 may be encoded by the same chromosome (*cis* configuration) or different chromosomes (*trans* configuration).<sup>92</sup> Most commonly, it is encoded in *cis* by the DR3–DQ2 (DQB1\*02:01–DQA1\*05:01–DRB1\*03:01) haplotype, but may also be encoded in *trans* by the DR5–DQ7 (DQB1\*03:01–DQA1\*05:05–DRB1\*11/12) and DR7–DQ2 (DQB1\*02:02–DQA1\*02:01–DRB1\*07) haplotypes.<sup>93</sup> Though the HLA association is with DQ2.5, DQ2.2, and DQ8, these haplotypes demonstrate the close linkage disequilibrium between the DR and DQ loci. Of note, these haplotypes can make it difficult to determine the associated disease-related allele.

The association of HLA antigens with most other autoimmune disorders usually does not carry the high relative risk that narcolepsy, ankylosing spondylitis, and celiac disease do. Although these HLA associations are generally less useful in diagnosis, they provide important insights into the pathophysiologic mechanism of these diseases and may help assess prognosis. For example, approximately 95% of patients with type 1 diabetes mellitus have either the DRB1\*03 or the DRB1\*04 allele or both.<sup>94</sup> Patients heterozygous for DRB1\*03/\*04 have a relative risk for type 1 diabetes mellitus three to six times greater than that of patients with DRB1\*03 or DRB1\*04 alone or in combination with another DRB1 allele. Susceptibility to type 1 diabetes mellitus appears to be linked to haplotypes containing DRB1\*03 or DRB1\*04 with DQB1\*02 and DQB1\*03 alleles. Many persons with rheumatoid arthritis (RA) have inherited DRB1\*04 alleles, which may bind better as a result of the peptide citrullination found in patients with RA.<sup>87</sup> Heterozygosity and homozygosity for alleles encoding this epitope may be predictive of a more severe course of arthritis. Thus, allele identification may be helpful in assessing prognosis.<sup>95</sup>

Of note, not all HLA disease associations confer risk of disease. In fact, some HLA alleles are thought to be protective against some diseases. For example, in addition to risk alleles, there are some alleles—DQB1\*06:03, DQB1\*05:01, DQB1\*06:09, and DQB1\*02—that appear to be protective against narcolepsy.<sup>96</sup> Some have also implicated DQA1 in disease susceptibility, demonstrating that certain DQA1 alleles form heterodimers with DQB1 subunits that do not bind to implicated peptides/autoantigens as readily, and are, thus, more protective.<sup>97</sup> Also, certain DRB1\*13 alleles have been shown to be protective against some autoimmune diseases such as systemic lupus erythematosus, Sjogren's syndrome, and rheumatoid arthritis.<sup>98</sup> Different mechanisms have been proposed, including conserved amino acid sequences within the DRB1\*13 protein that may function in tolerance.

Because the MHC contains genes with no obvious role in immune system function, some diseases caused by point mutation or deletion of genes in this region cause disorders not directly related to immunity. However, because of linkage disequilibrium, over-representation of specific Class I or Class II antigens may occur in these disorders. Congenital adrenal hyperplasia is caused by mutations in the MHC Class III region genes encoding 21-hydroxylase.<sup>99</sup> Although linkage to specific HLA alleles is present in persons with congenital adrenal hyperplasia, direct genotyping is generally preferable for diagnostic purposes. Similarly, genetic hemochromatosis is caused by mutations in the HFE gene telomeric to the HLA-A locus.<sup>100</sup> Although the presence of A\*03 confers several-fold excess risk of hemochromatosis, the most direct route to genetic diagnosis is HFE genotyping.

### Pharmacogenetics

There appear to be HLA alleles that interact with other genetic and environmental factors to influence the outcome of this multifactorial disease. For instance, Steven Johnson Syndrome-like hypersensitivity reactions to the antiretroviral drug abacavir was linked to the presence of HLA-B\*57:01 in treated patients.<sup>101,102</sup> Near complete elimination of hypersensitivity morbidity was achieved by first screening patients to exclude 5–10% with B\*57:01 from exposure to

this agent. In this example, HLA allele identification serves as a pharmacogenomic test to stratify a patient population for targeted therapy. Other pharmacologic reactions associated with specific HLA alleles can be found in Table 54.4.<sup>86</sup>

### Summary

The MHC region, located on chromosome 6, represents one of the most polymorphic regions in all of the human genome. This exceptionally high degree of polymorphism appears to be maintained in part, to ensure appropriate responses to the infectious organisms encountered by the human population. However, as the function of HLA molecules is to present foreign peptides to the immune system, mutations within this system seem to be well tolerated. MHC polymorphisms have several implications in medicine and biology beyond driving a specific immune response: (1) MHC genetic variation can be exploited as a tool for anthropologic study of human migration and development; (2) specific HLA alleles are associated with a propensity to develop particular disease entities, especially autoimmune disorders and hypersensitivity reactions; and (3) they present a challenge in finding appropriately HLA-matched donors and recipients for both stem cell and organ transplantation.

## CHAPTER 55

# Chimeric antigen receptor T cells and other cellular immunotherapies

Andrew D. Fesnak & Don L. Siegel

Division of Transfusion Medicine and Therapeutic Pathology Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

## Introduction

Immunotherapy may be in the form of cellular therapy, antibodies, cytokines, or other modalities that induce, enhance, suppress, or release suppression of the immune system response. *Adoptive* immunotherapy typically refers to treatment with a cellular product in order to re-establish or newly establish immune effector function. For these cell therapies, the donor may be autologous or allogeneic, and the product may be minimally manipulated (e.g., donor lymphocyte infusion) or the result of a complex isolation, expansion, and modification by genetic engineering (e.g., chimeric antigen receptor [CAR] T cells). Clinical use of CAR T cells has revolutionized the field of cellular immunotherapies in recent years and has led to US FDA approvals of the first gene-modified “living drugs.” This chapter reviews the history of cellular immunotherapy with a particular focus on CAR T cells to illustrate lessons learned through their development and commercialization. Many of these lessons are applicable to other cellular therapies and inform future directions.

## T-cell immunotherapy

### Introduction

T cells have a powerful ability to distinguish self from non-self via the T-cell receptor (TCR). TCR recognition of peptide antigens presented to naive T cells by major histocompatibility complex (MHC) molecules in conjunction with appropriate costimulatory signaling can elicit potent antitumor and antiviral effector function. Through this signaling, a naive endogenous T cell can be activated to proliferate, differentiate into effector- and memory-type T cells, and orchestrate a specific immune response including direct cytotoxicity, cytokine production, and appropriate immune regulation. This natural killing ability was recognized as potentially transferrable over 50 years ago in mouse foreign tumor studies.<sup>1</sup> Since that time, increased knowledge of T-cell biology and subset function and technical progress with expansion and manufacturing have improved the success and breadth of in vivo studies. The goal of adoptive T-cell immunotherapy is to introduce an antigen-specific arsenal to combat neoplastic or virally infected cells. Broadly speaking, immunotherapeutic T cells may be introduced

without redirection (nonspecific T cells) or following antigen exposure (antigen-specific), genetic engineering, or other modifications to direct T-cell specificity. In addition, T-cell immunotherapy ex vivo manipulation may be used to not only enhance specificity, but also potency. In this section, we provide an overview of endogenously derived (e.g., donor lymphocyte infusions) T-cell immunotherapies as well as those that are redirected through ex vivo manipulation (e.g., CAR T cells) to treat cancer and infection.

### T-cell therapy for cancer

In the last decade, engineered T-cell therapy and particularly CAR T-cell therapy has generated unprecedented clinical results and an explosion in T-cell immunotherapy research. However, T-cell treatments for cancer have been an active area of interest long before the first reports of CAR T-cell therapy in humans in 2011.<sup>2</sup> In fact, the biological and clinical developments of donor lymphocyte infusions (DLIs) and later tumor infiltrating lymphocytes (TILs) provided the framework for the first genetically modified T-cell therapies. DLIs relied upon the presence of antileukemic lymphocytes in the collected cellular product. Treatment with TILs takes this observation one step further, enhancing their activation state or preferentially expanding T cells with desired specificity ex vivo. Finally, genetically engineered T cells build upon these approaches to T-cell collection and expansion but rely upon introduction of DNA or RNA sequences to achieve expression of a novel receptor and therefore redirection. The next generation of engineered T cells will again expand upon the existing platform to include gene editing in addition to redirection through novel receptor expression.<sup>3,4</sup>

### Nonengineered cell therapy products

#### Donor lymphocyte infusions

Allogeneic hematopoietic stem cell therapy (HCT) as treatment for hematopoietic cancers is itself a form of highly effective cellular immunotherapy that has been recognized since the 1950s. Even before mechanisms were well understood, the indirect relationship between graft versus host disease (GVHD) and leukemia relapse became clear.<sup>5</sup> T cells were soon implicated for their roles in both processes, as T-cell depletion improved GVHD complications but led to higher relapse rates.<sup>6</sup> T cells are essential for controlling

tumor cells that survive any preparative regimen (i.e., the graft-versus-leukemia [GVL] effect), but the difficulty is balancing this benefit while preventing severe GVHD.<sup>7,8</sup> These discoveries led to a number of strategies to enhance the limited effect of DLI in non-CML transplantation protocols, where outcomes have been inferior. Higher doses of DLI, combined with lymphodepleting chemotherapy as well as unrelated donors, have been associated with increased GVHD risk, which limits efficacy.<sup>9</sup>

Specific CD4, CD8, and  $\gamma/\delta$  T-cell subsets continue to be explored as immunotherapeutic agents.<sup>7,10</sup> For example, the generation of CD4<sup>+</sup> T helper 2 (Th2) cells through ex vivo IL4 and IL2 stimulation and infusion into T-cell-replete allogeneic HCT patients led to accelerated lymphocyte reconstitution and increased inflammatory cytokine pathways without elevations in GVHD.<sup>11</sup> Another clinical trial infused rapamycin-resistant donor CD4<sup>+</sup> Th2/T helper 1 (Th1) cells after matched-sibling low-intensity-regimen HCT for refractory hematologic disease.<sup>12</sup> Recipients had preferential and rapid immune reconstitution with the CD4<sup>+</sup> Th2/Th1 cells, demonstrating the possibilities of achieving donor immunity (and thus GVL) with reduced-intensity preparative regimens. Acceptable GVHD rates were observed, making this platform an attractive candidate for future comparative efficacy studies.

Overall, DLIs have helped transplant patients overcome relapses of leukemia and low-grade lymphoma with rates of success ranging from 70% to 80% in chronic myeloid leukemia to 15–45% in acute myeloid leukemia (AML), 40–60% in multiple myeloma, 60% in low-grade lymphomas (including Hodgkin lymphoma), but only 5% in acute lymphoblastic leukemia.<sup>13</sup> The varying response rates and durations continue to be areas of active research, but likely relate to the regulation of T-cell recognition molecules, progression of disease, and tumor antigen phenotypes.

### Tumor-infiltrating lymphocytes

Many tumors are infiltrated by reactive T cells *in vivo*; although these T cells have specific antitumor activity, they can fail to control tumor growth.<sup>14</sup> Emerging evidence suggests that these TILs are suppressed by the upregulation of a variety of proteins.<sup>15</sup> Removing these TILs from the *in vivo* environment can facilitate activation and expansion. Additionally, host lymphodepletion and chemoradiotherapy prior to TIL transfer significantly enhance engraftment and efficacy of the transferred cells.<sup>16</sup> Subsequent reinfusion of this tumor-specific population has led to measurable responses in patients with metastatic melanoma, ranging from 49% to 72% depending on the preconditioning regimen.<sup>17</sup> Whereas the three- and five-year survival rates were only 36% and 29%, respectively, those patients who initially achieved complete tumor regression had rates of 100% and 93%. Other groups have reproduced these findings with initial response rates closer to 50%.<sup>18</sup> Efforts to extend this application to epithelial tumors have been generally unsuccessful. One theory suggests that the high number of mutations in melanomas makes this tumor well suited for T-cell-mediated therapy, whereas tumors predominated by epigenetic changes may be less immunogenic and thus less responsive to T-cell-mediated therapy.<sup>14,19,20</sup>

A recent exception to TILs' melanoma-limited efficacy is the durable response seen in a patient with cholangiocarcinoma.<sup>21</sup> Whole-exome sequencing of extracted TILs revealed a population of CD4<sup>+</sup> Th1 cells that recognized an HER2 mutation expressed by the patient's metastatic epithelial cancer. Infusion of ex vivo expanded TILs enriched for this mutation-specific population led to disease stabilization and regression in a dose-dependent manner.

This study underscores the concept that T cells, given the right microenvironment, stimulation, dose, and specificity, are effective tumor eradication tools. As our knowledge and ability to obtain detailed genetic information continue to increase, T cells are positioned as excellent targets for *ex vivo* engineering specificity, as addressed further in this chapter.

### Regulatory T cells

Immunotherapy with an additional CD4<sup>+</sup> subset, the regulatory T cell (Treg), has been explored to take advantage of its role in suppressing immune system activation and promoting tolerance.<sup>22,23</sup> Specifically, Tregs have been targeted for depletion and inactivation because they can effectively limit the expansion of tumor-specific T cells.<sup>24</sup> The best Treg receptor(s) to target for depletion is an area of active research; early clinical studies of CD25 blockade have shown mixed results for enhancement of antitumor activity in patients with metastatic melanoma and breast cancer.<sup>25,26</sup>

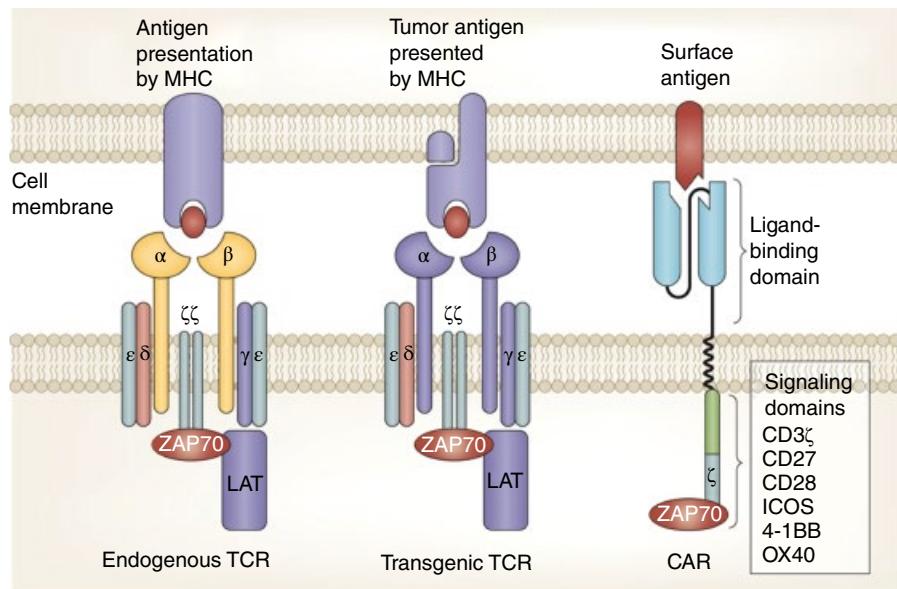

Interestingly, the majority of Treg cancer applications take a different approach than the direct antitumor effects sought with other lymphocyte subsets. Tregs can promote the immune tolerance that is essential to both solid organ transplant and HCT, with the latter showing promising clinical trial results. Infusion of CD25<sup>+</sup> Tregs harvested from partially HLA-matched human umbilical cord blood and expanded *ex vivo* by activation with anti-CD3/CD28 beads and recombinant human IL2 reduced the incidence of GVHD in 23 HCT patients, as compared to 108 controls.<sup>27</sup> Adult expanded Tregs from HCT HLA-haploididentical donors have also helped reduce chronic GVHD in high-risk acute leukemia patients.<sup>28</sup> Additional trials of adoptive Treg therapy are currently underway in the setting of solid organ and bone marrow transplant.

### Genetically engineered T cells

T cells can be genetically modified for cancer immunotherapy via three primary approaches: (1) modifying natural TCRs genetically to create receptors specific for a target antigen, (2) creating synthetic chimeric antigen receptors (CARs) that link a target-specific ligand (usually the variable region of an antibody) to a TCR intracellular domain that activates the T cell, and/or (3) using gene editing approaches such as zinc finger nucleases (ZFNs), transcription activator-like effector nuclease (TALENs), or clusters of regularly interspaced short palindromic repeats-Cas9 (CRISPR-Cas9).<sup>29</sup> Engineered expression of a novel receptor, whether it be a transgenic TCR or CAR, can redirect *in vivo* T-cell activity with high specificity and potency. This is a rapidly growing sector of biotechnology; a September 2013 meeting of the Office of Biotechnology Activities at the National Institutes of Health reported 111 registered protocols for the two approaches combined, with 90% of the TCR trials targeting solid tumors and 50% of the CAR trials focusing on hematologic cancers.<sup>29</sup> Since that time, clinical development of gene modified T-cell protocols has exploded. Recent examples of these clinical protocols include the first use of CRISPR-edited, TCR redirected T cells, and TALEN-edited allogeneic CAR expressing T cells.<sup>30,31</sup> While studies are ongoing, to date results have proven these therapies to be relatively safe and well tolerated.

### Engineered TCR-expressing T-cell therapy

Engineered expression of a full length transgenic TCR closely mirrors expression of a T cell's endogenous TCR with one crucial difference (Figure 55.1). The variable domains are specifically selected to confer TCR specificity and affinity. Once expressed in a T cell, this transgenic TCR allows for highly specific and potent

**Figure 55.1** Comparison of basic structures of native, transgenic, and engineered (CAR) T-cell receptors.<sup>21</sup> Fesnak *et al.* (2016).<sup>3</sup> With permission from Springer Nature.

in vivo activity against target-positive cells. One of the first studies of TCRs in human trials engineered T-cell expression of the melanoma antigen recognized by T cells 1 (MART-1). Transfer of these cells into 15 patients with metastatic melanoma resulted in high levels of engraftment (>10% of peripheral blood lymphocytes) for at least two months post infusion, and for one year in two patients who experienced regression of metastatic lesions.<sup>32</sup> Within several years, the applications extended beyond melanoma. Cancer-testis antigens (CTAs) are genes whose overexpression has been demonstrated in many carcinomas, hematologic malignancies, melanoma, and testicular cancers.<sup>33</sup> Transfer of T cells engineered with the CTA NY-ESO-1 provided tumor regression in 16 of 20 patients with NY-ESO-1-expressing tumors.<sup>34,35</sup> Next-generation NY-ESO-1 TCR expressing T cells with gene edited PD1, TCR alpha, and TCR beta loci have also been shown to be safe and well tolerated.<sup>31</sup> Others have targeted the Wilms tumor-1 antigen found at high levels on leukemic cells with TCR-transduced T cells.<sup>36</sup>

### Chimeric antigen receptor-expressing T-cell therapy

#### Biology

Whereas the use of engineered TCR-expressing T cells for recognizing cancer cells exploits the natural ability of T cells to kill their target, the design of TCRs for a particular application is not as straightforward as in, e.g., the creation of a monoclonal antibody to a target antigen through the use of animal immunization and B-cell cloning approaches or through the use of in vitro methods for antibody discovery like phage display. TCRs recognize their antigens as peptides expressed on cell surfaces in the context of the host's major histocompatibility complex (MHC). Thus, the design of a cancer-specific TCRs requires knowledge of the peptide sequences that are processed by the cell as well as the ability to design the amino acid sequences of TCR chains that are specific to those peptides when embedded in an MHC. Furthermore, at best, TCRs designed to recognize particular cancer antigen peptides may be MHC-restricted, i.e., only function in patients with that particular MHC. The recognition of a self-surface antigen on a cancer cell by an antibody is neither MHC-restricted nor limited to

reactivity with only certain peptides of the target. However, unlike T cells, the effector functions of antibodies with respect to the killing of cancer cells is generally limited to their ability to activate complement or induce antibody-dependent cellular cytotoxicity (ADCC). The concept behind CAR T cells is to exploit the antigen-recognition properties of antibodies with the effector (killing) ability of T cells. As shown in Figure 55.1, a CAR is a synthetic molecule that couples the antigen-binding portion of an antibody with the intracellular signaling machinery of a TCR complex to enable the CAR T cell to become activated through engagement of its antibody domain with a cancer cell target. The antigen-recognition portion is usually in the form of an scFv (single chain fragment variable) that comprises the heavy and light chain variable regions of an antibody expressed as a single polypeptide chain. As discussed below, the design of CARs has gone through several iterations referred to as “generations” in which additional signaling molecules have been used to affect cell effectiveness, persistence, and other properties.

First-generation CARs linked the scFv to the CD3ζ chain, a signal-transduction component of the T-cell antigen receptor.<sup>37</sup> The B-cell antigens CD19 and CD20 are the most common antibody targets for CAR hematologic protocols. These B-cell-specific CARs are designed to eradicate the neoplastic populations in B-cell lymphomas and leukemias and, by nature of CD19 and CD20 expression, also the nonneoplastic B cells. Although these early trials with anti-CD19 and anti-CD20 CARs were safe, efficacy was limited and detection of the transferred CTLs was short-lived (24 hours to 7 days).<sup>38</sup> This poor persistence was thought secondary to the absence of costimulation, and thus second-generation CARs incorporated dual signaling molecules such as CD28, 4-1BB, or OX-40.<sup>39</sup>

Indeed, direct comparisons of first- and second-generation CARs revealed improved expansion and persistence for those CTLs engineered with CD28 costimulation.<sup>40</sup> Clinical trials of these second-generation CARs have been directed toward CD19 in chronic lymphoid leukemia (CLL) and pediatric, adult, and relapsed B-cell acute lymphoblastic leukemia (B-ALL).<sup>41-44</sup> The clinical

efficacy and adverse event profile differ somewhat by indication, disease status, and prior treatment regimens. For example, patients with bulky CLL showed mixed responses in lymphadenopathy whereas in some studies all B-ALL subjects achieved complete molecular remission.<sup>41-46</sup> Although these results suggest that autologous CAR-expressing T cells have the potential to induce rapid remission and/or provide a bridge to curative transplant, the emergence of tumor cells with antigen evasion may mandate targeting multiple molecules. Further, persistence of autologous CAR T cells is crucial for long-term remissions.

Third-generation CARs add a second costimulatory domain. Early clinical trials with CD20-specific CARs coupled to CD28 and 4-1BB produced modest antitumor activity with relatively low circulating CTLs at one year.<sup>47</sup> Interestingly, this protocol used electroporated DNA plasmids as opposed to the retroviral vectors or transposons used in other work and proved not to be as effective for transformation.

Second- and third-generation CARs have shown extraordinary ability to affect antitumor response *in vivo*. Next-generation CAR T cells are likely to alter CARs or endogenous T-cell molecules to improve efficacy, persistence, and/or safety. CAR systems have been designed such that full activating signal is only transduced when two distinct antigens are present on the target cell.<sup>3</sup> Alternatively, the coexpression of a standard second-generation CAR with a suppressive CAR, combining an extracellular scFv with intracellular CTLA4 or PD1 signaling domains in lieu of the CD3 $\zeta$  signal domain, can prevent activation in the presence of the suppressive CAR target. CAR T cells can be engineered to coexpress chemokine receptors or cytokines that can recruit endogenous innate immune cells to improve trafficking to tumor and modifying immunosuppressive tumor microenvironment. Checkpoint receptors can be ablated from CAR T cells via gene editing to improve antitumor efficacy. Finally, T cells can be engineered to express a two-part CAR, wherein both primary and costimulatory signaling domains only colocalize and transduce signal when an adaptor molecule is provided. With this last approach, if the adaptor molecule is a bioavailable drug (e.g., rapamycin), the administration of this molecule may allow for titratable *in vivo* response.<sup>48</sup>

#### **Indications—leukemia**

CAR T cells have demonstrated unprecedented clinical efficacy treating refractory relapsed B-cell leukemias. The first reported clinical use of CAR T cells was published in 2011 and describes the use of CD19-directed CAR T cells to treat three patients with relapsed, refractory chronic lymphocytic leukemia.<sup>49</sup> All three subjects demonstrated robust and durable antitumor response in some cases lasting years. Subsequent trials in pediatric B-cell acute lymphoblastic leukemia demonstrated even more impressive responses, with 80–90% of patients experiencing complete remissions within three months of treatment. These initial response rates have been reproducible across institutions and with the use of different anti-CD19 CAR T-cell drug products.

Other tumor targets, most notably CD22, have been targeted by CAR T cells in patients with B-cell leukemia. Patients who previously failed CD19-directed CAR T-cell therapy have been treated with CD22-CAR T cells with 70% complete remission rate.<sup>50</sup> Promising results support the use of CD22-targeted CAR T cells either alone or in conjunction with CD19-directed CAR T cells to treat a variety of B-cell malignancies.<sup>51,52</sup>

While many B-cell leukemia targets are under active investigation, significant challenges limit durability of overall response.

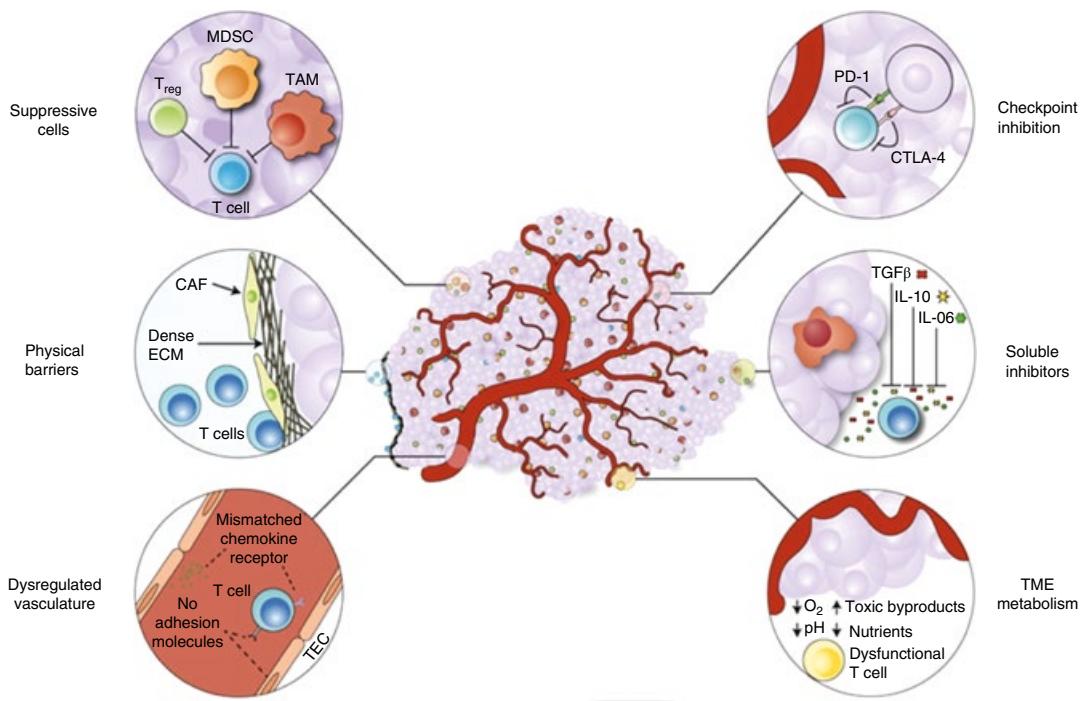

Specifically, failed CAR T-cell persistence after transfer can lead to relapse in approximately half of those treated with CD19-CAR T cells. Persistence has been enhanced with better preinfusion lymphodepletion; however, these regiments come with their own risks. It is worth noting that the manufacture of autologous CAR T therapies for patients with refractory relapsed disease begins with collection of T cells from patients who are often treated with years of cytotoxic chemotherapy. A growing body of evidence suggests that cumulative treatment burden impairs T-cell function in ways that could decrease *in vivo* persistence.

If autologous T cells provide suboptimal material for manufacturing long-lasting CAR T cells, then allogeneic CAR T-cell therapy is one solution to this problem. Allogeneic CAR T cells allow for preselection of optimal donors and collection of T cells that have not been exposed to high levels of cytotoxic therapy. However, allogeneic CAR T cells, unless modified, continue to express both the endogenous TCR and the endogenous MHC molecules. If reinfused into an allogeneic recipient, the allogeneic CAR T cell could recognize host via the endogenous TCR and cause graft-versus-host disease. Alternatively, donor MHC molecules may mark the allogeneic CAR T cell as foreign and lead to rejection by the recipient. Gene editing shows promise in efficiently ablating these molecules from the surface of CAR T cells; however, it is still unclear what the tolerable thresholds are.

#### **Indications—other malignancies**

Compared to leukemia, CAR T-cell therapy response rates lag for B-cell lymphoma, multiple myeloma, and other hematologic malignancies. B-cell maturation antigen (BCMA)-directed CAR T cells demonstrated a 73% overall response rate in patients with refractory/relapsed multiple myeloma.<sup>53</sup> CD19-directed CAR T cells led to overall response rates of around 50% of patients with B-cell lymphomas.<sup>54</sup> To date, CAR T-cell therapies against solid tumors have demonstrated lower response rates. These results are encouraging nonetheless, particularly given that these clinical responses are observed in refractory/relapsed populations for whom little or no alternative therapies are available and prognosis is already poor. Nonetheless, overall and complete response rates for CAR T-cell therapies seen when treating non-B-cell leukemia hematologic malignancies are consistently below those seen when treating leukemias.

There are many possible explanations for this discrepancy as summarized in Figure 55.2 including a tumor microenvironment comprising immunosuppressive cells, soluble immune inhibitors, and unfavorable metabolic conditions.<sup>55</sup> Many cancers, including lymphoma and solid tumors, are capable of suppressing the endogenous antitumor immune response.<sup>56</sup> Like their endogenous counterparts, the current generation of CAR T cells, such as those that are currently commercially approved, are also subject to tumor-mediated immunosuppression. For an immune cell to generate an antitumor response, it must have access to the tumor, activate at the appropriate site, and generate a robust and sustained effector function. Unlike leukemia, solid tumors may present physical barriers by generating fibrosis and necrosis, making tumor sites inaccessible to immune cells. Further, the overexpression of immune checkpoint signaling molecules (e.g., programmed cell death protein 1 [PD-1], its receptor PD-L1, cytotoxic T lymphocyte-associated protein 4 [CTLA-4], T-cell immunoglobulin and mucin-domain containing-3 [TIM3], and lymphocyte-activation gene 3 [LAG3]) leads to blockade of activation and downstream effector function of infiltrating endogenous and CAR T cells.<sup>57</sup>

**Figure 55.2** Mechanisms of immune suppression in the tumor microenvironment. Labanieh *et al.* (2018).<sup>55</sup> With permission from Springer Nature.

The challenges posed by a tumor microenvironment that is inhospitable to immune cell infiltration and activation is made worse by a limited number of optimal tumor targets. A large part of CD19-directed CAR T-cell success can be attributed to the features of CD19 which make it a near-ideal tumor target. CD19 is expressed solely on B cells though not just on malignant B cells which is why technically CD19 is not “ideal.” The majority of B-cell leukemias express CD19, and a given case of CD19-positive B-cell leukemia is expected to express CD19 on all of its malignant cells. Finally, the on-target, off-tumor effect that results in B-cell aplasia is tolerable in that patients can live without normal B cells provided their immunoglobulin levels are maintained with regular infusions of intravenous gamma globulin. Together, these features make CD19 an excellent tumor target for CAR T-cell therapy. For most solid tumors, such an ideal tumor target rarely exists. Targets such as EGFRvIII are highly specific for glioblastoma but are only expressed in a subset of cases and within a given tumor show high expression heterogeneity from cell to cell.<sup>58</sup> Other solid tumor targets such as mesothelin are overexpressed in a number of different cancers and can be uniformly expressed on a given tumor; however, mesothelin is widely expressed in many benign tissues. Lack of optimal tumor targets force solid tumor CAR T-cell therapies to balance efficacy against toxicity, limiting the therapeutic window.

Next-generation CAR T cells aim to overcome the limitations highlighted here. Concurrent chemotherapy, antiangiogenic therapy, or radiation in combination with CAR T cells can enhance tumor infiltration.<sup>59–62</sup> Alternatively, CAR T cells can be engineered to coexpress chemokine receptors to improve homing and infiltration.<sup>63,64</sup> CAR T-cell therapy can also be combined with checkpoint blockade therapy to improve CAR T-cell function once at the tumor site. Checkpoint blockade therapy in the form of monoclonal antibodies against PD-1, PD-L1, or CTLA-4 can be used to disrupt suppression of CAR T cells. While this combination therapy has been shown to enhance CAR T-cell efficacy, systemic

checkpoint blockade therapy is associated with its own risks. A more targeted approach is to engineer CAR T cells to ablate checkpoint receptor expression.<sup>65,66</sup> In this way, only those CAR T cells redirected toward a target antigen are unable to be suppressed by checkpoint signaling, therefore limiting potential checkpoint blockade-associated autoinflammation.

Improving upon the current solid tumor target selection process will require re-engineering of the current CAR T-cell platform. Next-generation CAR T cells redesign the receptor itself to only provide robust activation signals when two targets are present (e.g., “dual CAR T cell”) or when one target is present but another is absent (e.g., “suppressive CAR T cell”). These redesigned CAR T cells allow for Boolean-gated activation and expand the pool of potential targeting strategies. This is most important for solid tumor targets for the reasons mentioned above. For example, a dual CAR against EGFRvIII and a second glioblastoma marker could improve efficacy, whereas a suppressive CAR that activates in the presence of mesothelin but inactivated in the presence of a benign tissue marker could limit off-tumor effects.

### T-cell therapy for viral infections

T-cell therapies for viral infection rely on the ability of T cells to detect viral peptides presented on the surface of infected cells. Alternatively, if T cells are a reservoir for infection, as is the case with HIV, T therapies may generate infection-resistant T-cell populations to reestablish functional T-cell immunity.<sup>67</sup> Recipients of hematopoietic cell transplants (HCTs) often lose the bulk of their cell-mediated immunity and become susceptible to viral infections that carry high morbidity and mortality. These patients are at particular risk for reactivation of cytomegalovirus (CMV) leading to enteritis and pneumonia, Epstein–Barr virus (EBV) causing post-transplant lymphoproliferative disease (PTLD), and adenovirus-associated enteritis, hepatitis, hemorrhagic cystitis, and pneumonia.<sup>68</sup> Effective antiviral agents and anti-B-cell CD20-mediated therapy have

improved many of these complications, but negative side effects and treatment failures are still too common.

The first reports of viral-specific therapy employed autologous fibroblasts as APCs for stimulation and expansion of sibling donor CD8<sup>+</sup> T cells pulsed with CMV.<sup>69,70</sup> The CMV-specific CD8<sup>+</sup> population was infused into recipients of matched sibling donor grafts, who showed no adverse effects and successful reconstitution of CD8-mediated immunity for at least eight weeks. Manufacturing approaches include retroviral transfer of CMV-specific T-cell receptors (TCRs) for HLA-matched immunotherapy in HCT recipients from CMV-negative donors.<sup>71</sup> Multimer-based selection of antigen-specific T cells has also been applied to CMV reactivation disease.<sup>72,73</sup> In these assays, reactive T cells are enriched from a donor population using peptide multimers bound to magnetic particles. Although initial clinical study results are promising, the strategy requires a high donor blood volume as well as HLA matching and a high baseline frequency of viral-specific T cells.

Manufacturing protocols must be adapted to create T cells capable of targeting Epstein-Barr, adenovirus, and others. Latency type III EBV-specific T cells can be generated by repeated stimulation from irradiated lymphoblastoid cell lines (LCLs) produced from donor peripheral blood mononuclear cells infected with a laboratory EBV strain.<sup>74,75</sup> Multiple clinical studies have demonstrated the efficacy of this protocol for both prophylaxis and sustained remission in more than 70% of post-HCT EBV-associated PTLDs.<sup>76–78</sup> In contrast to EBV and CMV, only a minority of healthy donors have adenovirus-specific T cells, presenting a challenge for source availability. In a manner similar to that discussed for CMV-negative donors, transfecting naive T cells with adenovirus-specific TCRs may prove to be a productive strategy. Positive *in vitro* results have recently been published applying this technology to TCR-transfected  $\gamma/\delta$  subset T cells, which are not alloreactive and thus can be used in mismatched donor-recipient pairs.<sup>79</sup> IFN $\gamma$  capture is a promising emerging selection strategy. Donor T cells are challenged with viral-specific antigens, and the activated IFN $\gamma$ -secreting subset is isolated. Advantages of this approach include shortened manufacturing times and no HLA restriction. CMV-, EBV-, and adenovirus-specific CTLs have been tested in patients with active disease, with response rates of at least 83%, 50%, and 44%, respectively.<sup>10,80–83</sup>

Expanded viral coverage has been achieved from CMV-positive donors using monocytes and EBV-LCLs transfected with adenoviral vectors expressing CMV antigens, producing a single culture of CMV-, EBV-, and adenovirus-specific CTLs. Infusion of these trivirus-specific cells provided immune reconstitutions for CMV and EBV, but response to adenovirus only in the context of reactivation or active infection.<sup>84</sup> Comparable results were observed in patients receiving CMV-negative donor bivirus-specific CTLs.<sup>85</sup> Third-party T-cell lines with common polymorphisms have been used in the treatment of EBV, CMV, and adenovirus.<sup>76,86,87</sup> Generally, the results of these studies have shown significant rates of remission for patients with active infections, although of lower magnitude than traditional specific donor-derived CTLs. Of note, the risk of alloreactivity does not appear to have increased with one case-reported exception of bystander-induced liver GVHD.<sup>88</sup>

Treatment for long-term control of HIV infection has greatly advanced over the previous decades. Curative therapies have been more elusive. In 2009, an HIV1+ patient with acute myeloid leukemia received a stem cell transplant from a CCR5 delta32/delta32 donor and demonstrated undetectable viral load. This suggested the ability to use infection-resistant T-cell therapy to cure or control HIV. Adoptive transfer of ex vivo, zinc-finger nuclease

CCR5 ablated CD4 T cells demonstrated postviral rebound control of viremia in HIV positive patients.<sup>67</sup> Alternatively, CD4 T cells redirected to HIV-infected cells by a CAR and made infection resistant by expression of a C34-CXCR4 fusion are capable of generating specific antiviral response.<sup>89</sup> Given the decades long persistence of gene-modified cells in HIV patients, these therapies hold great promise in long-term control.<sup>90</sup>

### Dendritic cell immunotherapy

DCs, named for their tree-like cytoplasmic projections, are innate hematopoietic cells that reside in all body tissues, including the lymph tissue.<sup>91</sup> Through environmental surveillance, DCs capture protein antigens and present them as peptides in both MHC class I and II molecules (as well as lipid antigens in nonclassical MHCs).<sup>92</sup> Through these DC-initiated interactions, naive T cells are differentiated into antigen-specific and effector T cells, Th cells can be expanded, and B cells, NK cells, and mast cells may be stimulated. Some DC subsets, such as immature DCs in peripheral tissues, can present self-antigens and induce immune tolerance through T-cell depletion or activation of regulatory and suppressor T cells. DCs are known to infiltrate the tumor microenvironment, picking up antigens from tumor cells.<sup>93</sup> Both protumor and antitumor responses are generated by DC interactions.<sup>94–96</sup> As such, DCs engineered to enhance antitumor or prevent protumor activity are a potentially effective path to antitumor immunity.

*Ex vivo* generated DC vaccines have been used with varied levels of success for the treatment of multiple myeloma, colon cancer, renal cancer, prostate cancer, and advanced-stage melanoma.<sup>92</sup> DCs are generally derived from hematopoietic progenitor cells or monocytes with cytokine cocktails, the exact nature of which can yield improved antitumor activity.<sup>93</sup> DC culturing *ex vivo* helps avoid some of the functional deficiencies and tumor tolerance observed with DCs developed in the tumor microenvironment.<sup>97</sup> The selection of the antigen for DC processing is also crucial to immunogenicity. DC loading with nonmutated self-antigens can lead to negative selection due to high-avidity self-antigen, and using unique mutated tumor antigens will require highly patient-specific vaccine formulations.<sup>98</sup> Importantly, dendritic cell vaccines expand the *in vivo* T-cell response to neoantigens, potentially overcoming poor naturally occurring antitumor T-cell effector function.<sup>99,100</sup>

An alternative to single antigen loading is fusing autologous DCs with patient-derived whole tumor cells as an antigen source via electrofusion or polyethylene glycol.<sup>101–103</sup> Processed antigens are presented in both MH class I and II, generating both CD4- and CD8-specific responses. These preparations show increased *in vitro* tumor killing compared to T cells stimulated by DCs pulsed with tumor lysate or apoptotic bodies.<sup>104</sup> Early clinical studies in patients with renal cell and breast cancer demonstrated the excellent safety profile of the DC-tumor cell fusion vaccines, as well as their ability to expand tumor-specific T cells.<sup>105</sup> More recent studies have shown significant clinical success with DC-myeloma cell hybridomas in the period following autologous stem cell transplant leading to the expansion of CD4<sup>+</sup> and CD8<sup>+</sup> myeloma-specific T cells. Seventy-eight percent of the phase II study patients achieved a best response of complete response (CR) or very good partial response, and 47% achieved a CR or near CR.<sup>101</sup>

### NK-cell immunotherapy

NK cells are lymphocytes of the innate immune system responsible for surveillance of malignant transformation or infection. They become educated and acquire function by interaction with MHC class I molecules. Malignant and viral transformed cells may lose

expression of MHC class I in a process of “loss of self” and as a result become “susceptible” to NK-cell killing.<sup>106–108</sup> In the clinic, haploidentical NK cells can be adoptively transferred to treat cancer. Persistence and *in vivo* expansion of NK cells depend on lymphodepleting chemotherapy to make space, eliminating suppressor cells, and releasing endogenous IL15. *In vivo* expansion is also enhanced by cytokine administration of IL2 or IL15. It is believed that IL15 may be superior because IL2 has the downside of stimulating CD25<sup>hi</sup> Tregs. Recent developments of specific NK-cell engagers may help address the limitations of NK-cell therapy, including the complexity of exporting cell therapies and lack of specificity.

Until the discovery of NK-cell receptors that recognize class I MHC (killer immunoglobulin-like receptors [KIRs] and the lectin NKG2 receptors representing the main families), it was assumed that NK cells kill targets in an MHC-unrestricted fashion.<sup>109</sup> Karre and Ljunggren overturned this belief in 1985 with their discovery that NK-cell killing is directed to targets with “missing self.”<sup>110</sup> Inhibitory KIR and NKG2A recognize classical class I MHC or nonclassical HLA-E, respectively, to prevent lysis and thereby induce NK-cell tolerance. Both of these receptor families contain activating receptors and thus engender even greater complexity.<sup>111</sup> Although activating KIR2DS1 can recognize HLA-C2<sup>122</sup> and KIR2DS2 recognizes HLA-A11<sup>112</sup>, many other activating KIR ligands are unknown. Like NKG2A, NKG2C can bind to HLA-E.<sup>113</sup> Notably, NKG2C is an activating receptor of particular importance that is induced by CMV infection.<sup>114,115</sup>

Under normal homeostatic conditions, a balance of activating and inhibitory signals tightly controls NK-cell function. Activating NK-cell receptors include natural cytotoxicity receptors NKp30, NKp44, and NK46, and others such as NKG2D and DNAM-1 that are constitutively expressed on all NK cells.<sup>116,117</sup> Activating receptors recognize stress-induced molecules, HLA class I-related MICA and MICB, class I-like CMV-homologous ULBP proteins, and ligands CD155 (PVR) and CD112 (Nectin-2).<sup>118</sup> Tumors vary in these activating ligands they express. *In vitro*, NK cells can mediate the direct killing of freshly isolated human tumor cells from AML, acute lymphoblastic leukemia, multiple myeloma, neuroblastoma, and ovarian, colon, renal cell, and gastric carcinomas.<sup>119,120</sup> NK cells can also be activated or primed directly by cytokines. After incubating NK cells with cytokines, in particular IL2, IL12, IL18, or IL15, NK cells acquire the capacity to lyse a broad array of fresh and cultured tumor targets not normally sensitive to NK lysis.<sup>121</sup> Furthermore, cytokine-activated NK cells are synergistic with monoclonal antibodies against resistant cell lines *in vitro* and in mouse xenograft models.

Early clinical trials of *ex vivo* IL2-activated autologous NK cells followed by daily subcutaneous IL2 in patients show adoptive transfer of NK cells to be safe, but with limited efficacy in several indications.<sup>122</sup> Because self-MHC can inhibit NK cells, allogeneic NK-cell therapy was pursued. In clinical trials using allogeneic T-cell-depleted HCT from haploidentical donors in patients with AML, Rugierri *et al.* showed that NK-cell cytotoxicity is enhanced if a KIR-HLA class I mismatch occurs. Allogeneic donor-derived NK cells were not associated with GVHD<sup>123,124</sup> suggesting a role for NK-cell therapy in the absence of HCT for patients with AML.

### Mesenchymal stromal cell immunotherapy

Mesenchymal stromal cells (MSCs) were first described in 1968 by Friedenstein *et al.* as bone-marrow-derived, adherent, fibroblast-like cells capable of differentiation to bone.<sup>125</sup> Since then, MSCs have been isolated from a variety of tissue sources, including

umbilical cord blood, Wharton’s jelly, and adipose tissue,<sup>126</sup> and an abundance of studies exploring a wide array of potential clinical utilities have been undertaken. In an initial effort to better characterize MSCs, Dominici *et al.* determined minimal criteria for defining these cells.<sup>127</sup> Subsequent work has moved characterization forward; however, there is still a need for further efforts.<sup>128</sup>

Basic research has suggested several possible mechanisms of action, including the ability of MSCs to home to injured tissue and to secrete bioactive molecules to stimulate recovery/repair and inhibit additional inflammation (Figure 55.3).<sup>129</sup> Additionally, many studies have shown that allogeneic MSCs lack immunogenicity and are essentially immunologically privileged.<sup>130</sup>

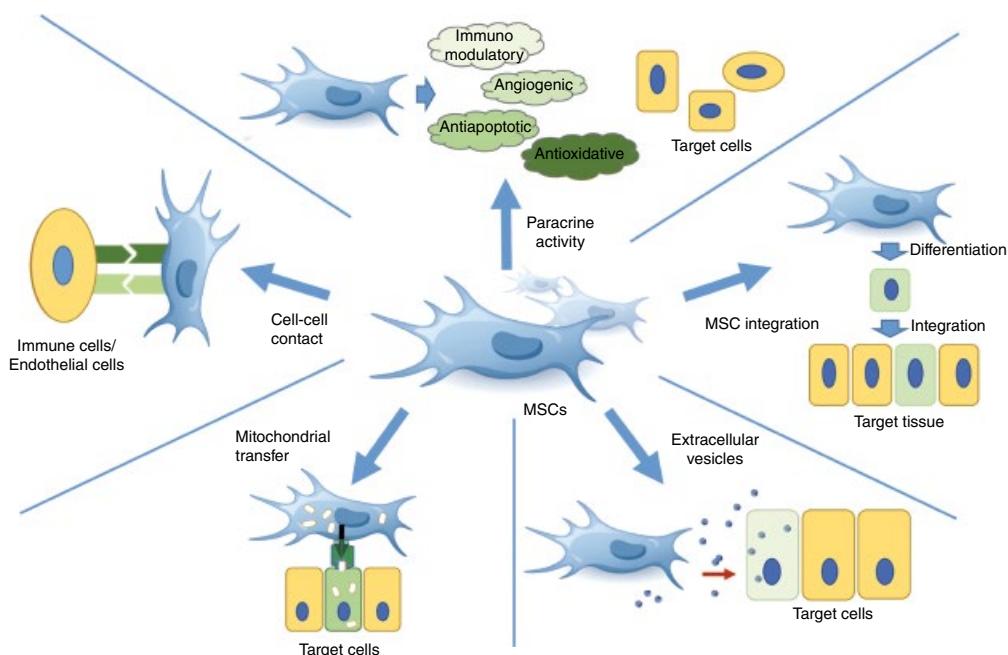

Clinical applications of MSCs can be categorized with some overlap into regenerative medicine and immunomodulation or immunotherapy.<sup>130</sup> As of 2020, more than 300 MSC clinical trials have been completed.<sup>131</sup> Several MSC-based therapies have been approved for use internationally.<sup>132</sup> Nonetheless, clinical trial results have varied significantly. While this could be due to a number of factors, MSC source material likely contributes to some of these discrepancies. It remains to be determined which source is best, and it may be that a certain source is better for a given application. In the case of marrow, donor age has been shown to affect MSC quality and quantity.<sup>133</sup> The importance of age is further exemplified by studies indicating a 2-log greater number of MSCs in umbilical cord blood as compared to adult marrow.<sup>134</sup> In addition to different sources of starting material, studies have involved both autologous and allogeneic (related and unrelated) donations. In trials involving allogeneic donors, the concept of the “qualified” donor has surfaced.<sup>135</sup> As our understanding of MSCs advances, the need for a more robustly characterized, or “qualified,” donor may be appreciated.

Although MSC manufacturing methods have advanced significantly over the past decade, it is still too early to propose standardization of manufacturing. This is particularly true given the variability in starting material, product characterization, as well as dose and administration. Generally, MSCs have been shown to be safe and well tolerated, and several studies point toward efficacy in the immunomodulation/immunotherapy application, making the future appear promising for this cell type. Better understanding of basic immunomodulatory mechanisms will allow for more effective MSC therapies.

### Conclusions

Several adoptive immunotherapies have shown considerable promise in the clinical arena, and their applications have expanded substantially in recent years. Early studies involved nonspecific T cells and lymphokine-activated killer cells, but subsequent studies have applied the knowledge gained in cell biology and immunology to exploit or harness the function of various subsets of T cells, DCs, NK cells, and MSCs. Advances in technology have further enhanced our ability to bring the next generation of cellular immunotherapies into the clinic.

Development of redirected T-cell therapy beginning with observations in allogeneic stem cell transplant and culminating in successes with CD19 CAR T-cell therapy taught us many lessons that are generally applicable to all of cell therapy. Variable starting material and dynamic cell populations behavior in culture limit the ability to generate reproducible final drug products when applying standardized processes. Further, working in closed systems and regulated environments present obstacles to efficient scale-up and scale-out. These major challenges apply to all cell therapies to varying degrees and pose a threat to cell therapies’ sustainable role

**Figure 55.3** Mechanisms underlying MSC-based therapy. Fan *et al.* (2020).<sup>129</sup> Springer Nature / Public Domain.

in the immunotherapy armamentarium. Nonetheless, unprecedented clinical results, particularly in patients with otherwise terminal disease, motivate investigators to contend with and overcome these challenges.

Next-generation cellular immunotherapies promise to expand indications and improve safety. CAR expression in non-T cells, such as macrophages, is a novel approach to the treatment of solid tumors.<sup>136</sup> Compared to T cells, macrophages may have superior ability to penetrate solid tumors and overcome tumor mediated immunosuppression. Anti-HER2 CAR macrophages show potent antitumor activity in humanized mouse models and are under active clinical investigation.<sup>137</sup> CAR expression in NK cells holds similar promise. Incredibly, early-phase CAR-NK-cell trials demonstrated significant complete response rates in patients with CD19 cancers with no associated cytokine release syndrome, avoiding the major adverse effect of most CAR T-cell therapies.<sup>138</sup>

Beyond malignancy, redirected T cells have been designed to treat autoimmune disease. Pemphigus vulgaris is an autoimmune disease in which patients generate autoantibodies against desmoglein 3 which disrupt tissue architecture leading to mucosal blisters. Lee *et al.* generated a chimeric receptor in which a portion of the desmoglein 3 protein (the autoantigen), rather than an antibody fragment, is fused to the transmembrane, costimulatory, and CD3ζ signaling domains. When transduced in T cells, this chimeric auto antigen receptor (CAAR) leads to the specific elimination of autoreactive B-cell clones in preclinical models by engaging cell surface (auto)immunoglobulin.<sup>139</sup> Others have developed similar approaches such as using T regulatory cells to suppress anti-FVIII antibody production in a targeted fashion.<sup>140–142</sup> Though not targeted to specific auto- or alloantibody-producing cells as in the above approaches, the infusion of “conventional” autologous CD19-directed CAR T cells was shown to be effective at inducing rapid remission in a case of refractory systemic lupus erythematosus (SLE).<sup>143</sup> Infusion was subsequently associated with the disappearance of double-stranded DNA serum autoantibodies,

normalizations of C3 and C4 complement levels, decreased proteinuria, and reduction of an SLE disease activity index score from 16 to 0. These striking results suggest that CD19-expressing plasma blasts may be the major source of pathogenic autoantibodies in SLE and suggest the exciting possibility that other autoantibody-mediated autoimmune diseases may be amenable to nonspecific B-cell-targeted CAR T therapy.

In the age of clinical scale gene editing, these and many other exciting scientific developments have translational prospects. Efficient and safe product development still poses a number of challenges. Despite prior clinical successes, new cellular immunotherapy drug development can be a financially risky endeavor. Commercial success is by no means a guarantee; less than a decade ago, the world's first cancer vaccine bankrupted its manufacturer.<sup>144</sup> In this risky environment, cellular immunotherapy development requires significant upfront investment to scale up, scale out, navigate the regulatory system, and build necessary infrastructure. Uncertainty about future reimbursement adds to the risk of early-phase investing. Autologous therapies in particular are subject to extraordinary manufacturing costs as there can be no batch processing to take advantage of economies of scale. These operational challenges must be overcome to successfully commercialize cellular immunotherapies. Streamlined regulatory processes, technologic advances in automated processing, and expansion of allogeneic platforms all may potentially shift the balance to effective and efficient translation of next-generation therapies.

<sup>4</sup>Department of Laboratory Medicine and the Yale Stem Cell Center, Yale School of Medicine, Yale University, New Haven, CT, USA

## Introduction

The delivery of genetic material into a patient's cells as a medical therapy is referred to as *gene therapy*. Since the first human studies of gene therapy on Severe Combined Immunodeficiency (SCID) in the early 1990s, gene therapy has evolved to have diverse and creative applications across many conditions.<sup>1,2</sup> Here, we review the multiple variables to be considered when gene therapy is performed based on the type of genetic material to insert, the target cells, and the route of administration with a focus on applications of gene therapy to transfusion medicine.

Traditionally, transfusion medicine has provided supportive therapy for patients with inherited hematologic diseases rather than a curative treatment. For example, chronic transfusion can be used to treat anemia associated with sickle cell disease (SCD) or thalassemia, and the administration of clotting factor concentrates can be used to treat or prevent hemorrhage in patients with hemophilia. However, in the future, novel therapies directed at the genetic basis of these diseases may reduce, or even prevent, the need for such patients to require chronic supportive therapy. In this transformation, transfusion medicine will be involved in providing gene-modified cells for curative treatments.

## Gene therapy and transfusion medicine

Gene therapy falls within the purview of transfusion medicine when it requires the infusion of either gene-modified cells or direct administration of vectors that contain the therapeutic genetic material. In addition, transfusion medicine will surely be impacted by gene therapies used to treat diseases that are currently managed with transfusion or factor infusion. For example, hemophilia B, a disease in which patients lack expression of functional clotting factor IX, has been successfully treated with gene therapy in small, early-phase clinical trials.<sup>3</sup> Gene therapy also shows promise as a possible treatment for sickle cell anemia and hemophilia A.<sup>4,5</sup>

Three major considerations for the design of a gene therapy strategy are which gene to insert, which vector to use, and how to administer the vector. Because hematopoietic stem cells can be mobilized, modified, and reinfused to patients, many hematologic disorders are uniquely suited to gene therapy. At the same time, hematological disorders also pose several unique challenges. This is due to the difficulty of delivering the often large genes required to

treat hematologic disease and the risk of malignancy from gene insertion. Yet another challenge is to isolate hematopoietic cells in suitable quantities for transduction-transfection and to support them ex vivo in culture, which is required for most gene modification approaches specific to the hematopoietic system.

## Gene selection and targeted insertion

Based on the disease to be treated, the gene that will be inserted can have a variety of attributes. The gene can provide a functional form of a missing or defective gene, it can augment, inhibit, regulate the expression of a dysfunctional gene, or it can regulate cell survival. Ideal vectors should be designed to target specific cells. The importance of controlling where a gene therapy vector integrates into the genome became clear during the initial gene therapy trials for X-linked immunodeficiency (SCID-X1). Patients with SCID-X1 lack expression of the common gamma chain called CD132 or IL2RG, which serves as a coreceptor for at least six different cytokines. In the initial clinical studies, the retroviral vectors used to deliver the correct copy of the gene integrated into genomic sites that activated the nearby proto-oncogene LMO2. Together with induction of LMO2, overexpression of the common gamma chain caused leukemia in treated patients.<sup>6</sup> The importance of targeting the gene therapy vectors to specific cells was illustrated in a gene therapy trial for hemophilia B, in which the vector itself was administered to the patients. This trial was stopped after the viral vector was detected in a subject's semen, raising concern that a therapeutic gene could be inherited by a subject's future offspring.<sup>7</sup> The health concerns that arose during these initial clinical studies led investigators to return to the bench to develop improved safer approaches for gene therapy. Recent advances in gene therapy strategies and the improvement of existing technologies have reopened the prospect of using gene therapy in the clinic.

## Gene therapy administration

Gene therapy vectors can be delivered to cells ex vivo and then returned to the patient. Alternatively, nonviral and replication-incompetent viral vectors can be directly administered to the patient for transduction of target cells in vivo. There are several benefits to the ex vivo approach (see Table 56.1).<sup>8</sup> By not administering

**Table 56.1** Advantages and Disadvantages of Different Modes of Vector Administration

Manner of Vector Administration	Ex vivo	In vivo
Possible advantages	<ul style="list-style-type: none"> <li>Ability to select transduced cells prior to reinfusion</li> <li>Minimizes infection of nontarget cells</li> <li>Exposes patient to smaller dose of viral vector</li> <li>Ability to insert a suicide gene to inactivate a therapeutic gene</li> </ul>	<ul style="list-style-type: none"> <li>No need to maintain ex vivo fully functional cells that can engraft long term after administration to the patient</li> </ul>
Possible disadvantages	<ul style="list-style-type: none"> <li>Can be technically difficult to maintain and transduce fully functional cells ex vivo</li> </ul>	<ul style="list-style-type: none"> <li>Exposes patient to larger dose of viral vector</li> <li>Vector may have unforeseen effects on unintended target cells</li> <li>Immune system may target the vector for destruction</li> </ul>

the viral vector systemically, the ex vivo approach minimizes infection of nontarget cells, significantly decreases the potential risks of exposing the patient to large amounts of viral vector, and allows for the confirmation of cell transduction prior to reinfusion. On the other hand, direct administration of vectors to the patient overcomes the challenge of maintaining fully functional cells during ex vivo culture. Because there are risks associated with transgene expression in unintended host cells, it is critical that a vector administered in vivo has target specificity or minimal toxicity if expressed by cell types other than the intended target.

### Vector selection

The ideal vector should have no toxicity, lead to minimal inflammation, have a large gene carrying capacity, and should be able to efficiently deliver the gene of interest to the host cells. In addition, vectors should be able to target specific cell types and genetic integration sites within the host. Other factors to consider are whether gene expression needs to be inducible and if lifelong expression is necessary. Unfortunately, a single vector that achieves all of these goals is not yet available. However, based on the above needs, a suitable vector can often be selected. Many research laboratories are developing strategies to optimize current vectors to meet the criteria for an ideal vector. The most well-established viral vector systems for clinical trials are retroviruses, lentiviruses, adenoviruses, and adeno-associated viruses. (Note that the use of retroviral vectors in T cell therapies is covered in Chapter 55, “Chimeric antigen receptor T cells and other cellular immunotherapies,” but such vectors are not limited to use in immunotherapy.) Table 56.2 summarizes the salient features of these viral vectors. Nonviral techniques that are under development for gene therapy are discussed below.<sup>9</sup>

### Ensuring viral vectors are replication incompetent

For safety reasons, all viral vectors for gene therapy must be incapable of replication in the human host. For example, replication-incompetent retroviruses (RIRs) are produced by the removal of the *gag*, *pol*, and *env* genes, which are the genes essential for viral replication and native virus tropism. Before viral vectors can be used in clinical trials, each batch must be tested extensively to ensure that no replication-competent particles are present.

### Risks

The major risks associated with viral vector-based gene therapy are the generation of replication-competent viruses and gene integration that could lead to the activation of oncogenes or loss of function

**Table 56.2** Common Viruses that Have Been Modified for Gene Therapy Research

Family/Subfamily and Characteristics	Specific Virus
<b>Retroviruses</b> (single-stranded RNA, maximal insert size ~8 kb)	Murine leukemia virus Spleen necrosis virus Rous sarcoma virus Avian leukocytosis virus Human immunodeficiency virus, type 1 Human immunodeficiency virus, type 2 Foamy virus Adenovirus, type 5
Oncoretroviruses	
Lentiviruses	
Spumaviruses	
<b>Adenoviruses</b> (double-stranded DNA, maximal insert size ~ 8 kb for first generation; up to 37 kb for new generation)	
<b>Adeno-associated virus</b> (single-stranded DNA, maximal insert size ~ 5 kb)	Adeno-associated virus, type 2 (AAV2), AAV5, AAV6, AAV2/6, AAV8

of tumor suppressor genes. Evidence of the importance of the continual evaluation of risks related to gene therapy is highlighted by the recent revelation that two patients who participated in an NHLBI-funded trial of a lentiviral vector for the treatment of sickle cell disease went on to develop myeloid neoplasms, leading to the pausing of the trial in February 2021 in order to assess whether the leukemia was due to the chemotherapy administered prior to transplantation with modified cells or to the modified cells themselves.<sup>10</sup>

### Recombination to form replication-competent viruses

Replication-competent viruses require the presence of the *gag*, *pol*, and *env* genes encoding the retroviral core structure, reverse transcriptase, and the viral envelope proteins, respectively. Such replication-competent viruses can develop either by the recombination of the constituent parts of the vector system with separately encoded viral sequences in the vector packaging cell lines at the time of viral production or by the activation of endogenous proviral sequences in cells after infection with replication incompetent vectors. The significant risks of retroviral reactivation for gene therapy were elucidated when primate studies were performed in the early 1990s. In these studies, CD34-selected primate marrow cells were infected with what was thought to be pure replication-incompetent virus produced by packaging cell lines. There were, however, some replication-competent viruses that had not been detected by existing assays. Upon infusion, three of eight primates subsequently developed lymphomas containing the active, rearranged retrovirus.<sup>11</sup> Since that time, multiple approaches have been incorporated

to optimize safety by improved assays for any replication-competent vectors, and minimizing the regions of homology between the vectors, packaging cell lines, and endogenous retroviruses. Currently, clinical trials require stringent testing to guarantee that the retroviral vector to be used in humans is entirely replication incompetent.

### Insertional mutagenesis

Genotoxicity occurs when genetic material is inserted in proximity to a proto-oncogene or disrupts expression of a tumor suppressor gene. The presence of the strong viral promoter near a proto-oncogene can lead to transcriptional activation of the gene. This has led to the development of malignancy in patients enrolled in a clinical trial for X-linked immunodeficiency.<sup>6,12–14</sup> In addition, insertion of a transgene into a portion of the genomic DNA that is essential for cell survival can lead to disruption of critical cell processes, resulting in cell death.

Advancements have allowed gene therapy to become more precise. For example, it is now possible to use AAV to insert a therapeutic gene at a specific and desired location.<sup>15</sup> The groundbreaking work on Clustered Regularly-Interspaced Short Palindromic Repeats (CRISPR), which led to the winning of the 2020 Nobel Prize in Chemistry to Dr. Jennifer Doudna and Dr. Emmanuelle Charpentier, has paved the way for targeted gene therapy, opening the door for many potential breakthroughs.<sup>16,17</sup>

### Nonviral gene therapy vectors

Nonviral vectors for gene therapy are also undergoing intensive investigation.<sup>18</sup> Unlike viral vectors, nonviral methods do not need to overcome the extensive immune mechanisms that inhibit transduction *in vivo*. There is also no risk of replication-competent forms of the vector. These methods include DNA microinjection, chemical transfection of exogenous DNA, or nanoparticles filled with DNA or RNA. This is the approach used for the SARS-CoV-2 vaccines produced by Moderna and Pfizer, as discussed below.<sup>19</sup>

Nanoparticles have numerous utilities. When it comes to vaccines, they can be crosslinked to a protein antigen to promote antigen immunogenicity while decreasing antigen degradation.<sup>20,21</sup> When protein and RNA-based vaccines are administered with nanoparticles, there is little to no risk of incorporation into the host genome, and the RNA vectors and proteins they encode are short-lived. With these advantages in mind, beyond their practical applications to infectious diseases, there has also been interest in their utility to other scopes of medical practice such as the development of cancer vaccines, in order to boost the host immune system to achieve antitumor activity.<sup>21</sup>

### Gene editing

Various gene-editing approaches, such as transcription activator-like effector nucleases (TALENs), zinc finger nucleases (ZFNs), and CRISPR with CRISPR-associated 9 (Cas9), have been described.<sup>22</sup> All three of these technologies use exogenous programmable nucleases (e.g., FokI, Cas9, and Cpf1) that are designed to generate sequence-specific double-strand breaks (DSBs) of the DNA. DSBs activate endogenous cellular repair mechanisms that will induce homology-directed repair (HDR) of the mutated sequence in the patient's DNA in the presence of donor DNA containing the corrected sequence as template.<sup>23</sup> Gene editing can be used to disrupt, add, or correct genes in animal cells.<sup>22</sup>

Studies that have assessed the possible application of gene-editing techniques to hemoglobinopathies are discussed in the

"Transfusion-medicine-related gene therapy trials" section. Notably, gene-editing approaches have also shown promise for other conditions. For example, a trial of HIV patients treated with autologous T cells that were engineered to have dysfunctional CCR5 genes using a targeted ZFN was reported in 2014.<sup>24</sup> Although 1 of the 12 patients in the trial had a transfusion reaction to the infusion of T cells, the study found that the infusion of these engineered cells appeared to be safe.<sup>24</sup> Long-term monitoring of study participants is ongoing to confirm the safety of this approach. There are currently at least 19 interventional clinical trials with CRISPR/Cas9 gene-editing technology, spanning from blood diseases to cancer and HIV.<sup>23</sup>

### Transfusion-medicine-related gene therapy trials

Herein, we review select conditions for which gene therapy is rapidly progressing as a novel treatment strategy.

#### Hemophilia B

Hemophilia B is an X-linked genetic disease that results in bleeding due to reduced or absent activity of factor IX, a serine protease synthesized in the liver. At present, bleeding prevention in hemophilia B is typically accomplished via administration of recombinant factor IX concentrates.

Treatment alternatives that do not require factor administration are needed. Severe hemophilia B is an attractive target for gene therapy because even a small increase in endogenous factor IX activity could reduce dependence on factor IX infusions and prevent spontaneous bleeding episodes. In the late 1990s, researchers using various animal models of hemophilia B found that gene therapy with an adeno-associated virus (AAV) vector could be used to induce sustained circulation of factor IX.<sup>25,26</sup> Shortly thereafter, a human trial established that the administration of an AAV vector to human subjects was safe.<sup>27</sup> A subsequent study of seven patients with severe hemophilia B showed that treatment with a recombinant AAV vector (rAAV-hAAT-F.IX) led to only transient elevations in circulating factor IX.<sup>28</sup> Because the reduction in factor IX activity was associated with an increase in hepatic transaminases, the study authors concluded that immune-mediated destruction of transduced hepatocytes expressing the AAV capsid may have occurred. In contrast to animal models, humans are frequently infected by AAV during childhood. This may explain why animals were capable of a sustained response to AAV-mediated gene therapy whereas humans generated a secondary immune response that led to the destruction of transduced hepatocytes.

Early-phase trials have established the potential for AAV-mediated gene therapy approaches to improve bleeding outcomes in patients with hemophilia B.<sup>29,30</sup> However, controlling immune responsiveness to engineered cells remains a barrier.<sup>29</sup> It appears that the immune response to engineered cells is primarily driven T cells and can result in loss of transduced gene product in a dose-dependent manner.<sup>28</sup> Consideration of the vector quantity that is required to attain sufficient factor IX expression level to provide clinical benefit, without triggering an unfavorable immune response, is an important topic for continued evaluation.<sup>29</sup>

#### Hemophilia A

Hemophilia A is caused by a deficiency in factor VIII, which is the only clotting factor synthesized by endothelium (rather than hepatocytes). Similar to factor IX deficiencies, even a small increase in factor VIII activity would be expected to protect patients from

many bleeding episodes. Therefore, hemophilia A is another appealing target for gene therapy.

However, unlike factor IX, factor VIII is a large protein that is difficult to efficiently express in vitro. Attempts to induce cultured cells to produce factor VIII can result in the production of misfolded factor VIII protein, which can, in turn, activate the unfolded protein response and trigger apoptosis of the cells. Also, because the gene encoding factor VIII is so large, in the absence of complex laboratory manipulations, it is too large to fit into the AAV vector.<sup>31</sup> Finally, patients with hemophilia A are more likely to develop circulating inhibitors to factor VIII. Such inhibitors result in factor neutralization and require bypass factor therapy, such as factor VII. For these reasons, gene therapy for hemophilia A lags behind gene therapy for hemophilia B.

The complexity of the immune response in this application is demonstrated by the results of a recent phase I/II study on valoctocogene roxaparvovec (BMN 270), which uses an AAV-based vector encoding factor VIII. Reassuringly, this study did not identify the development of factor VIII inhibitors.<sup>32</sup> However, antibodies to the AAV5 capsid were detected.<sup>32</sup> While immunity to the AAV5 capsid was not harmful to study participants, this reactivity will need to be further addressed.<sup>32</sup>

### Hemoglobinopathies and thalassemias

Much like hemophilia, the hemoglobinopathies are attractive targets for gene therapy. Sickle cell disease (SCD) and thalassemias are some of the most common single-gene defects worldwide. SCD affects approximately 275,000, and β-thalassemia affects approximately 56,000 newborns every year.<sup>33</sup> Current treatment for these diseases is primarily supportive therapy, which includes chronic transfusion for the management of sickle crises and/or anemia. However, this approach comes with several consequences, including alloimmunization to minor red blood cell antigens and iron overload, and even under ideal conditions transfusion does not prevent all morbidities associated with these chronic diseases.<sup>34</sup> Thus, a curative therapy is highly desirable. One option is hematopoietic stem cell transplantation, although this approach usually requires a matched sibling donor who is not affected.<sup>35</sup> Alternative therapies that lead to decreased reliance on transfusion and other supportive therapies would be beneficial. Compared to bone marrow transplantation, gene therapy would bypass the need to find a donor and the risks of long-term immunosuppression.

These chronic anemias have traditionally been difficult to treat with gene therapy as they require large genetic sequences with stable, long-term expression to be effective.<sup>4</sup> In addition, they require a high level of gene expression for correction, which is difficult to achieve with traditional vectors.<sup>4</sup> Mouse models of SCD have demonstrated that lentiviral vectors carrying an antisickling globin are able to persistently express the globin gene at levels high enough for symptomatic correction.<sup>36</sup> Understanding of hereditary persistence of fetal hemoglobin and its well-characterized protective effects in SCD has sparked special interest in exploring gene therapy as a means to turn on the beta chain of fetal hemoglobin (the γ-globin gene) to produce this protective phenotype.<sup>37</sup> As discussed below, inactivation of the transcriptional repressor BCL11A can lead to reactivation of endogenous γ-globin gene expression, making BCL11A and its genomic binding sites excellent targets for gene-editing approaches.

Clinical trials for the treatment of β-thalassemia with gene therapy have progressed more quickly than for SCD. Approaches that use viral-mediated addition of a γ-globin gene expressed from a

**Table 56.3** Some Key Ongoing Clinical Trials in the Realm of Gene Therapy

Condition	Clinical Trials (with ClinicalTrials.gov Identifier)
Sickle cell disease (SCD)	Gene transfer for sickle cell disease: Single infusion of autologous bone-marrow-derived CD34+ HSC cells transduced with the lentiviral vector containing a short-hairpin RNA targeting BCL11a (NCT03282656) A study evaluating gene therapy with BB305 lentiviral vector in sickle cell disease: genetic LentiGlobin BB305 drug product for SCD (NCT04293185) Stem cell gene therapy for sickle cell disease: biological βAS3-FB vector-transduced peripheral blood CD34+ cells (NCT02247843) CSL200 gene therapy in adults with severe sickle cell disease: biological: autologous enriched CD34+ cell fraction that contains CD34+ cells transduced with lentiviral vector encoding human γ-globin G16D and short-hairpin RNA734 (NCT04091737)
Hemophilia A	Study to evaluate the efficacy and safety of PF-07055480 in moderately severe to severe hemophilia A adults: biological recombinant AAV2/6 human factor VIII gene therapy (NCT04370054) Lentiviral FVIII gene therapy: biological YUVA-GT-F801 (NCT03217032) A gene transfer study for hemophilia A: genetic SPK-8011 (NCT03003533) ASC-618 gene therapy in hemophilia A patients: biological ASC-618 (NCT04676048)
Hemophilia B	A factor IX gene therapy study (FIX-GT): biological FLT180a (NCT03369444) Lentiviral FIX gene therapy: biological YUVA-GT-F901 (NCT03961243) A study to evaluate the efficacy and safety of factor IX gene therapy with PF-06838435 in adult males with moderately severe to severe hemophilia B: biological PF-06838435/fidanacogene elaparvovec (NCT03861273) A study to evaluate the efficacy and safety of valoctocogene roxaparvovec, with prophylactic steroids in hemophilia A: biological valoctocogene roxaparvovec (NCT04323098)
Beta thalassemia	Gene therapy for beta-thalassemia major using autologous hematopoietic: genetic autologous CD34+ cells genetically modified (NCT03276455) Safety and efficacy evaluation of gamma-globin reactivated autologous hematopoietic stem cells: biological gamma-globin reactivated autologous hematopoietic stem cells (NCT04211480) A safety and efficacy study evaluating CTX001 in subjects with transfusion-dependent beta-thalassemia: biological CTX001 (NCT036555678)

β-globin promoter to ensure expression in adults have been promising in mouse models.<sup>38</sup> A single patient with β<sup>E</sup>/β<sup>0</sup>-thalassemia, who lacked an HLA-matched hematopoietic stem cell donor, was reported to have achieved transfusion independence three years after undergoing transplantation with autologous cells that had undergone lentiviral β-globin gene transfer ex vivo.<sup>39</sup>

Other novel approaches to hemoglobinopathies use a gene-editing technique. Early studies using induced pluripotent stem cells showed that TALENs and CRISPR/Cas9 could be used to correct mutations causing β-thalassemia,<sup>40,41</sup> and CRISPR/Cas9 and ZFNs could be used to correct the SCD mutation.<sup>42,43</sup> TALENs have been reported to correct mutations causing α-thalassemia major in induced pluripotent stem cells.<sup>44</sup> It is hoped that gene therapies for these conditions will continue to progress quickly through clinical trials. Some key trials are discussed in detail below. For a more comprehensive list of current clinical trials, see Table 56.3.

### BCL11A targeted therapy (lentiviral approach)

One recent trial leveraged a lentiviral vector targeting BCL11A in autologous CD34+ cells with the goal of increasing fetal

( $\gamma$ -globin-containing) hemoglobin among patients with sickle cell disease.<sup>45</sup> The approach used a short hairpin RNA (shRNA) targeting the BCL11A gene.<sup>45</sup> The infusions were well tolerated, with all toxicity believed to be linked to the preparative chemotherapy.<sup>45</sup> Remarkably, the investigational therapy resulted in the production of fetal hemoglobin as well as improved clinical parameters.<sup>45</sup>

### BCL11A-targeted therapy (CRISPR approach)

Investigators reported the use of CRISPR-Cas9 to target BCL11A in autologous patient cells obtained from one patient with sickle cell disease and another with transfusion-dependent thalassemia.<sup>46</sup> Twelve months after myeloablation, and infusion of these autologous CRISPR-modified cells, both patients demonstrated increases in fetal hemoglobin, signifying successful engraftment of the modified stem cells.<sup>46</sup> Incredibly, neither patient required transfusions and sickle cell pain crises were eliminated, thus correlating engraftment with improved clinical markers.<sup>46</sup>

### Adverse effects

In early 2021, a clinical trial for severe sickle cell disease was stopped after two participants who had received a lentiviral vector-based investigational treatment unexpectedly developed myeloid neoplasms (NCT02140554).<sup>10</sup> This raised concerns for potential side effects of gene therapy stemming from lentiviral vectors more generally. As a measure of caution, the National Heart, Lung, and Blood Institute (NHLBI) halted a separate gene transfer study for sickle cell disease (NCT03282656) targeting BCL11A pending further study of the myeloid neoplasms that occurred in NCT02140554.<sup>10</sup> The evaluation of this safety concern will be key to the future development of lentiviral gene therapy for sickle cell disease as well as other chronic anemias.

### Wiscott-Aldrich syndrome (WAS)

WAS is a rare, X-linked immune deficiency caused by mutations in the WAS gene. Patients classically present with thrombocytopenia with small platelets, susceptibility to infections, and eczema.<sup>47</sup> Patients also have an increased risk for the development of autoimmune diseases and cancer.<sup>47</sup> Patients may be treated with a stem cell transplant if an HLA-matched donor is available. Patients with WAS may come to the attention of the transfusion service as a result of bleeding in the context of thrombocytopenia.

A phase I/II clinical trial of three pediatric patients with WAS, who lacked an HLA-matched donor or were otherwise ineligible for stem cell transplant, was reported in 2013.<sup>48</sup> In this trial, autologous CD34+ cells were transduced with a normal WAS gene ex vivo using a lentiviral vector. When the engineered hematopoietic stem cells were infused, they engrafted successfully. The patients went on to demonstrate improvements in hemostasis and immunity.<sup>48</sup> In recent years, data from additional clinical trials have also demonstrated the short-term and medium-term efficacy of gene therapy using a lentiviral vector for WAS.<sup>49</sup> There has been some restoration of immune function post therapy with protection from infectious agents and improved control against autoimmune disease.<sup>49</sup>

Promising beginnings for CRISPR/Cas9-based editing as a future treatment for WAS have also been reported. In a mouse model of WAS, genetically modified cells persisted for at least 26 weeks after treatment, and the approach was not associated with overt toxicity to the animals. In human cells, CRISPR/Cas9 has been shown to correct the majority of WAS gene mutations in vitro, without interfering with basic cellular machinery.<sup>50</sup>

### Severe combined immunodeficiency

Finally, in the realm of genetic immunodeficiencies, severe combined immunodeficiency (SCID) deserves a brief mention. Adenosine deaminase (ADA) is responsible for approximately one-half of the cases of autosomal recessive SCID.<sup>51</sup> Patients with ADA-SCID have a high risk of infections by opportunistic organisms at an early age, and up to this point, definitive treatment has relied predominantly on bone-marrow transplantation from a histocompatible-related donor.<sup>51</sup> Despite its rarity, SCID is considered a prime candidate for gene therapy, and since the late 1990s, scientists have been exploring gene therapy via gamma-retroviral vectors using multiple infusions of genetically corrected autologous peripheral blood lymphocytes.<sup>51,52</sup> After a decade of efforts, the introduction of low-intensity conditioning represented the crucial step in achieving stable gene-corrected hematopoietic stem cell engraftment and therapeutic levels of ADA-expressing cells.<sup>52</sup> Finally, in 2016, retroviral therapy received marketing approval in Europe for patients with ADA-SCID without a suitable human leukocyte antigen-matched related donor, becoming the only viral-based gene therapy protocol approved for ex vivo CD34+ gene therapy.<sup>52</sup> Overall, the safety and efficacy of viral vector-based treatments for SCID has fundamentally revolutionized the treatment of this rare disease.<sup>52</sup>

### Gene therapy and vaccines: a unique frontier of exploration

In early 2020, COVID-19, a respiratory and vascular multisystem disease caused by SARS-CoV-2, rapidly transformed into a pandemic.<sup>53</sup> The pandemic resulted in expedited funding and research efforts aimed at containing the crisis, and resulted in the first widespread use of mRNA-based vaccines.<sup>54,55</sup> Two such vaccines, one made by Pfizer in collaboration with BioNTech and the other by Moderna in collaboration with United States National Institute of Allergy and Infectious Diseases, utilize lipid–nanoparticle-encased RNA molecules.<sup>55</sup> Mechanistically, after the mRNA is taken up by human cells, it encodes a modified (stabilized) version of the SARS-CoV-2 spike protein.<sup>54</sup> Consequently, an immune system response is generated.<sup>55</sup> Data from clinical trials has shown that both vaccine candidates are over 94% effective in preventing symptomatic SARS-CoV-2 infection.<sup>54,55</sup> While side effects from the vaccines appear to be mild overall,<sup>55</sup> the ongoing global vaccinations are likely to shed light on population-wide efficacy and unknown potential long-term side effects. Furthermore, if successful and safe in the long term, the development of other genetically based vaccines seems likely.

### Summary

Gene therapy continues to offer much promise for the treatment of genetic and acquired diseases. Transfusion medicine laboratories are currently involved in clinical gene therapy trials and, in the future, as these therapeutic modalities become more mainstream, will likely play a role in what may be “routine” administration of gene therapy vectors and vector-infected cells. Finally, we have listed, in tabular format (Table 56.3), some of the ongoing gene therapy clinical trials for selected pathologic conditions.

## CHAPTER 57

# Tissue engineering and regenerative medicine

Cecilia Motta<sup>1</sup>, Qi Xing<sup>1</sup>, Cynthia Wilkins<sup>2</sup>, & Julie Allickson<sup>2</sup>

<sup>1</sup>Wake Forest School of Medicine, Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston Salem, NC, USA

<sup>2</sup>Mayo Clinic, Center for Regenerative Medicine, Rochester, MN, USA

As the number of individuals awaiting organ transplant continues to increase, tissue engineering and regenerative medicine technologies present promising new options for addressing the critical tissue and organ shortages that currently exist.<sup>1</sup> This interdisciplinary field integrates engineering and life science principles in an effort to restore function to impaired tissues and organs.<sup>2</sup> Sophisticated grafts, often in combination with cellular therapies, are designed to mimic native tissues in an effort to promote or enhance the body's intrinsic regenerative capacity to restore tissue integrity. The fields of tissue engineering and regenerative medicine have become expansive and diverse in the last few decades, creating the potential for patient-specific, engineered treatments. Great progress has been made in identifying biomaterials that support the healing process. However, only a limited number of approaches that incorporate cellular strategies have been successfully translated and approved by the FDA for commercialization,<sup>3–5</sup> even though the use of cellular components in tissue engineering has been shown to improve the extent of regeneration and increase scaffold integration to the native tissue.<sup>6</sup> The inclusion of biochemical factors and functional groups in natural and synthetic scaffold materials provide a microenvironment that promotes cell attachment, differentiation, and migration to facilitate tissue repair,<sup>7</sup> while the scaffold architecture and porosity support vascularization and nutrient diffusion to nascent tissue.<sup>8,9</sup> Decellularized tissues from allogenic and xenogeneic sources have demonstrated potential in a number of applications,<sup>10,11</sup> and 3D printing provides a path forward for fabricating networks that mimic the native tissue matrix with high fidelity.<sup>12</sup> New strategies for large scale in vitro cell expansion and tissue maturation will advance the prospect of "off-the-shelf" regenerative therapies that meet FDA guidelines and are readily available for patient treatment.<sup>5</sup>

In the previous edition of this book, Niklason et al. provide a comprehensive review of tissue engineering and regenerative medicine technologies related to skin, blood vessel, bone, cartilage, cardiac, urology, and corneal tissue. In this edition, we have added several additional areas including lung, reproductive system, peripheral nerve, skeletal muscle, gastrointestinal system, and renal tissue engineering, as well as provided review of some of the latest advances.

## Lung Tissue Engineering

Pulmonary disease is a worldwide public health problem. Recent developments in stem cell biology and lung tissue engineering have shown promise in addressing various pulmonary diseases, including chronic obstructive pulmonary disease,<sup>13</sup> congenital lung hypoplasia,<sup>14</sup> sarcoidosis,<sup>15</sup> cystic fibrosis,<sup>16</sup> interstitial fibrosis,<sup>17</sup> and pulmonary hypertension.<sup>18</sup> While lung transplantation appears to be the ultimate remedy for advanced lung diseases, significant shortages of compatible donor organs is an issue and transplant recipients must endure lifelong immunosuppression. Engineering an entire lung using autologous cells or allogenic stem cells seems optimal for increasing organ availability and minimizing the need for post-transplantation immunosuppression.

## Scaffolds

Current lung tissue engineering research has focused on generating whole lung or constituent lung parts by seeding cells onto scaffolds with the ultimate aim of grafting these constructs into the human body.<sup>19</sup> Generally, these scaffolds are classified into two groups, based on the source or origin: natural and synthetic. Natural, extracellular matrix (ECM)-derived scaffolds obtained from decellularized donor lungs retain the unique structural and functional architecture of this complex tissue.<sup>20</sup> Developing whole lung decellularization procedures that yield native matrices is a rapidly growing field. Studies have addressed the utilization of different reagents and techniques to preserve structural proteins such as collagen, laminin, elastin, fibronectin, and other growth promoting biomolecules that are essential for regulating cellular behavior. Decellularization processes have included detergents, such as sodium dodecyl sulfate (SDS), 3-[3-Cholamidopropyl] dimethylammonio]-1-propanesulfonate hydrate (CHAPS), and Triton X-100, which have been utilized to remove cells from whole lung tissue. The zwitterionic detergent CHAPS has been shown to preserve airway and vascular structures with retention of collagen and elastin but does not conserve glycosaminoglycans (GAGs).<sup>21</sup> Decellularization with SDS also maintains alveolar and vascular structures,<sup>22</sup> while decellularization with Triton X-100 and SDS with DNase allows for retention of collagen, elastin, laminin, and GAGs.<sup>23</sup> Understanding the relative roles of lung tissue ECM

elements in cell attachment, differentiation, migration and immunogenicity will help to identify the advantages and disadvantages of each technique. These decellularized matrices have been shown to be successfully reseeded with pulmonary cells such as epithelial,<sup>21</sup> endothelial cells,<sup>22</sup> and fetal alveolar type II cells.<sup>23</sup> Notably, in experimental models, instances of gas exchange have been observed for short-term intervals.<sup>21</sup>

Other examples of natural scaffolds include biological materials such as collagens, proteoglycans, and Matrigel®. In a study using fetal rat lung cells, Gelfoam®, a gelatin-based scaffold, was grafted in combination with the cells into lung parenchyma. The rat pulmonary cells formed into “alveolar-like structures” at the border between the Gelfoam sponge and the surrounding lung tissue and positive immunohistochemical staining for epithelial and endothelial cells.<sup>24</sup> Another study performed with fetal rat lung cells utilized a scaffold consisting of a Type I collagen-chondroitin 6-sulfate matrix and demonstrated cell forming and maintaining alveolar-like structures.<sup>25</sup> Natural ECM hydrogels such as Matrigel and Type I collagen gels are rapidly growing in use due to their biochemical and mechanical features, which provide an appropriate 3D matrix for pulmonary cell morphogenesis and differentiation.<sup>26,27</sup>

Synthetic materials such as polyglycolic acid (PGA), poly lactic-co-glycolic acid (PLGA), and poly-D,L-lactide (PDLLA) are also being extensively studied for lung tissue engineering due to their porous properties, elasticity, and biodegradability.<sup>28–31</sup> Synthetic polymers, however, often fail to drive the differentiation of cultured cells<sup>32</sup> and frequently initiate an inflammatory response. Surface modification of these synthetic matrices with natural ECM proteins such as laminin, collagen, or Matrigel can facilitate cell attachment and subsequently support the development of a pulmonary cell phenotype.

### Cell source

The lung is a highly complex organ comprised of diverse cell types including parenchymal, ductal, vascular, and structural cells (e.g., fibroblasts), most of which would be necessary in order to engineer a replicate organ.<sup>33,34</sup> The use of autologous cells reduces the potential for rejection and therefore the need for immunosuppressive agents. Despite extensive research into creating lung tissue constructs using primary pulmonary cells, these cells can rapidly lose phenotypic marker expression in vitro and the expansion to large numbers of cells can be difficult and costly.<sup>35–40</sup> A key challenge for the reconstruction of human lung tissue is the lack of an abundant source of pulmonary epithelial cells.<sup>41–43</sup> Utilization of stem cells presents an alternative avenue that may overcome the limitations experienced with primary cells.

Stem and progenitor cells, including cells such as embryonic stem cells (ESCs), induced pluripotent stem cells (iPSC), lung stem cells, umbilical blood cord (UBC) stem cells, and mesenchymal stem cells derived from bone marrow or adipose tissue, have been extensively studied in the lung tissue industry. Embryonic stem cells are true pluripotent stem cells with the capacity to differentiate into all three germ layers and evolve into any cell lineage, and have therefore been used to generate upper airway epithelial cells, alveolar epithelial type II (AECII)-like cells, and pneumocytes.<sup>24,31,44</sup>

In addition to rapid in vitro expansion, a beneficial effect of using mesenchymal stem cells (MSCs) in tissue engineering is that they secrete paracrine factors that modulate the immune response. In a recent study using MSC microvesicles in an ex vivo *E. coli*-injured human lung model, alveolar fluid clearance was restored, and a reduction in inflammation and antimicrobial activity was observed.<sup>45</sup>

Mesenchymal stem cells have also demonstrated the capacity to differentiate into Type I collagen-producing fibroblast-like cells<sup>46</sup> and lung epithelial phenotypes<sup>47</sup> when grown on a decellularized lung scaffold, supporting a potential role for these cells in addressing pulmonary cell therapies and tissue engineering.

Induced pluripotent stem cells are an attractive cell source for the generation of lung epithelial cells as they have the potential to avoid immune rejection and can be expanded to cell numbers necessary for repopulating decellularized human-sized lung scaffolds. Additionally, these stem cells can be induced into a population of type II epithelial-like progenitor cells using a stepwise differentiation protocol<sup>48</sup> and have been shown to repopulate the alveolar and airway compartments of decellularized lungs.<sup>49</sup> Introducing differentiated iPSCs into decellularized lung scaffolds has been shown in multiple studies to result in perfusable and functional vascular lumens.<sup>50,51</sup>

### Bioreactors

Bioreactors provide precisely controlled physicochemical factors such as pH, O<sub>2</sub>, CO<sub>2</sub>, and metabolites for supporting the growth of engineered tissues.<sup>32,52</sup> In addition to adequate nutrient transfer, oxygen transport, and waste removal, lung tissue bioreactors require mechanical stimuli, including an air-liquid interface and ventilation generated by negative-pressure to support pulmonary tissue development.<sup>27</sup> A decellularized scaffold is often perfused via cannula at physiological pressure, and a syringe pump is used to simulate negative-pressure ventilation by inhalation and exhalation of liquid medium.<sup>53</sup> Microfluidic-based bioreactors can be cost-effective and high throughput, which is ideal for pharmaceutical and toxicity studies. Macroscale automatable closed systems that benefit from pressure-controlled perfusion and ventilation would be necessary, however, for generating transplantable lungs that would progress into clinical therapies. Notably, a fully automated high-throughput bioreactor system capable of ex vivo lung recellularization and biomimetic culture under varying perfusion and ventilation parameters has been reported and can easily be scaled to support the maturation of 20 or more cultured lungs.<sup>54</sup>

### Bioprinting

Three-dimensional (3D) bioprinting has recently emerged as a potential method for generating bioengineered tissues or supporting structures. The lung is a large complex tissue containing multiple cell types, interconnected bifurcating airways, and varying degrees of vasculature all of which pose significant fabrication challenges. A major advantage of bioprinting is the ability to print complex patterns within a large geometry. There are currently no published reports on attempts to 3D print whole lung tissues that are capable of gas exchange; however, 3D-printing technologies have advanced enough for printing supporting structures such as trachea and bronchus.<sup>55,56</sup> In general, most studies addressing tracheal construction combine biological hydrogels seeded with cells that surround a sturdy polymer structure. For example, a tissue-engineered trachea was created by assembling chondrocyte-seeded, functionalized gelatin sponges into the grooves of a 3D-printed polycaprolactone (PCL) bellows scaffold; the construct demonstrated similar mechanical behavior to that of a native trachea and substantial regeneration of tracheal cartilage in vivo.<sup>57</sup> Similarly, a 3D-printed biodegradable PCL tracheal scaffold impregnated with chondrocyte laden hydrogel was grafted in a rabbit animal model and demonstrated cartilage formation.<sup>58</sup> 3D printing has been applied clinically for the treatment of tracheobronchomalacia<sup>59</sup> and

tracheal collapse with 3D-printed patient-specific tracheal splints for supporting structures.<sup>60,61</sup> The future of lung bioprinting will depend upon overcoming multiple obstacles including cell sourcing, maintaining lumen patency, maintaining a sealed air/fluid interface, and developing a dynamic bioreactor to provide efficient gas and nutrient transport while maintaining mechanical stimulation.<sup>62</sup>

### **Cell therapy for pulmonary complications of COVID-19**

The coronavirus, SARS-CoV-2, has caused a novel coronavirus disease (COVID-19) that has spread worldwide since its outbreak in 2019. COVID-19 has the potential to cause severe pulmonary complications such as pneumonia and acute respiratory distress syndrome (ARDS). Severe ARDS is often accompanied by a massive attack of proinflammatory cytokines and chemokines, which can cause vascular leakage and tissue inflammation in the affected organs. Immunomodulatory intervention is therefore desired in order to mitigate disease progression and severity.<sup>63</sup> Stem cells, natural killer (NK) cells, T cells, dendritic cells (DN), and exosomes have been identified as leading therapeutic candidates for regenerating damaged lung tissue.

Among cell-based therapies currently registered in clinical trial for COVID-19, the most prevalent approach has been mesenchymal stem cell (MSC) therapy. Mesenchymal stem cells can easily be isolated from a variety of tissues and are well known for possessing immune-modulatory capabilities that manifest through multiple mechanisms.<sup>64</sup> In clinical studies for COVID-19 treatments, the use of human umbilical cord mesenchymal stem cells (hUCMSCs) was shown to produce inflammatory remission in a patient with severe level symptoms.<sup>65</sup> Similarly, case reports have indicated that clinical improvements and changes in the inflammatory and immune cell populations occurred following MSC transplantation in critically ill patients with COVID-19.<sup>66,67</sup> Wharton's jelly-derived MSCs (hWJCs) were additionally reported as treatment for a patient with severe symptoms due to COVID-19 pneumonia. Significant improvement was observed two days following hWJC transplantation.<sup>68</sup> Exosomes derived from allogeneic bone marrow MSCs (ExoFlo™) and administered as treatment in 24 patients exhibiting severe symptoms due to COVID-19 also produced significantly improved clinical status and oxygenation.<sup>69</sup> These reports demonstrated tolerance for allogenic MSCs as well as promising clinical outcomes in COVID-19 treatment.

Adoptive NK and chimeric antigen receptor (CAR)-NK cells provide another promising approach to treating severe COVID-19 symptoms.<sup>70,71</sup> The NK cells are innate immune responders critical for viral clearance and immunomodulation. Several clinical trials have been initiated to evaluate the safety and immunogenicity of adoptive and CAR-NK cells.<sup>71</sup> SARS-CoV-2-specific T cells from recovered COVID-19 patients maintained an immune response six months following infection.<sup>72</sup> These allogeneic virus-specific T-cells have therefore been introduced as an emergency treatment for critically ill patients (ClinicalTrials.gov Identifier: NCT04401410 and NCT04351659).

### **Reproductive System Tissue Engineering**

Reproductive system disorders are generic terms relating to diseases that damage reproductive tissues. These include congenital and acquired abnormalities, malignant tumors, trauma, infectious etiologies, inflammation, and iatrogenic injuries.<sup>73</sup> At present, no

effective treatments that target congenital and acquired abnormalities, malignant tumors, and traumatic injuries exist. Tissue for autologous grafting is specialized and therefore limited, and may lead to secondary donor site damage. Allogeneic transplantation faces issues regarding donor shortages, as well as problems with tissue rejection and compatibility. The application of regenerative medicine technologies as a biological alternative is currently under consideration for treating several types of reproductive system disorders.

### **Scaffolds**

A wide variety of biomaterials have been utilized for scaffolding in reproductive tissue engineering including acellular matrices, collagen, fibrin, silk, and synthetic materials such as PLA, PLGA, and PCL. Autologous transplantation of murine ovarian cells in a fibrin scaffold resulted in survival and growth of the ovarian follicles, suggesting that fibrin may be a promising candidate for the construction of an artificial ovary.<sup>74</sup> It was reported that both MSC-seeded and acellular silk scaffolds restored urethral function; notably, the cell-seeded scaffolds improved neo-tissue formation and mechanical strength.<sup>75</sup> Various forms of decellularized tissues have been applied in developing engineered ovarian,<sup>76–78</sup> uterine,<sup>79–81</sup> testis,<sup>82–84</sup> and placenta<sup>85,86</sup> tissues. A bioengineered uterine patch made from decellularized uterine scaffold seeded with primary uterine cells and MSCs was used to repair a partial defect in a rat uterus. Host cell infiltration and uterus-like tissue structure were observed in the implanted patch.<sup>80</sup> An autologous-cell, tissue-engineered vaginal organ constructed by seeding vaginal smooth muscle and epithelial cells on small intestinal submucosa (SIS) segments has been investigated in a pilot cohort study. No long-term postoperative surgical complications were noted, and the reconstructed tissues displayed trilayered structure similar to native vaginal tissues with phenotypically normal smooth muscle and epithelial cells.<sup>87</sup>

### **Cell source**

Cells for reproductive tissue engineering include both autologous and allogeneic sources; however, autologous cells are preferred. Ideally, the cells are isolated from patient biopsy tissue and expanded *in vitro* for subsequent reimplantation. Some patients, however, do not have sufficient functional tissue from which to procure a biopsy. In these cases, alternative approaches such as stem cells (either autologous or allogeneic) may also be considered for use in engineering a regenerative therapeutic.<sup>88,89</sup>

Autologous vaginal epithelial and smooth muscle cells have been studied extensively in combination with scaffold materials such as polyglycolic acid (PGA),<sup>90</sup> hyaluronic acid embedded gauze,<sup>91</sup> and SIS<sup>87</sup> for reconstructing vaginal tissue. Clinical studies employing these methodologies suggest that the restoration of normal epithelium can be achieved, and that, for long term, a normal range of function could be established, as determined using the Female Sexual Function Index (FSFI).<sup>87,91</sup>

A series of studies have also demonstrated that the penile corporal body can be replaced using naturally derived collagen matrices seeded with human corporal SMC and endothelial cells (EC).<sup>92–94</sup> In a rabbit model of penile defect, the implantation of an engineered penile tissue segment resulted in the restoration of structural integrity as reported by cavernosography.<sup>93,94</sup> Similarly, the restoration of functional integrity was demonstrated in rabbits following the implantation of a full-length engineered penile corpora. Sperm presentation on vaginal swabs and pregnancy rates for mated female rabbits were 83% and 30%, respectively. Most untreated

control rabbits, however, did not attempt copulation after introduction to their female partners; all vaginal swabs were negative for sperm, and none of the females were impregnated.<sup>95</sup>

Studies have also shown that the restoration of fertility in prepubescent boys who have been subjected to cancer treatments may be achievable through preemptive collection and cryopreservation of their spermatogonial stem cells (SSCs).<sup>96</sup> Autotransplantation of the SSC would then occur at a later point in time, following cessation of the treatments, and would enable these individuals to mature into functionally reproductive adults.

A regenerative-based approach to creating testicular prostheses has also been pursued. Cartilage-based testes engineered from chondrocytes that have been cultured in testis-shaped PLA scaffolds formed the basis for this methodology. These prostheses can be created in bioreactors and designed to release testosterone over a prolonged period of time,<sup>97</sup> providing a regenerative mechanism for individuals who require testicular prostheses and chronic hormone supplementation.

### **Bioprinting**

Recent advancements in 3D printing technologies have elevated the geometric precision of this technique, allowing for sophisticated biomimicry and customization. Prosthetic ovaries that maintain the tortuous distribution patterns of ovarian follicles, for example, have been produced with bioprinted gelatin and electrospun polycaprolactone (PCL) materials,<sup>98,99</sup> and 3D-printed alginate scaffolds have been developed for generating testes organoids.<sup>100</sup> Additionally, extrusion-based 3D bioprinting with human trophoblast-cell-laden gelatin/methacrylate hydrogel bioinks has been applied in studies addressing the impact of trophoblast migration on preeclampsia.<sup>101</sup> Bioprinting human mesenchymal stem cells onto conventional PCL meshes has been evaluated as a potential path forward in treating pelvic organ prolapse; improved tissue integration and reduced inflammation were demonstrated compared to cell-free meshes.<sup>102</sup> Continued development of 3D-printing and bioprinting techniques will aid in the advancement of customizable scaffolds that can be engineered to support cell-specific niches and provide clinical solutions for patients.

### **Conclusions and future development**

Numerous efforts have been made toward developing and enhancing tissue-engineered methodologies for reproductive tissues. Translation of these approaches into human clinical trials has been limited; however, preclinical studies have demonstrated tremendous potential for advancing these important regenerative therapies into the clinic to provide restorative and reconstructive alternatives in the near future.

### **Peripheral Nerve System Tissue Engineering**

The peripheral nervous system (PNS) is a vast neural network that transmits motor, sensory, and autonomic information from the central nervous system (brain and spinal cord) to all regions of the body.<sup>103</sup> Peripheral nerve injury (PNI) often occurs during incidents of trauma as the PNS is not protected by a ridged barrier and is therefore vulnerable to damage.<sup>104,105</sup> In fact, PNI is reported in nearly 3% of all trauma patients.<sup>106</sup> Unfortunately, the peripheral nervous system has a limited capacity to regenerate, and such injuries often lead to poor recovery and lifetime disabilities. Satisfactory outcomes from surgical intervention have been limited, with approximately 50% of patients reporting good to normal restoration

of function.<sup>107</sup> Tissue engineering and regenerative medicine offer an opportunity to address the limitations in current clinical approaches and improve functional recovery following nerve injury and repair.

### **Scaffolds**

Current methodologies for surgical intervention following nerve damage are dependent upon the type and degree of the injury.<sup>108</sup> End-to-end suturing can rejoin the perineurium in cases where the nerve is transected, and there is no gap present. For gaps of 1 cm or less, a biological or synthetic nerve conduit can be put in place to guide regeneration; however, for gaps greater than 1 cm, autologous nerve grafting is still the most common approach.<sup>109</sup> In general, a section of the sural nerve is harvested from the patient's calf region and implanted at the site of the injury.<sup>110</sup> Autologous nerve grafting has several limitations, however, including the need for multiple surgeries. Alternatively, cadaveric or donor tissue allografts can be employed; however, this approach requires systemic immunosuppression for extensive periods of time.<sup>111–113</sup> Decellularization of allogenic nerve grafts can eliminate the potential for immunogenic constituents while still retaining extracellular matrix elements and structural architecture to support tissue regeneration.<sup>114</sup> Decellularization of graft material and development of bioengineered artificial conduits are promising tools in the field of PNS regeneration that may reduce or even replace the necessity for autologous nerve grafts.<sup>115</sup> The essential goal of these scaffolds is to decrease the gap of the PNI.<sup>116</sup> In order to achieve appropriate recovery, bioengineered conduits should provide structural and growth support, guiding regenerating neurons and promoting migration of cells, such as glia into the graft.<sup>117</sup> Some of these engineering strategies include intraluminal guidance structures, multichannel conduits, and microgrooved designs with hydrogel fillers that promote structural support and topographical guidance for regenerating axons and migrating Schwann cells.<sup>118</sup> A similar strategy involves using nanofibrous conduits.<sup>119</sup> Nerve guidance conduits (NGC) can be fabricated from natural or synthetic material. The material used, however, should conform to certain criteria including biocompatibility and biodegradability, while maintaining mechanical stability during regeneration. The material should also be resistant to tears from sutures and exhibit flexibility as well as compliance in order to prevent compression of regenerating axons. An NGC should provide guidance cues (physical and/or chemical) for the neurite extension while concurrently preventing fibrous tissue ingrowth, and support exchange of nutrients and growth factors with the extracellular environment. Lastly, an NGC material must be able to tolerate production requirements such as sterilization, storage, and surgical manipulation.<sup>120</sup>

### **Cell source**

The direct movement of cells plays an important role in inflammatory and wound repair processes *in vivo*. Following PNI, Schwann cells (SCs) migrate to the site of injury, assist in removing debris, release growth factor, organize the basement membrane, and myelinate the regenerating nerve.<sup>7,121</sup> Given the critical role of Schwann cells in nerve regeneration, these cells are generally targeted in PNI investigation<sup>122</sup> and have been the focal point of clinical safety and efficacy studies addressing augmentation of autologous nerve grafts after severe PNI.<sup>123</sup> *In vitro* investigations have also included cell types such as nerve stem cells, PC12 and SH-SY5Y,<sup>124–127</sup> induced pluripotent stem cells (iPSCs), and mesenchymal stem cells derived from bone or adipose tissue, as these cells possess the potential to differentiate into neural cells and neurons.<sup>128–131</sup>

## Preclinical, clinical, and FDA-approved hollow tube conduits

Nerve growth conduits are being used increasingly as an alternate treatment to nerve autografts; to date, there are several NGC products with regulatory approval.<sup>132</sup> One of the initial NGC synthetic devices that obtained FDA approval, Salubria™, is a permanent flexible tubular sheath made of polyvinyl alcohol hydrogel. This material provides a mechanically stable structure that provides a protective environment for nerve repair after injury; however, non-resorption leads to nerve compression and tension related issues after the regeneration has occurred.<sup>132</sup> Synthetic devices with resorbable properties have incorporated materials such as polyglycolic acid (Neurotube™) and polylactate with poly-ε-caprolactone (Neurolac™). Polyglycolic acid has favorable degradation and mechanical properties, and in clinical studies has been shown to be efficient for gaps up to 20 mm; nevertheless, the acid degradation and low solubility of byproducts remains a limitation.<sup>133</sup> Similarly, the polylactate and poly-ε-caprolactone copolymer which has been extensively used in preclinical and clinical studies may have limitations due to its degradation process.<sup>134,135</sup> Natural material devices such as Avance® Nerve Graft (allogenic) and AxoGuard® Nerve Protector (xenogeneic) provide an acellular graft that preserves the inherent structural and mechanical characteristics of the tissue.<sup>136</sup> AxoGuard® is indicated for sutureless neurorrhaphy but is contraindicated in gap management, unless used in conjunction with allografts.<sup>137</sup> Collagen Type I is the most commonly used natural, resorbable material used for NGC (Neuragen®, Neuroflex®, NeuroMatrix®, NeuraWrap®, and NeuroMend™)<sup>138,139</sup> as it is biocompatible and has been shown *in vivo* to support nerve tissue regeneration.<sup>140</sup> Alternative naturally occurring materials that are currently in use for NGC devices include chitosan (Neuroshield and Reaxon® Plus)<sup>141,142</sup> and a combination hydrogel containing polysaccharides alginate and hyaluronic acid (Versawrap Nerve Protector).<sup>143</sup> Additionally, ongoing clinical phase studies include a minimally processed human umbilical cord membrane tissue (Axogen®) and a combination product of decellularized processed peripheral nerve allografts with autologous bone marrow aspirate concentrate (Avance®).

## Conclusions and future trend

With expansion of an aging population, the incident rate of peripheral nerve injury continues to rise while the accessibility of nerve autografts has become limiting. Bioengineered NGCs will become an increasingly critical component in PNI repair. Combinations of natural and/or synthetic materials are being considered in fabrication methodologies such as electrospinning, micropatterning, and 3D printing. Advances in these approaches will benefit the availability of customized scaffolds/conduits that will target and individualize the regenerative potential of the patient by introducing the appropriate cells and neurotropic factors to the site of injury.

## Skeletal Muscle Tissue Engineering

Skeletal muscle represents about 40% of the total human body mass.<sup>144</sup> It has an innate mechanism to self-heal wounds; however, the regeneration of large defects is limited.<sup>145</sup> Volumetric muscle loss (VML) occurrences due to skeletal muscle injuries from trauma or tumor ablation often result in deficiencies of extracellular matrix (ECM), muscle fibers, and satellite cells resulting in limitations in muscle regeneration.<sup>146</sup> Every year in the United States, approximately 4.5 million patients undergo reconstructive procedures to

restore normal soft-tissue function, but in many cases, the extensive muscle defect results in the impairment of tissue function and physical deformity.<sup>147</sup> Standard surgical intervention for these types of injuries include autologous muscle tissue transfer from adjacent regions (also known as muscle flap or graft transplantation).<sup>148</sup> While this option can provide lifesaving outcomes, limitations on functional restorations and challenges such as muscle tissue availability and donor site morbidity exist. In addition, infection and necrosis lead to failure in approximately 10% of the cases.<sup>10</sup> Approaches that are grounded in volumetric replacement though tissue engineering are therefore needed to increase functionality and restore the native skeletal muscle.<sup>149</sup>

Skeletal muscle contains satellite cells that are located underneath the basal sarcolemma membrane and are stimulated to divide when the tissue is injured, fusing with damaged muscle fibers to regenerate and restore function.<sup>8,150</sup> This mechanism for repair is limited, however, to mild injuries because skeletal muscle fibers cannot divide themselves; consequently, in VML the muscle cannot remodel and the function remains impaired after ablation or denervation.<sup>151</sup> Additionally, following VML fibroblasts deposit scar tissue more quickly than myoblast fusion and regeneration can occur, thereby contributing to the impediment of muscle regeneration within the defect size and increasing the functional deficit.<sup>152</sup> Tissue engineering strategies therefore target the restoration of muscle tissue volume as well as the regeneration of vascularized and innervated muscle for full functional recovery of an injured site.

## Scaffolds

Many tissue engineering approaches have been investigated for achieving functional recovery following VML. These include strategies for decellularized ECM (dECM), synthetic and natural polymer scaffolds, 3D-bioprinted constructs, and myogenic-inducing factor delivery systems.<sup>153</sup> An appropriate bioengineered scaffold needs to provide adequate porosity and interconnection in order to distribute growth factors and support vascularization.<sup>154</sup> Common natural scaffold materials include fibrin, hyaluronic acid, laminin, collagen, chitosan, and gelatin. These materials are generally biocompatible, and when combined with the right fabrication method have been shown to facilitate muscle, vascular, and neural regeneration.<sup>155</sup> Decellularized ECM scaffolds, which contain proteins such as collagen, laminin, and fibronectin, retain the architectural environment of the native tissue and contain residual growth factors and cytokines that promote tissue restoration. Studies have shown that myogenic factors, such as insulin growth factor-1 (IGF-1), can also be incorporated into the scaffold to improve the regeneration process by facilitating progenitor cell migration, proliferation, and differentiation.<sup>10,156</sup> The decellularization process can also diminish the potential for immune response rejection by removing antigenic cellular elements and therefore prevent allograft failure.<sup>10</sup>

Another promising approach for addressing skeletal muscle tissue replacement is minced muscle grafts, also known as muscle fiber therapy. The minced muscle tissue can be further processed into uniform structures to allow for rapid reassembly and engraftment within the defect site.<sup>157,158</sup> This strategy has been tested in several preclinical models to address muscle atrophy, VML, and urinary incontinence.<sup>159</sup> Developing organized muscle constructs composed of prealigned muscle fibers within multilayered myofiber bundles has also been targeted through recent advances in 3D bioprinting. Preclinical data demonstrate greater muscle functionality post-VML following the incorporation of human promyogenic cell bioink, such as muscle progenitor cells,

compared with acellular constructs; this approach promoted the regeneration of a highly mature and organized tissue with vascular and neural integrity.<sup>160,161</sup>

Synthetic materials commonly applied in skeletal muscle tissue engineering include polypropylene, poly-(lactic acid), poly-(glycolic acid), poly- $\epsilon$ -caprolactone, polyurethane, and polyethylene glycol.<sup>147</sup> These materials offer the advantage of tunable mechanical properties such that the degree of hardness, the fracture strength, or the durability of the scaffold, for example, can be adjusted to match the properties of the tissue to be replaced. While synthetic materials may be challenged with biocompatibility and degradation issues, they offer the benefit of increased batch-to-batch reproducibility, a feature that does not always exist with natural materials.

Tissue-engineered muscle grafts have been implanted in a variety of preclinical VML models; however, the lack of standardization in muscle type and location for this model still exists. Additionally, universal consensus on the definition of a critical sized defect in the model has not been achieved.<sup>144</sup> Consequently, a broad range of pre-clinical studies with mixed results support the efficacy of cell-based therapies, and acellular and cell seeded scaffolds for the treatment of VML defects.

### Cell sources

Skeletal muscle tissue engineering generally involves satellite cells or muscle-derived precursor cells; however, alternative sources of stem cells such as perivascular, bone marrow, umbilical cord, or adipose-derived stem cells may also be considered, and recently induced pluripotent stem cells have been targeted as a potential cell source.<sup>162–166</sup> Considerations for myogenic cell sources include expansion capacity, immunogenicity, translatability, differentiation potential, and engraftment potential *in vivo*. Cell-sheet-derived 3D constructs have been developed by culturing muscle-derived cells in monolayers until confluent and then forming a cylindrical construct with the cells to implant into the defect site.<sup>167</sup> This approach has produced promising results in small VML models; however, there is limited ability for scale up to clinically relevant sizes, and the lack of a supporting scaffold causes difficulties in manipulation.<sup>168</sup> Repair of sizeable tissue defects requires the implantation of either large tissue-engineered constructs or a substantial dose of cells. Oxygen diffusion to implanted cells under these conditions is difficult, however, which can impede the dissemination of vascularization cues.<sup>169</sup> Another issue is inefficient cell grafting within the implanted tissue. Delivery of human muscle progenitor cells in multiple doses has been shown to sustain cellular viability through the initial stages of vascularization and thereby improve muscle function in a rodent model of VML.<sup>169</sup> Translation of this technology into the clinical settings will require optimization of areas such as the cell injection parameters and the choice of a biomaterial for cell delivery that can maintain the implant volume for an appropriate period of time.<sup>170</sup> In general, cell-based approaches for repairing skeletal muscle injuries have gained attention; however, improvements in cell sourcing and expansion prior to implantation are still under investigation.

### Conclusions and future trend

Several Phase I clinical trials have addressed the regenerative potential of acellular dECM for mitigating human VML defects. These include the utilization of acellular non-crosslinked porcine collagen scaffolds, XenMatrix, and MatriStem UBM.<sup>171–174</sup> Subjects demonstrated average improvement in strength and range-of-motion

compared with preoperative performance, providing early evidence of feasibility for the use of bioscaffolding as a viable treatment for VML.

Although extensive work has been done to demonstrate the practicality of bioengineering scaffolds and cell therapies to treat skeletal muscle defects, challenges remain in clinical translation. Going forward it will be necessary to evaluate these approaches in relevant preclinical muscle injury models that standardized the critical defect size for VML. Evidence of the long-term contributions each technique provides to restoring muscle function will be essential given the highly organized and complex vascular and neural components that support native skeletal muscle function.

### Gastrointestinal Tissue Engineering

The gastrointestinal (GI) tract is a continuous hollow organ with structural complexities that include two layers of musculature, which regulate peristalsis and propulsion through coordinated interactions of the enteric nervous system and interstitial cells of Cajal, and a specialized epithelium that controls the secretion and absorption of nutrients.<sup>175–177</sup> Lymphatic and microbiome systems add an additional layer of complexity to this system creating, overall, a challenging prospect for tissue engineering.<sup>178</sup>

Multiple diseases, including cancer and congenital disorders, can adversely impact the function of the GI system.<sup>176</sup> Treatments generally include surgical intervention and pharmacological management of symptoms, but these are often temporary solutions and do not necessarily address the root cause of the pathology. Regeneration of the tissue is a promising approach, provided a functional bioengineered gut can be engineered.<sup>179</sup> Recent work has focused on regenerative alternatives through the use of cells and scaffolds, organoids, and organ-on-a-chip.<sup>180</sup>

### Scaffolds

Tissue engineering segments of the gut requires scaffold materials that promote cell-cell interactions, support the mechanical behavior of each tissue layer, and allow for adequate vascularization. Porosity and physical modifications, such as a micropatterned surface, are some of the strategies used to guide circumferential cell alignment and improved functionality.<sup>181</sup> Some common natural biomaterials utilized in GI scaffolds include collagen, silk fibers, and chitosan.<sup>182–184</sup> Natural materials generally have the advantage of biocompatibility and easily support cell growth and survival; however, these substances often possess weak mechanical properties and may therefore require reinforcement with synthetic materials. Decellularized small intestine submucosal (SIS) extracellular matrix tissue formed the basis for one of the first approaches in GI tissue reconstruction. This acellular material was shown to support both epithelial and muscle tissue regeneration in small intestinal repair.<sup>185</sup> Similarly, acellular porcine small intestine and urinary bladder matrix scaffolds have been used for esophageal reconstruction.<sup>186</sup> Natural intestinal scaffolds that retain their native architecture and connective tissue components are generated by detergent-enzyme treatments and used not only for drug testing and biological assays *in vitro* but have also shown similarly support for the regeneration of intestinal tissues in clinical applications.<sup>11</sup>

Utilization of synthetic scaffold materials, such as poly- $\epsilon$ -caprolactone alone or in combination with lactic acid and polyglycolic acid, has been investigated in esophageal indications.<sup>187</sup> Synthetic materials are often used as coating material in order to

strengthen the mechanical properties of natural biomaterial scaffolds and regulate degradation rates. Chemical modifications can be used to adjust the biocompatibility of these materials and enable modifications for incorporating bioactive molecules, such as growth factors that support vascularization of the implant.<sup>188,189</sup> Like natural material, scaffolds derived from synthetic substances are expected to promote infiltration of native cells, encouraging tissue remodeling and regeneration. In certain cases, wrapping the engineered organ in donor omentum or amniotic membrane facilitates metabolic exchange and vasculogenesis to support organ tissue restoration.<sup>190,191</sup>

### Cell sources

Composed of several layers, each segment of the GI track has a cellular complexity and specific architecture that is essential to its physiological function. In order to recreate a functional replacement, it is essential to consider the unique roles of the cells that normally populate a particular segment.<sup>192</sup> Various cell sources have been considered for tissue engineering portions of the gut, including primary cells isolated from biopsy, expanded in vitro and subsequently seeded onto a scaffold for implant.<sup>193–195</sup> While this approach has been shown to be promising for regenerating innervated musculature of the gut in preclinical studies, expanding these cells to clinically relevant numbers and maintaining phenotype is often proving to be a challenge.<sup>176</sup> Mesenchymal stem cells and other progenitor cells have also been shown to promote the regeneration of muscular components when stimulated with soluble factors to direct their differentiation.<sup>179,196</sup> Regeneration of the epithelial component of the gut, however, still faces complications regarding the initial in vitro expansion of precursor cells, and the downstream survival and differentiation when matured on scaffolds.<sup>197</sup> Importantly, induced pluripotent stem (iPS) cells have exhibited promising characteristics and abilities to differentiate into the various cells that populate the gut; this has been particularly encouraging for generating cells of epithelial lineage.<sup>198</sup>

### Alternative systems

Organoid systems are another promising approach for understanding the cellular complexities associated with engineering GI structures.<sup>199</sup> These small functional units mimic the original organ, essentially recapitulating its biological intricacy and function.<sup>200</sup> Recent preclinical work has demonstrated the capacity for stomach organoids to differentiate into rudimentary stomach-like structures.<sup>201</sup> A majority of the work associated with GI organoid systems has focused on the regeneration of epithelial components; however, models that successfully achieved contractility and immune functions and integration of the enteric neural system have also been reported.<sup>202</sup> Organ-on-a-chip is another emerging technology that will be instrumental in evaluating GI pathology and repair. This system uses microfluidic devices to generate and maintain organoid units and has been used to support drug discovery, toxicology, and pharmacokinetics.<sup>203</sup> Notably, investigations employing organ-on-a-chip technology for small intestine and colon biopsies have demonstrated spontaneous peristalsis like motion.<sup>204</sup> 3D printing technology has been used to create scaffold-free structures for the regeneration of esophageal tissue, composed of multicellular spheroids containing cell types such as human dermal fibroblasts, smooth muscle cells, and mesenchymal stem cells, which could then be transplanted into the injured site.<sup>205</sup> Studies to optimize these systems will facilitate advances in the field of GI regenerative medicine.

### Clinical data

Promising work that targets tissue engineering techniques for the regeneration of GI tissue has been performed in preclinical models; however, limited results have been reported from clinical trials. Esophageal reconstruction has been attempted using urinary bladder matrix (MatriStem™, ACell) to augment and restore damaged esophageal tissue in four patients with varying etiologies including progressive dysphagia, esophageal perforation, and mediastinitis, caustic ingestion, and adenocarcinoma.<sup>206</sup> A second trial (single patient) used an acellular dehydrated scaffold sprayed with autologous platelet-rich plasma to support esophageal regeneration and function.<sup>207</sup> Additionally, porcine small intestine ECM scaffolds (Surgisis®, Cook) were used in five patients for esophageal preservation following endoscopic resection,<sup>208</sup> and an extracellular matrix scaffold composed of collagen and natural proteins is currently been investigated in clinical pilot study for similar purposes.<sup>209</sup> In Japan, two separate studies have used endoscopic transplantation of tissue-engineered autologous oral mucosal epithelial sheets to prevent the formation of strictures after endoscopic submucosal dissection.<sup>210,211</sup> Finally, allogenic mesenchymal stem cells and endothelial cells derived from human umbilical vein are being used in separate studies as cell therapy for the treatment of conditions from Crohn's Disease.<sup>212,213</sup>

### Conclusions and future trends

From stem cell therapies, biomaterials and scaffolds, to organoids and organ-on-a-chip, the regeneration of digestive organs through tissue engineering is making promising progress. Most of these techniques, however, have only been observed in animal models; additional work will be necessary in order for many of these technologies to reach clinical applications. The GI system is a complex multilayer structure with uniquely functional segments driven by the integration of multiple cell types. To achieve tissue regeneration at this level of complexity, it will be important to develop effective strategies for incorporating and sustaining these unique components.

### Renal Tissue Engineering

Kidney disease is one of the leading causes of death globally; with acute kidney injury (AKI), chronic kidney disease (CKD) and end-stage renal disease (ESRD) representing the most common forms the disease. Medical therapies for AKI and CKD primarily involve hemodialysis or kidney transplantation. Currently, kidney transplantation is the only solution for resolving ESRD; the availability of transplantable donor kidneys, however, is less than 20% of the demand.<sup>214</sup> Regenerative medicine-based approaches employing cellular and tissue-engineered therapies present a promising alternative.

### Scaffolds

Cultured renal cells are generally seeded onto scaffold material where the cell population expands and matures into renal structures to form a 3D kidney construct. Currently, scaffold systems for engineering renal constructs include natural and synthetic polymers, and decellularized native tissue matrices. Natural polymers have biocompatible characteristics that can support cell proliferation, migration, and differentiation, thereby providing a potential option for regenerating native tissues. Collagen and collagen-based materials have been extensively used to produce scaffolds for kidney regeneration. Glomerular epithelial and mesangial cells isolated

from renal tissues have, for example, been used with collagen-vitrigel mixed membrane scaffolds,<sup>215</sup> and collagen Matrigel was used to reconstruct 3D renal tissues in vitro with neonatal rat renal cells.<sup>216</sup> The cells within the 3D collagen-Matrigel hydrogel self-assembled into tubule and glomeruli-like structures. Hyaluronic acid (HA), which exhibits the appropriate mechanical properties and plays a vital role in mammalian development, has also been utilized for fabricating 3D renal-like tissues in vitro where it supported ureteric bud branching, promoted mesenchymal-to-epithelial transformation, and stimulated differentiation of the metanephric mesenchyme and ureteric buds.<sup>217</sup> Natural polymers such as chitosan, fibrin, and alginate have also been studied for use in kidney tissue engineering. These materials have successfully supported the formation of hollow tubules, providing a platform for further renal tissue regeneration.<sup>218–220</sup> Decellularized native tissue is also highly attractive as scaffold material because it maintains the complex architecture of the kidney as well as many extracellular matrix components. Optimization of decellularization/recellularization processes has supported progress toward bioengineering whole kidneys in vitro. When transplanted orthotopically, these bioengineered grafts were ultimately perfused by the recipient's circulation and produced urine through the ureteral conduit.<sup>221</sup>

In order to improve the mechanical strength of scaffolds, synthetic biodegradable polymers such as poly(lacticacid) (PLA), poly(glycolic acid) (PGA), and poly(lactic-*co*-glycolic acid) (PLGA) have been evaluated for use as renal scaffold sources. These biopolymers are nontoxic, simple to fabricate, and have well-controlled degradation. Kidney-like constructs engineered from renal cells seeded onto PGA scaffolds, and subcutaneously implanted into athymic nude mice recapitulated nephron-like segments and tubule-like structures in the implant.<sup>222,223</sup> A PLGA scaffold containing kidney-derived ECM has also been shown to be an effective matrix for repair and reconstitution of glomeruli and blood vessels, in partially nephrectomized mouse model.<sup>224</sup>

### Cell sources

Studies indicate that it is possible to isolate renal stem and progenitor cells from the Bowman's capsule, papilla, and tubular sections of the kidney.<sup>225</sup> Progenitor cells derived from the Bowman's capsule and injected into a preclinical model of renal injury resulted in morphological and functional improvements such as reduced proteinuria and glomerular damage.<sup>226,227</sup> Notably, stem cells from non-renal tissues, including embryonic stem cells (ESC), induced pluripotent stem cells (iPSC),<sup>228–231</sup> amniotic fluid-derived stem cells (AFSC),<sup>232–235</sup> bone-marrow-derived mesenchymal stem cells (BM-MSCs),<sup>236–239</sup> adipose-derived stem cells (ADSC),<sup>240–243</sup> have also been evaluated as potential cellular sources for treating renal failure and demonstrated elements of renal regeneration in each case. Additionally, clinical studies applying intravenous administration of autologous MSC to improve the outcomes of renal transplantation have established that this therapeutic approach is safe, results in a lower incidence of acute rejection, provides a decreased risk for opportunistic infection, and supports better estimated renal function after one year.<sup>244,245</sup>

Primary kidney cells also represent a conceivable source of cells for regenerative therapies as these cells can be grown in three-dimensional culture systems to generate tubule structures that are positive for proximal, distal tubule, and collecting duct markers in vitro.<sup>246</sup> Administration of in vitro cultured human renal cells has been shown to result in functional and structural improvements in a

rat chronic kidney injury model.<sup>247</sup> Importantly, a Renal Autologous Cell Therapy (REACT), consisting of progenitor cells isolated from a patient's renal tissue, has been developed to delay or prevent renal replacement therapy, and is currently in clinical trials in the United States for safety and efficacy (clinicaltrials.gov, NCT04115345).

### Acellular therapy

Acellular approaches to kidney repair and regeneration include injection of extracellular vesicles (EV), biomolecules, and biomaterials. Administration of bone morphogenic protein-7 (BMP-7), a member of the TGF- $\beta$ 1 family that is highly expressed in the kidney, has been shown to be closely associated with reversal of chronic renal injury through epithelial-to-mesenchymal transition.<sup>248</sup> Naturally secreted extracellular vesicles derived from MSCs is one of the most studied methods for therapeutic use of EV. Mesenchymal stem cells have a distinct capability for renal repair as MSC-derived EVs reproduce the immunomodulatory and cytoprotective activities of their parent cells.<sup>249</sup> Adipose tissue-derived MSC-EVs, for example, were found to be enriched with IL-10 mRNA, an anti-inflammatory cytokine. Notably, a single intrarenal delivery of MSC-derived EVs ameliorated renal injury in chronical experimental model of pigs with metabolic syndrome.<sup>250</sup> Increasing evidence from various experimental models of acute kidney injury suggests that delivery of MSC EVs can restore renal structure and function by reducing inflammation, improving renal microvasculature, medullary oxygenation, and resident cell viability and proliferation.<sup>250–253</sup>

Besides working as a scaffolding system, naturally occurring extracellular matrices have also been used to promote *in situ* renal regeneration. For example, polymerized collagen (P-collagen), a mixture of pepsinized porcine Type I collagen and polyvinylpyrrolidone, has been used to reduce renal pathology and improve anatomic and functional renal properties in a model of nephrotoxicity.<sup>254</sup>

### Bioprinting

Three-dimensional bioprinting may also provide a potential solution to the widening gap between need and availability of transplantable kidney organs. This process constitutes engineering 3D functional living macrotissues and organ constructs through layer-by-layer robotic biofabrication with cells and bioink as building blocks.<sup>255</sup> Challenges include the hierarchical architecture and functional complexity of the native tissue/organ, which make it difficult to replicate on a large scale using current techniques.<sup>256</sup> Reported strategies include creating 3D renal proximal tubules in vitro that are fully embedded within an extracellular matrix and housed in perfusable tissue chips;<sup>257</sup> taking a microfluidics approach to build a 3D renal kidney tubulointerstitium using primary tubular cells suspended in a polysaccharide biomaterial ink solutions;<sup>258</sup> and engaging a cellular extrusion technique to produce 3D kidney organoids from iPSCs in bioink, for use in drug screening, disease modeling, and ultimately kidney organ engineering.<sup>259</sup>

### Conclusions and future development

Much research has been performed to develop strategies for repairing and regenerating tissue damage due to kidney failure. Various approaches, including cell therapies with autologous or "off-the-shelf" allogeneic cell sources and engineered acellular or cell-based kidney constructs, have been proposed. Improvements in 3D tissue and organ printing will support the generation of precise, customizable, and complex structures; current techniques, however, do not

yet provide a viable solution for addressing the shortage of organs for kidney transplantation. A combination of the strategies described in this section may be necessary in order to satisfy the heterogeneity, hierarchical structure, and complex functionality of this multidimensional organ as the field moves forward.

### Bone Tissue Engineering Update

Worldwide there is an increased need for bone grafting; it is the second most frequent tissue transplantation after blood transfusion.<sup>260</sup> The restoration of large bone defects is a critical issue that can negatively impact the quality of life and consequently have significant socioeconomic repercussions, particularly with increasing age expectancies.<sup>261</sup> Until recently, bone repairs were primarily done with autologous bone tissue or tissue from compatible donors.<sup>262</sup> This approach has had several limitations however, including shortages in tissue supply, donor site morbidity, and tissue incompatibility, all of which have led to greater focus on tissue engineering methods to address these insufficiencies. Significant progress has been made in the last two decades with respect to new materials and new fabrication methods.<sup>263</sup> While initial efforts focused mainly on mimicking the macrostructure of bones, recent work has targeted fabrication of scaffolds that create an ideal condition for tissue regeneration.<sup>264</sup> Advances in medical imaging and software have made it possible to design patient-specific scaffolds with high resolution, which can be shaped and targeted for a specific tissue.<sup>265</sup> New technologies focused on personalized medicine tailored to meet patient requirements, together with improvements in scaffold manufacturing techniques such as 3D printing, promise to improve outcomes. In addition to fine control over scaffold geometry, newer fabrication methods also refine scaffold pore size to facilitate cell infiltration, mechanical properties, structural characteristics, and degradation rates.

Developments in the area of biomaterials for bone-tissue engineering must integrate properties such as biocompatibility, biodegradation, cell attachment, differentiation, and early stage mineralization.<sup>266</sup> Efforts to mimic the composition and structure of native bone tissue generally involve a range of polymers, bioceramics, metals, and composites. Most of these materials require physiochemical modifications, however, such as incorporating osteoconductive factors, such as hydroxyapatite or bioglass, and bioactive factors such as vascular endothelial growth factor (VEGF) and osteogenic growth peptide (OGP) to improve vascularization and osteogenesis.<sup>267–270</sup>

Despite advances in the area of bone tissue engineering, most have yet to be tested in preclinical studies and only a few have been translated into clinical trials. A single-patient trial using a 3D-printed bioresorbable scaffold made of polycaprolactone (PCL) has been tested for periodontal repair. A limitation of the study was determined to be the material of choice; it was suggested that a more rapidly resorbing material with a porous structure would improve tissue ingrowth and vascularization for this specific application.<sup>271</sup> In a pilot clinical trial, PCL scaffolds were used for ridge preservation for dental implant placement following tooth extraction and reportedly supported better outcomes when compared to control group.<sup>272</sup> Additionally, several trials for the treatment of mandibular fractures with customized 3D-printed scaffolds have been initiated,<sup>273–275</sup> and EpiBone®, a decellularized bovine trabecular bone scaffold, is in clinical trial as a potential treatment for ramus continuity defects in the mandible. The EpiBone® scaffold can be crafted into the defect shape and seeded with autologous

adipose-derived stromal/stem cells, which have the capacity for osteogenic differentiation.<sup>276,277</sup>

Tissue engineering holds great promise for the treatment of bone defects due in part to advances in stem cell biology, development of novel biomaterials, and optimization of 3D bioprinting. Successful translation into a clinical setting will depend however, on whether these new approaches can outperform current treatments and overcome quality, safety, and regulatory challenges.<sup>278</sup> Decisions on dosage and the route of application will require an understanding of the underlying cellular and molecular mechanisms associated with stem cell action in bone regeneration.<sup>261</sup> The future of the field relies on combining cell therapy with biodegradable osteo-conductive scaffolds that exhibit suitable mechanical properties.

### Vascular Tissue Engineering Update

The clinical demand for safe and effective vascular grafts is significant. Synthetic vascular grafts constructed from expanded polytetrafluoroethylene (ePTFE) or polyethylene terephthalate (Dacron) have been widely applied in the clinic over the past four decades.<sup>279,280</sup> High risk of infection, thrombosis, and other complications however have limited the application of synthetic grafts in small diameter blood vessels. Vascular tissue engineering has progressed substantially, generating biological grafts that incorporate the functionality of structural layers, withstand physiologic stressors of the cardiovascular system, and effectively integrate into the tissue without serious immunologic rejection.<sup>281</sup> Several approaches for small vessel engineering have progressed to clinical trials, including vascular grafts from Cytograft, Gunze Limited, and Humacyte.<sup>282–284</sup> Humacyte has reported results for their bioengineered human acellular vessels tested in end-stage renal disease patients in a Phase II clinical trial; the patency results at 6 and 12 month intervals demonstrated safe and functional hemodialysis access, warranting further evaluation in randomized controlled trials.<sup>285</sup> Humacyte also achieved favorable results in a clinical trial for peripheral arterial bypass surgery. These engineered blood vessels were shown to be safe, with acceptable patency and a low incidence of infection.<sup>284</sup>

Various 3D-printing techniques, including laser-assisted, droplet-based, and extrusion-based manufacturing processes, are being considered for bioprinting cellular and acellular vascular grafts.<sup>286,287</sup> Studies in which small-diameter biomimetic blood vessels with two distinct proliferating cell layers (vascular endothelial cell [VECs] and vascular smooth muscle cell [VSMCs]) were created using an advanced coaxial 3D-bioplotter platform and demonstrated the feasibility of this approach in generating biocompatible small-diameter blood vessel replacements.<sup>288</sup> At the other end of the spectrum, the fabrication of scaffold-free tubular tissue grafts from multicellular spheroids composed of 40% human umbilical vein endothelial cells, 10% human aortic smooth muscle cells, and 50% normal human dermal fibroblasts resulted in patent tubular tissues that exhibited remodeling (enlargement of the lumen area and thinning of the wall).<sup>289</sup> Results from the “Ring Stacking Method,” in which bioprinted tissue rings are stacked to create a tubular construct mimicking the natural form of a blood vessel, also support the potential for manufacturing artificial blood vessels in a variety of dimensions and lengths that will meet the specific needs of the clinic and patient.<sup>290</sup> Recent developments in microfluidics and 3D-bioprinting technologies have also enabled the generation of highly controlled and reproducible patterns of microvasculature.<sup>291,292</sup> In one format, a densely cell-populated 3D vascular

network was produced by printing carbohydrate glass filaments into lattices surrounded by extracellular matrix. Dissolution of the glass filaments resulted in a 3D tubular network that could be perfused and loaded with cells.<sup>292</sup> Patterned vascular structures have also been created by lithography, using hydrogel micropatterning to form a microvascular network when bonded to another flat layer of hydrogel.<sup>293</sup>

Recent progress in tissue engineering and bioprinting techniques such as these suggests that we are entering a new era in treating vascular diseases, an era in which regenerative alternatives will play a key role in treating and replacing vascular tissues that are no longer functioning at optimal capacity.

### **Cardiac Tissue Engineering Update**

The restricted regenerative capacity of cardiomyocytes, coupled with limited supplies of heart tissue for transplantation, has produced challenges in treatment options for cardiovascular diseases, which are the leading cause of death in the world.<sup>294</sup> Alternative approaches to myocardial regeneration through tissue engineering and regenerative medicine technologies may provide a solution to this current deficit. Cell types such as MSCs, ESCs, and iPSC-derived cells, in addition to cardiomyocytes, have been transplanted into injured myocardium or used to investigate new methods for myocardial tissue engineering. Compared with other cell types, autologous MSCs are a prime candidate for cardiovascular tissue engineering as they are generally plentiful, easy to expand, do not require immunosuppressive therapies, and do not incur ethical issues.<sup>295</sup> MSCs derived from a variety of tissues have been utilized in preclinical as well as clinical studies. Several Phase I and II clinical trials have established safety and efficacy following intravenous (IV) administration of MSCs, demonstrating improvements in left ventricular ejection fraction, heart function, and quality of life.<sup>296–298</sup> A major limitation to this approach, however, is the low survival rate for MSC engraftment in the ischemic lesion. Strategies to address the poor longevity of engrafted MSCs following IV administration include tissue engineering with cell-biomaterial combinations that produce tissue-like architecture, such as a cardiac patch or 3D-printed cardiac structure. In preclinical studies, bioengineered cardiac patches constructed from stem cells (MSCs, cardiac progenitor cells, and endothelial progenitor cells) seeded on a multilayered scaffold and applied to the ligated left coronary artery (LCA) resulted in improved heart function that was accompanied by increased levels of several angiogenic cytokines (bFGF, vWF, and PDGF-B) and cardioprotective factors.<sup>299</sup> Recently, an MSC and scaffold-based therapy was approved for use in a clinical trial to treat infarcted myocardial tissue (ClinicalTrials.gov Identifier: NCT03798353). This cell-matrix construct, comprised of human pericardial matrix (PeriCord) together with allogeneic MSCs derived from Wharton's jelly, will be used to treat areas of ischemia that are noncandidate for revascularization by surgical intervention. The applications of 3D-bioprinting technology in the field of cardiovascular repair and regeneration have achieved significant progress in the past few decades.<sup>300–302</sup> Patterns engineered to mimic the original structure of cardiac tissue types can be generated through precise printing and crosslinking of cell-loaded cardiac bioinks. Structures including a neonatal-scale human heart,<sup>303</sup> an adult-scale trileaflet heart valve,<sup>303</sup> simplified anatomic heart and aorta tissues,<sup>304</sup> a cardiac chamber with large vessel extensions,<sup>305</sup> and microvascularized holistic engineered heart tissue<sup>306</sup> have been investigated through bioprinting techniques. Importantly, these

advanced 3D-bioprinted cardiac tissues have demonstrated elements of cardiac functions that include expression of cardiac-specific biomarkers,<sup>307</sup> spontaneous muscle-like contraction,<sup>305</sup> electrical function measured via calcium transients,<sup>308</sup> and cardiomyocyte-like depolarization–repolarization action potentials.<sup>309</sup> Additionally, the transplantation of a 3D-patterned cardiac patch into the infarcted heart tissue of immune-deficient rats was shown to greatly reduce the infarction area, significantly increase neovascularization in the tissue, and statistically improve both the ejection fraction and cardiac output of the animal.<sup>310,311</sup> Currently, preclinical studies in large animal models, as well as early clinical studies, continue to be indispensable for determining the safety and efficacy of bioprinted cardiac tissue as an acceptable therapeutic option for cardiovascular pathologies going forward.

### **Cartilage Tissue Engineering Update**

Cartilage defects caused by traumatic injury, disease, and aging are major problems requiring orthopedic surgery and a common cause of disability.<sup>312</sup> Due to the lack of vascularization, nutrient supply and cell (chondrocyte) density, cartilage has a limited capacity for self-repair.<sup>313</sup> Traditional treatments for cartilage repair include moisacplasty (transplantation of cylindrical plugs of bone and cartilage from less weight-bearing areas to the defect site), microfracture, osteochondral allograft, and autologous chondrocyte implantation.<sup>314</sup> These traditional treatments may have satisfactory outcomes initially, but often have poor long-term results, frequently leading to problems such as fibrocartilage formation. Various tissue engineering approaches have been engaged to address the challenges associated with cartilage regeneration. Among cell-based therapies, technologies for fabricating scaffolds and developing biomaterials that mimic the extracellular matrix facilitate cell growth, proliferation, and differentiation at the site of the defect.<sup>315</sup>

While autologous chondrocyte products such as MACI® (autologous cultured chondrocytes on porcine collagen membrane) are commonly used for the treatment of traumatic cartilage lesions, this type of approach has been known to experience limitations in cell sourcing, effectiveness in aged patients, and donor site recovery.<sup>316,317</sup> Clinical trials using Neocartilage Implant/DeNovo (RevaFlex) cartilage disks derived from juvenile donor chondrocytes report a low immunologic response, supporting the use of this therapeutic approach as an alternative for restoring cartilage in older individuals.<sup>318</sup> Stem-cell-based therapies also offer a promising approach for cartilage replacement as many of these cells exhibit a strong chondrogenic potential.<sup>319</sup> In addition to mesenchymal stem cells, induced pluripotent stem cells (iPSCs), peripheral blood mononuclear cells (PBMCs), and human umbilical cord blood-derived mesenchymal stem cells have also been used in cartilage engineering.<sup>320–322</sup> Recently, adipose tissue-derived stem cells (aMSCs) have become the second most common source of stem cells for cartilage applications as large numbers of cells can be isolated with minimal manipulation and subsequently expanded in vitro without losing chondrogenic potential.<sup>323</sup> In preclinical and clinical studies, this method was shown to block the progression of osteoarthritis and promote cartilage regeneration.<sup>324–326</sup> Recently, a clinical study reported high patient satisfaction following treatments composed of microfractures (creation of small fractures that penetrates the subchondral bone allowing for influx of pluripotent stem cells and growth factors) in combination with an aMSC-laden hydrogel scaffold (polyglucosamine/glucosamine carbonate).<sup>327</sup> The presence of aMSCs in the hydrogel proved to be

a significant factor leading to an improved chondrogenic environment. Approaches to enhance cartilage regeneration have also been linked with immunotherapy.<sup>328</sup> A cell-based combination therapy using aMSC- and TH1-specific autoimmune lymphocytes (effector cells) has been shown to improve cartilage repair in an experimental model of grade 3–4 osteoarthritis.<sup>329</sup>

Hydrogels are a versatile biomaterial often used in cartilage tissue engineering due to its similarity with natural tissue extracellular matrix.<sup>330</sup> The structure, composition, biochemical, and mechanical properties can be engineered to suit the application requirements. Hydrogels can also influence cellular attributes and behaviors such as morphology, proliferation, and differentiation at the defect site. Hydrogels populated with cells and chondrogenic promoting factors have the potential to address some of the challenges encountered with full-thickness cartilage regeneration.<sup>331</sup> Natural hydrogels products based on hyaluronic acid (Hyalograft C, no longer in the market) and collagen (GelrinC, current in clinical trial) have been evaluated clinically for efficacy in cartilage repair. While they are biocompatible and exhibit chondrogenic potential in vitro, the mechanical properties are weak; consequently, a role for these molecules in the regeneration of cartilage may be limited.<sup>332–335</sup> Hybrid hydrogels that combine natural and synthetic materials are designed to ensure adequate mechanical strength for shape maintenance and load bearing capacity.<sup>336</sup> Currently, only a few hybrid scaffolds have undergone clinical trials; these are mainly used to augment existing treatment strategies, such as microfracture surgery.<sup>337,338</sup>

Advanced biofabrication techniques enable the production of scaffolds with precise spatial control over the internal structure to facilitate the appropriate mechanical properties.<sup>339</sup> With 3D printing/bioprinting capabilities, it is now possible to create scaffolds that will match the defective area precisely and in combination with cells generate a living template that can develop into functional artificial tissue.<sup>337</sup> Several commonly used 3D printing technologies are used in the medical field; these include fused deposition modeling, extrusion, and inkjet.<sup>340</sup> Recently, a method called low-temperature deposition manufacturing has been introduced, which preserves the bioactive status of the material because of its nonheating feature. This allows for printing 3D structures containing natural biopolymers.<sup>341</sup>

Despite advances, many of the newer tissue-engineered technologies for cartilage repair have failed to demonstrate significant clinical benefits over older approaches.<sup>342</sup> Most existing methodologies have been unable to treat large defects or those associated with advanced osteoarthritis. Additionally, none of the current technologies have shown the potential for reconstructing an entire structural unit such as a joint head.<sup>316</sup> The research community is making efforts to determine how new and advanced technologies can be translated into measurable clinical gains by considering safe, standardized, cost-effective, and good manufacturing practice-compliant production. Some challenges remain with cell-based therapies, such as dedifferentiation of chondrocytes when expanded *in vitro* and limited stem cell chondrogenesis that can lead to fibrocartilage.<sup>336</sup> From a materials perspective, matching the rate of scaffold degradation with neocartilage formation has been problematic, and the bioadhesive properties of the material need to be considered in order to facilitate the integration of scaffold and newly formed cartilage to the host tissue.<sup>337</sup> Efforts to address these issues will make it possible to target the optimum conditions for producing tissue-engineered therapies that can promote human cartilage regeneration and repair.

## Skin Tissue Engineering Update

Significant progress has been made over the past few decades in the development of *in vitro* engineered substitutes that mimic human skin, either as grafts for the replacement of lost skin or for the establishment of *in vitro* human skin models. Several acellular (Biobrane®, AlloDerm®, and Integra®), allogenic (Apligraf®, Dermagraft®, and OrCel®), and autologous (Epicel®) skin substitutes have been approved by FDA.<sup>343</sup> This section primarily focuses on bioprinting as the next wave in tissue-engineered skin substitutes.

Cells used for the successful construction of an *in-vitro* epidermal-dermal skin-equivalent include keratinocytes, Langerhans cells, fibroblasts, endothelial cells, and mesenchymal stem cells.<sup>344</sup> A variety of natural hydrogels (fibrin, collagen, chitosan, etc.) and synthetic hydrogels (polyethylene glycol, polyacrylic acid, polyvinyl alcohol, etc.) have been investigated as potential sources for scaffolds.<sup>345,346</sup>

Recent advances in 3D printing (bioprinting) technologies have been explored in order to engineer cell-loaded scaffolds that match the structural complexity of native skin tissue.<sup>347</sup> Laser-assisted bioprinting, droplet-based bioprinting, and extrusion bioprinting are all commonly used bioprinting techniques for constructing skin tissue equivalents.<sup>344</sup> Bioprinting platforms support the programmed deposition of multiple skin cell types and allow for the utilization of various matrix biomaterials and processes that are lacking in conventional skin tissue engineering approaches. Fabrication of skin constructs using bioprinting techniques carries several advantages compared to conventional tissue engineering strategies including the potential for automation and standardization for clinical production. Autologous skin cells such as dermal fibroblasts and epidermal keratinocytes can be directly layered onto the wound area<sup>348</sup> or into a stabilized matrix such as collagen.<sup>349,350</sup> Alternatively, stem cells such as those derived from amniotic fluid or bone marrow may successfully support applications in skin tissue bioprinting. Stem-cell-driven wound closure and re-epithelialization, for example, have been shown to be significantly greater compared to wound closure and re-epithelialization with fibrin–collagen gel treatment alone.<sup>351</sup> Regeneration of fully functional skin substitutes using bioprinting methodologies is a complex process, requiring a variety of functionally discreet cell types. Recent studies targeting the incorporation of specialty cells such as melanocytes and epithelia that form sweat glands have had promising results.<sup>9,10,11</sup> Coprinting melanocytes and keratinocytes on top of a dermal layer resulted in producing freckle-like pigmentation in terminally differentiated keratinocytes,<sup>352</sup> and bioprinted sweat glands fabricated with epidermal progenitor cells in a composite hydrogel formulated with gelatin and sodium alginate supported functional restoration of sweat glands in burned mice.<sup>353</sup>

In general, technological limitations, including requirements for large numbers of specialized cells, high printing resolution, vascularization, and versatility in culture media, need to be overcome in order to achieve clinical translation for bioprinting skin.<sup>354</sup>

## Urology Tissue Engineering Updates—Urethra

Urethral stricture is a scar of the subepithelial tissue of the corpus spongiosum that constricts the urethral lumen, restricting the flow of urine and causing incomplete bladder emptying that can lead to urinary tract infection.<sup>355</sup> This condition affects approximately 1% of males over the age of 55.<sup>356</sup> Surgical intervention is available to repair the urethral defects; however, the management of long segment strictures represents an ongoing challenge due to the potential

for stricture recurrence following urethrotomy or urethral dilatation.<sup>357</sup> Autologous tissue transfer to support urethroplasty augmentation generally involves harvesting tissue from areas of the buccal mucosa, nonhairy skin, bladder, or colonic mucosa. These procedures often have associated limitations, including the availability of adequate tissue, the necessity for multiple surgeries, and the development of comorbidities.<sup>358</sup> Tissue engineering aims to reduce these limitations by through approaches such as seeding cells into damaged urethral tissue, implantation of acellular matrices, and implantation of a tissue-engineered substitute.<sup>359</sup>

Initial attempts at urethral reconstruction focused on nondegradable materials; this approach, however, resulted in complications such as tissue calcification and fistulae;<sup>360</sup> consequently, technologies to improve urethral tissue engineering currently rely on biodegradable scaffold materials with sufficient mechanical support to maintain an open lumen until newly forming tissue can fully regenerate.<sup>361</sup> Natural polymers such as collagen or gelatin cannot be used independently for urethral reconstruction due to their weak mechanical properties and rapidly biodegradability; however, natural biomaterials that may incorporate these polymers, such as acellular matrices obtained from cadaveric or animal organs, are an alternative source for scaffold material following decellularization.<sup>362,363</sup> Homologous transplantation of organ specific urethral acellular matrix from a donor has been shown to support complete epithelialization and regeneration of smooth muscle bundles.<sup>364</sup> Xenogenic small intestine submucosa (SIS), for example, has been tested clinically for repairing urethral strictures. While initial studies demonstrated a tendency for recurrent strictures,<sup>365</sup> recent studies have indicated that SIS may in fact function effectively in reconstructive procedures for ureters. Overall safety and long-term efficacy still require additional investigation however.<sup>366</sup> Decellularized cadaveric human bladder submucosa matrix has also been used clinically in urethral structure repair, but has demonstrated a lower success rate compared to utilization of buccal mucosa for recurrent and complicated strictures.<sup>367</sup> Nevertheless, preclinical studies using bladder submucosa as a matrix has produced promising results with a variety of cell types, including adipose-derived and urinary-derived stem cells, autologous bladder smooth muscle and urothelial cells, and autologous minced urethral tissue.<sup>368–370</sup> In general, various cell lines have been used in preclinical and clinical studies for urethral reconstruction, including human progenitor cells (epithelial cells and smooth muscle cells), adipose derived stem cells, fibroblasts, and keratinocytes.<sup>356</sup> Recently, urinary-derived stem cells have gained attention in tissue engineering due to the capacity for proliferation, adhesion, and differentiation into smooth muscle and urothelial cell lines.<sup>371</sup> Importantly, these cells can be obtained without the need of invasive procedures.<sup>372,373</sup>

Synthetic scaffolds for urethral tissue engineering include biodegradable poly(glycolic acid) (PGA), poly lactic-co-glycolic acid (PLGA), and poly(caprolactone) (PCL).<sup>374</sup> Scaffolds of PGA:PLGA containing autologous bladder smooth muscle and urothelial cells from bladder biopsies have been used clinically, in an observational study, to successfully bridge 4–6 cm urethral defects, in five patients.<sup>375</sup> This approach has currently been approved for a Phase I

clinical trial for safety and feasibility. Natural and synthetic materials are increasingly being used in combination to produce hybrid materials that meet desired properties on mechanical strength, porosity, cell affinity, biocompatibility, and biodegradability. Matching the scaffold degradation rate with the regrowth of healthy tissues is an important consideration. These materials can also be enriched with cytokines and growth factors that promote vascularization of the graft and tissue restoration.<sup>376,377</sup> Newly created functional and smart polymeric materials together with advances in composite biomaterials for 3D bioprinting will facilitate the optimization of tissue engineering solutions to meet clinical performance requirements in the future.<sup>378–380</sup>

## Concluding Remarks

In the last few decades, the field of regenerative medicine has made incredible strides in targeting tangible therapies for patients in need.<sup>381</sup> A variety of approaches involving diverse cellular, material and biochemical factor configurations have been explored for their capacity to support tissue regeneration. Complex tissues consisting of heterogeneous structure/function, such as skin, bone, cartilage, lung, kidney, and reproductive tissues, have been the object of innovative technologies such as programed bioprinting, which can mimic spatial architecture by depositing biological materials and cells in a well-controlled manner.<sup>382</sup> Platforms such as gene-editing using SiRNA<sup>383</sup> or CRISPR technology<sup>384</sup> also offer exciting pathways for regenerative and tissue-engineered inspired applications. Currently, clinical trials are investigating both cellular and acellular solutions for a variety of regenerative treatments.<sup>385</sup> Recent scientific advancements and clinical discoveries continue to inspire progress toward effective, clinically translatable therapies that will be amenable to commercialization in the near future, and thereby increase the availability of tissue-engineered products. Developments such as these will make it possible to achieve easily distributed, patient-specific regenerative treatments that will target a wide range of health issues going forward.

## CHAPTER 58

# Human tissue allografts: responsibilities in understanding the path from donor to recipient

Cassandra D. Josephson<sup>1</sup> & Matthew J. Kuehnert<sup>2</sup>

### Introduction

A growing number of patients benefit from donated tissues of human origin. Regulated as human cells, tissues, and cellular- and tissue-based products (HCT/Ps), FDA requires that HCT/Ps be minimally manipulated (or processed) and retain homologous use of graft function as in the donor. Allografts promoted for use today include bone, cartilage, and tendons used to reconstruct joints and other orthopedic structures; skin to treat burns (split thickness graft) and to support underlying structures (acellular dermal matrix); adipose to provide cushioning and aesthetic improvement; veins, arteries, and heart valves for cardiovascular repair; placenta as a wound covering; cornea to restore sight; and reproductive tissue to treat infertility. The most commonly transplanted allografts are bone, musculoskeletal tissue, and dermis (Table 58.1).<sup>1,2</sup>

Tissue may be “fresh,” with minimal processing, in whole grafts and sections, such as osteochondral and osteoarticular types, or may be ground, morselized, or shaped for needed function, such as gels, pastes, or strips in specific applications. Further processing may strip the graft of cells, creating an acellular matrix. Storage parameters may also vary, either requiring room temperature, refrigeration, or freezing, for days, months, or years. Even when meeting criteria as HCT/Ps, these grafts may bear little resemblance to their original form, transplanted in a variety of medical and dental applications, but it is important that each tissue form be recognized as of human origin, with appropriate tracking and consent.

Tissues may be recovered from the same person as the recipient (autograft) or from a different donor than the recipient (allograft). Allografts are recovered from either living (placenta and gametes) or deceased (bone, cardiovascular, and cornea) donors.

Some grafts thought of as “tissue” are not covered in this chapter, including stem cells for infusion, bone marrow for transplantation, solid organs, and vascularized composite allografts (e.g., face, limbs, and uterus).

The total number and range of tissues collected, processed, and transplanted in the United States are difficult to determine, in the absence of a national reporting system or systematic survey approach that otherwise exist for organs and blood. Surveys

are conducted sporadically by AATB with support from US HHS.<sup>3</sup> In 1999, tissue banks accredited by the American Association of Tissue Banks (AATB) distributed approximately 750,000 allografts for transplantation. By 2003, the figure had more than doubled. By 2007, more tissue banks became accredited and greater than 2,000,000 units were distributed. As of 2015, AATB members recovered from more than 39,000 donors resulting in more than 3,200,000 units distributed.<sup>3</sup> Eye banks are accredited differently, and corneal transplants numbered >85,000 from over 68,000 donors recovered by 69 EBAA accredited banks in 2019.<sup>4</sup>

In addition to such tissues from deceased donors, many tissues for clinical use are derived from living donors, including semen and oocytes for use in artificial insemination and assisted reproductive technology procedures. A major increase in tissue recovery from living donors is attributable to placentas donated from delivery mothers for grafts derived from the amniotic/chorionic membrane. Tissue from living donors is also considered by some to include human milk. The US Food and Drug Administration (FDA), however, does not subject human milk to regulations that apply to human allograft tissue, and thus it is also not covered in this chapter.

### General principles of tissue preservation, storage, and clinical use

Allograft transplantation is increasing in the United States partially because of the successful clinical application of tissue allografts from living donors (e.g., delivery mothers donating the placenta for grafts derived from the amniotic/chorionic membranes). Further, a myriad of surgical specialties use human tissue allografts: orthopedic surgery, neurosurgery, cardiothoracic surgery, plastic surgery, vascular surgery, urology, ophthalmology, burn and other skin wound care, podiatry, sports medicine, trauma, and cranio/maxillofacial surgery. Additionally, increasingly refined and innovative HCT/Ps are being developed by tissue suppliers to meet the clinically diverse needs of patients.<sup>2</sup>

**Table 58.1** Some Common Human Allograft Applications, by Clinical Specialty

Specialty	Procedure/Application	Allograft Tissue Type
General orthopedics	Trauma/fracture repair Osseous defect repair Acetabular repair Total joint revision/arthroplasty	Femoral head; femoral condyle; whole, proximal, or distal bone shaft (femur, tibia, and humerus); hemipelvis; cancellous bone; corticocancellous bone; cortical strut/screw/pin; bicortical strip; tricortical wedge; whole joint* (knee, ankle, shoulder, and elbow); osteoarticular graft*; osteochondral graft*; DBM; osteobiologics
Sports medicine	Tendons, anterior cruciate ligament, posterior cruciate ligament, other knee ligament repair; meniscus repair/replacement; osteochondral defects; rotator cuff repair; ankle/tendon ligament repair; hand/wrist repair	Patellar ligament; Achilles tendon; tibialis tendon; semitendinosus tendon; gracilis tendon; peroneus longus tendon; fascia lata; rotator cuff; meniscus; meniscus w/tibial plateau; osteochondral plug*; femoral hemicondyle*; acellular dermal matrix
Craniofacial/maxillofacial	Cranial reconstruction; maxillary/mandibular reconstruction; facial palsy repair	Mandible; dura mater*; pericardium; fascia lata; acellular dermal matrix; bicortical strip; tricortical wedge; DBM; osteobiologics; sclera
Dental	Alveolar ridge augmentation for dental implant placement; onlay grafting; sinus elevations/augmentation; socket/ridge preservation; intrabony defect repair	DBM; osteobiologics; sclera; acellular dermal matrix; particulate and structural cortical and cancellous grafts and combinations
Ophthalmology	Postcataract corneal edema repair; Fuchs dystrophy repair; glaucoma drainage valve implantation; corneo-scleral fistula repair; keratoconus correction; phaco burn repair; orbital reconstruction following enucleation; eyelid ectropion repair; eyelid reconstruction	Cornea*; sclera*; pericardium
Neurosurgical	Cervical/lumbar interbody fusion; intermedullary rod placement; dura replacement	Dura mater*; fascia lata; pericardium; cancellous bone; corticocancellous bone; cortical strut; bicortical strip; various machined and constructed proprietary bone forms*; amniotic membrane*; acellular dermal matrix
Burn treatment	Wound covering*	Fresh skin*; cryopreserved skin*; freeze-dried skin*; acellular dermal matrix; amniotic/chorionic membrane* Fascia lata; pericardium; lyophilized skin*; acellular dermal matrix; adipose tissue
General surgery	Urologic incontinence procedure; pelvic floor reconstruction; herniorrhaphy; breast reconstruction HIV lipodystrophy	
Plastic surgery	Anatomic defects for aesthetic improvement Plastic surgery reconstruction	adipose tissue; acellular dermal matrix DBM
Cardiac	Congenital anomaly repair (both valve and outflow tract major vessel repair/replacement*); cardiac valve and vessel repair/replacement; major vessel blood "shunting" procedures	Aortic valve*; pulmonary valve*; various conduit-use-only grafts* from the ascending aorta or thoracic aorta or from the pulmonary artery trunk or its branches

**Table 58.1** (Continued)

Specialty	Procedure/Application	Allograft Tissue Type
Vascular	Vaso-occlusive disease (peripheral, abdominal, and thoracic); cardiac artery bypass grafting; arteriovenous shunt insertion; muscle-flap or organ transplant vascular bed extensions; replacement of infected prosthetic devices	Greater saphenous vein*; aorto-iliac artery*; iliac vein*; iliac artery*; femoral vein*; femoral artery*

Human Tissue	Storage Condition*	Temperature
Musculoskeletal	Frozen ( <i>cryopreserved and noncryopreserved</i> ) long term Frozen ( <i>cryopreserved and noncryopreserved</i> ) temporary storage for six months or less Refrigerated, short term	-40 °C or colder -40 to -20 °C
Skin	Lyophilized, long term Refrigerated, short term Frozen, long term	1–10 °C Ambient temperature** 1–10 °C
Cornea	Lyophilized, long term Refrigerated, short term (defined by method)	-40 °C or colder Ambient temperature** 2–8 °C
Semen	Frozen, long term	Liquid nitrogen (liquid or vapor phase)
Cardiac, vascular	Frozen, <i>cryopreserved</i>	-100 °C or colder
Dura mater	Lyophilized, long term	Ambient temperature**

\* Or as defined and validated by the processor.

\*\* Ambient temperature monitoring not required for lyophilized tissue.

Source: Adapted from Osborne JC *et al.* (2017).<sup>5</sup> and Trainor and Reik (2014).<sup>6</sup>

The most common storage condition for tissue preservation is at cold temperatures, either by refrigeration or freezing. Bone most often is lyophilized (freeze dried). (Table 58.2).<sup>5,6</sup> Short-term storage usually requires refrigeration, 4 °C, whereas longer-term storage generally requires a frozen state, -40 or -80 °C, or even at liquid nitrogen (liquid or vapor phase) temperatures if the graft is not lyophilized. Several types of tissues can be preserved by multiple methods depending upon their use. Bone, dura mater, and amnion can be cryopreserved or lyophilized. For tissues that will provide a structural role in the recipient, the maintenance of cell viability is not necessary. Tissues of this type, which include dermis and some forms of placenta, are composed of an extracellular matrix (such as collagen) with few or no viable cells present to support the matrix after transplantation, although they can contribute growth factors or proteins to facilitate remodeling. Even when the processing method used is intended to preserve cell viability, the donor cells typically will die within hours or days following transplantation. The extracellular matrix, whether transplanted containing viable cells or devoid of them, is repopulated through the in-growth of metabolically active recipient cells. Gradually, depending in part on the size and type of the allograft implanted, remodeling occurs, and the transplanted structure may eventually be entirely replaced by host cells.<sup>7</sup> The transplantation of allograft heart valves and cardiac conduit tissues provided in an acellular matrix form has been studied to determine the rate and extent of repopulation with recipient cells.<sup>2,8</sup>

In some tissues, such as cornea, a single layer of viable donor cells is important, and this requirement necessitates the maintenance of

the tissue in culture medium at refrigerated temperature.<sup>9</sup> Other human tissues, such as marrow, skin, and gametes, are stored by either refrigeration or cryopreservation. In the latter, a controlled rate freezing process and a cryoprotectant remove water from the cells while maintaining viability. The usefulness of tissues requiring post-transplantation cell viability depends on their maintenance of not only metabolic activity, but also capacity to synthesize protein, proliferate, or differentiate.<sup>2</sup>

### Donor-recipient matching: is it necessary?

Donor-recipient HLA matching is not necessary for most tissues and is rarely performed. Tissues such as bone, fascia, tendon, cartilage, and dura mater are not preserved or transplanted in a viable state for donor cells; rather, they serve as a support or matrix that the recipient's own cells can enter and gradually replace. Immunologic rejection, therefore, is not a significant concern, and matching of blood group or HLA antigens is considered unnecessary. There are a few exceptions where immunologic graft rejection can occur. In patients who have received a repeat cornea graft, efforts are made to use HLA-matched corneas in subsequent transplants.<sup>10</sup> HLA sensitization has also been reported in recipients of vascular allografts or allograft heart valves.<sup>11</sup>

The ABO antigens are a significant consideration in organ transplantation because they constitute strong histocompatibility antigens that are expressed on vascular endothelium. A major ABO mismatch can cause rapid graft rejection resulting from endothelial

damage by ABO antibodies and subsequent widespread thrombosis within the graft. Therefore, ABO matching is important to the success of vascularized organ grafts (i.e., kidney, heart, liver, and pancreas). However, ABO matching is not critical for a successful outcome when using most tissue grafts (i.e., fascia, bone, heart valves, skin, and cornea). Rarely, hypersensitivity to antigens expressed by fresh or cryopreserved donor tissue can occur and appears to be dependent on an ill-defined immune response by the recipient.<sup>2</sup>

Alloimmunization to minor red blood cell antigens, RhD, Fy<sup>a</sup>, and Jk<sup>b</sup>, following transplantation of frozen unprocessed bone has been reported.<sup>12,13</sup> Consequently, frozen unprocessed bone allografts usually are matched with the donor for the D antigen if the recipient is a female of childbearing potential, in addition to being matched for ABO group.<sup>2</sup>

### Clinical uses of allografts

#### Bone—frozen and lyophilized

Bone allografts have many uses, including provision of acetabular and proximal femoral support for replacement of failed prosthetic hip joints, packing of benign bone cysts, fusion of the cervical or lumbar spine to correct disk disease or scoliosis, restoration of alveolar bone in periodontal pockets, reconstruction of maxillofacial deficits, and replacement of bone that has been resected because of a bone malignancy, such as osteosarcoma (Table 58.1). Bone malignancy surgical procedures are accomplished with large osteochondral allografts that permit tumor resection and achievement of a cure and are limb sparing, avoiding amputation.

Modern technology allows the cutting, machining, and piecing together of allografts via precision instrumentation, and has resulted in stronger and more versatile grafts that can withstand the challenges of new surgical techniques. Linear grooves, notches, or crosshatchings may be incised into bone surfaces to make the bone graft less likely to slip or become dislodged after placement. Many bone allografts, especially those used in neurosurgical applications, are now placed using precision instrumentation that not only ensures exact placement but also enhances stability. Allografts can be cut or shaped to precise angles that accommodate, for instance, lordosis of the cervical and lumbar spine. Advanced processing methods are being developed to improve availability while retaining or improving function.<sup>2</sup>

Fresh autograft can be taken from the patient's own iliac crest intraoperatively, but this practice is becoming less common.<sup>7</sup> Fresh bone autograft is preferred by some surgeons; however, preserved allografts are practical and accepted alternatives that approximate the results obtained with fresh bone autograft.<sup>14</sup> In some patients, an autograft is not an option because sufficient high-quality bone is not available. Other advantages of bone allografts versus autografts are a reduction in operating room time, and the number of operative sites, leading to a reduction in morbidity and surgical costs. The use of bone allograft does carry a minimal risk of donor-to-recipient transmission of infectious disease,<sup>15</sup> although this risk is mitigated through careful donor selection and testing, coupled with disinfection and sterilization of tissue during processing as described earlier.

#### Frozen bone

Frozen bone, collected under aseptic conditions and then frozen or cryopreserved, is available in a wide variety of shapes and sizes from deceased donors, or obtained from a living donor recovered as a femoral head or tibial plateau undergoing total joint replacement in

an operating room (an uncommon practice in the United States, but continuing in Canada, Australia, and Europe). Frozen bone carries an increased risk of disease transmission compared with processed tissue. Diseases known to have been transmitted by unprocessed bone include HIV, HCV, HTLV, tuberculosis, and hepatitis.<sup>15</sup>

Frozen bone can cause alloimmunization from exposure to antigens on the attached connective tissues, marrow, and blood, although such alloimmunization apparently does not affect the graft's efficacy. Detailed reviews addressing the role of histocompatibility and the immune response in bone allograft transplantation have been published.<sup>16</sup> Antibodies to histocompatibility antigens,<sup>17,18</sup> blood group antigens,<sup>12,13</sup> and bone matrix proteins have been induced by transplanted frozen bone. In order to avoid Rh alloimmunization, bone from an Rh-negative donor is usually selected when using bone that has not been processed to remove red cells, and the recipient is an Rh-negative female of childbearing potential.

Frozen bone allografts are available as whole bones or cut into usable shapes and sizes. Frozen bone can generally be stored up to five years at -40 °C or colder, but the maximal storage duration and expiration date may vary based on processing and storage methods, as validated by the tissue bank. There is no evidence that the biomechanical or osteoinductive properties decline during frozen storage. However, in the absence of cryopreservation, frozen bone does not maintain cellular viability. Thus, frozen bone is used for structural support that depends on an intact calcified extracellular matrix or is used as filler to promote new bone formation.

#### Lyophilized bone

Following aseptic recovery, deceased donor bone can be maintained frozen at -40 °C or colder, and then can later be sent to a tissue processor. Alternatively, immediately after recovery, the tissue can be placed on wet ice and expedited for transport directly to the processing tissue bank where, within hours of recovery, it is frozen at -40 °C or colder until processing. Such processing includes removal of surface tissues and internal fat, blood, and marrow by means of mechanical agitation, high-pressure water jets, or alcohol soaks. It can also include detergents or other solutions as part of a proprietary process. Then, the bone is milled into clinically useful shapes and sizes. This may include computer-guided milling and use of assemblies that result in complex mechanical structures. Conventional allografts include corticocancellous strips, wedges, and dowels; cortical struts and rings; and cancellous and corticocancellous cubes and chips.

DeminerIALIZED (i.e., extraction of calcium) freeze-dried bone allografts (DBM) is obtained from cortical bone and maybe found as specific granule or particle sizes, as a powder, or in entangled, twisted fiber configurations. DBM products are available in combination products in the form of gels, pastes, putties, and flexible strips or sheets. DBM primarily provides growth factors, but accompanying collagen can help play a structural role as a scaffold for future bone growth. The combining of DBM with approved polymer carriers results in moldable grafts that are user friendly for the surgeon, do not migrate after placement, and whose bone content does not dissolve following transplantation. Such grafts can readily be applied to completely fill bony defects and to act as a scaffold for ingrowth of the recipient's own cells, or they can be used to enhance other structural repair devices, such as dental implants, vertebral body spacers and cages, or support devices such as rods, screws, and plates.<sup>1</sup> Potency can be evaluated by using assays for osteoinductive capacity and biomechanical properties, but these

analyses are usually conducted only when there is a change in the production process. Lyophilized bone is brittle unless fully rehydrated before use. Lyophilized bone can usually be stored at ambient temperature for up to five years if the graft's package integrity and its vacuum are maintained, depending on validation performed by the tissue processor.

While the purpose of lyophilization is to allow for convenience, other preservation methods exist that also allow for ambient temperature storage of grafts. Some tissues can be dehydrated via chemicals (such as acetone), some kept in saline (e.g., costal cartilage), and some are packaged with a humectant (such as glycerol). The last two examples are considered prehydrated and are "ready to use" off the shelf. Expiration dates for all of these alternate methods are established by validation of the packaging by the tissue processor.

Bone collected aseptically in an operating room and processed aseptically can be lyophilized without use of a sterilant. In aseptic processing, bone is cultured extensively before release, and final or terminal sterilization with  $\gamma$ -irradiation may not be applied. In addition, bone grafts with "viable cells" have become more popular. Although the bone should be free of bacteria that can be cultured through routine microbiological methods, it still has the potential to transmit disease, including viruses, mycobacteria, and some fungi. Despite this risk, some physicians have preferred aseptically processed, nonsterilized lyophilized bone because it was thought to have better osteoinductive capacity than sterilized bone. However, controlled dose low-temperature radiation has been found to have no significant effect on osteoinductive capacity.<sup>2,14</sup>

## Connective tissues

### Cartilage and meniscus

Human cartilage can be transplanted at weight-bearing or non-weight-bearing sites. For non-weight-bearing uses such as nasal reconstruction and mandibular or orbital rim augmentation, the graft provides structural support and need not be viable. *Costal cartilage* can be recovered for this purpose. Gamma irradiation can be used to sterilize the cartilage and then stored in saline at refrigerated temperatures, or it can be lyophilized and stored at ambient temperature.

*Articular cartilage* can be transplanted to weight-bearing articular surfaces to replace focal cartilage defects caused by trauma or degenerative disease, particularly in the knee. Cartilage in an osteochondral or osteoarticular allograft can be obtained as a femoral hemicondyle, a tibial plateau or fragment, or a measured segment removed with a template cutter that can be press fitted into a similarly cut area in the recipient. Osteochondral allografts avoid autograft site morbidity and are advantageous when the focal articular cartilage defects being repaired are large (>2.5 cm).<sup>19</sup> It has been assumed that, in weight-bearing applications, chondrocytes must survive the collection and preservation process and remain viable, producing normal cartilage matrix to maintain mechanical properties. It appears that chondrocytes deep within the cartilage matrix resist cell-mediated immune responses by the recipient and, if kept viable during storage, are able to survive after transplantation. Cartilage grafts from histo-incompatible donors, stored <24 hours at 4 °C, have survived for as long as seven years after transplantation, if the grafts developed a sound union and if conditions for correct biomechanical functioning were present.<sup>20</sup> Articular cartilage collected in a sterile manner can be stored at 4 °C in antibiotic containing saline or electrolyte solution, with or without 10% fetal (bovine) calf serum.<sup>21</sup> For solutions containing calf serum,

screening procedures are now in place to reduce the risk of source animals that may have bovine spongiform encephalopathy (BSE). Osteoarticular and osteochondral allografts can be stored refrigerated for up to 28 days with successful clinical outcomes. If such grafts have been cryopreserved, expiry for these allografts can be extended to one year.

The use of a large osteochondral allograft, such as the femur with the articular cartilage attached, is thought to require preservation of cartilage viability in order to maintain biomechanical properties. To accomplish this, grafts have been stored at refrigerated temperatures in electrolyte solutions for up to one month, or have been frozen in 10% glycerol or 15% DMSO and stored at -70 °C or colder.<sup>22</sup> Following transplantation in humans and animals, the surface of the articular cartilage allograft undergoes degenerative changes within a few years. These grafts carry the same risk of disease transmission as other fresh tissue allografts.

*Menisci* are C-shaped disks of fibrocartilage interposed between the femoral condyle and tibia. The presence and integrity of the meniscus are essential for knee mechanics and biochemical functions. Loss or disruption of the meniscus is associated with pain, joint laxity, and degenerative arthritis. Meniscal transplantation has been proposed as a method of providing a biologically and biomechanically acceptable structure to replace a damaged or removed meniscus, with a goal of relieving pain, decreasing stress on the anterior cruciate ligament, and preventing late arthritis, although evidence of allograft tissue being chondroprotective is lacking. Although there have been unpublished reports of successful transplantation of menisci stored <24 hours at 4 °C, fresh menisci are not usually available. Cryopreserved menisci are used successfully, with good outcomes (including reduced pain and increased knee function) reported.<sup>2,23,24</sup>

### Tendon and ligament

The knee is the joint most frequently involved in sports-related injury. Arthroscopic methods for replacing the anterior or posterior cruciate ligaments with autografts, allografts, or artificial tendons and ligaments are frequently used. Despite the attendant need for sacrifice or weakening of normal structures, the use of autografts appears to have a high success rate and low incidence of complications. However, allografts may be indicated for multiple ligament knee injuries, anterior cruciate ligament revisions, or posterior cruciate ligament reconstruction, and when extensor mechanisms are impaired (as with previous tendon tears). It is also sometimes preferable to avoid the morbidity associated with autograft. In addition, there are occasions when sources of adequate autograft tissue are not available.<sup>25</sup> Allografts used to replace the injured anterior cruciate ligament are usually derived from deceased donor patellar ligaments, tendons of the leg (e.g., tibialis, semitendinosus, gracilis, and peroneus longus), or Achilles tendons. Ligament and tendon allografts are usually stored frozen, but some are stored lyophilized. In vitro biomechanical properties of tendons do not seem to be greatly affected by freezing, lyophilizing, or ethylene oxide sterilization.<sup>26</sup> However, many surgeons avoid lyophilized tendon allografts because of experiences with clinical failure. Frozen tendon allografts are commonly sterilized by  $\gamma$ -irradiation, although this can reduce their mechanical strength, particularly if performed at room temperature or if the dose exceeds 20 kGy.<sup>27</sup> There is no evidence that maintenance of cellular viability during processing and storage is important to clinical effectiveness, although some growth and other biologic factors may be important. The effect of irradiation on the biomechanical properties of human tissue has been explored

extensively, with inconsistent results. This is probably because the studies failed to use uniform irradiation methods and comparable study designs. A key study found a difference in average stress at failure between nonirradiated and  $\gamma$ -irradiated tendons; that difference is likely a consequence of the free radicals generated, which can cause minor crosslinking of collagen fibers and alteration of the tendon's material properties.<sup>28</sup> In order to eliminate the potential for elongation of irradiated grafts after implantation, the authors encouraged "pretensioning" (e.g., stretching to a desired uniform length range before packaging) of grafts before insertion.

### Fascia lata

The fascia lata is a broad fibrous membrane surrounding the thigh muscles. The thick lateral portion acts as a flattened tendon, and its muscular insertions serving to maintain the trunk in an erect posture. Fascia lata can be removed and transplanted as an autograft or allograft. As an allograft, fascia lata has been used to suspend the upper eyelid to correct ptosis, as a covering for bone grafts in dental surgery, to replace injured anterior cruciate ligaments, to provide support for bladder suspension, and to repair ankle, hip, and shoulder suspensions (e.g., repair of a ruptured shoulder rotator cuff). Fascia lata is usually preserved by lyophilization, resulting in a residual moisture of <6% or 8% (depending on measurement method), the graft is then sterilized by  $\gamma$ -irradiation and stored for up to five years at ambient temperature. After rehydration, the graft's biomechanical properties equal those of fresh frozen fascia lata. The use of fascia lata has become less popular because of the availability of alternative products, such as decellularized skin.<sup>2</sup>

### Dura mater

Dura mater is the outermost, toughest, and most fibrous of the three meningeal membranes covering the brain and spinal cord. The intracranial portion is collected, processed, stored, and distributed for several clinical applications; the most common use is the closure of dural defects caused by resection of tumor or the repair of traumatic injury. Human dura allograft is most commonly preserved by lyophilization. Ethylene oxide and  $\gamma$ -irradiation are effective in preventing transmission of viruses and bacteria; however, Creutzfeldt-Jakob disease (CJD) has been transmitted by dura mater treated by these methods. Following findings by Brown and coworkers,<sup>29,30</sup> in 1986 The Committee on Health Care Issues of the American Neurological Association recommended using 1N NaOH for one hour or steam autoclaving for one hour at 132 °C as standard sterilization procedures for CJD-infected tissue or contaminated materials. Donors with a history of clinical dementia or other central nervous system disorders are not accepted as donors. Lyophilization and sterilization treatments do not lessen the effectiveness of dura mater allografts. Reconstituted freeze-dried dura mater is thick and strong, holds suture well, and is incorporated into normal surrounding tissue without rejection.<sup>2</sup>

### Skin for burn

Human skin allograft is the dressing of choice for temporary grafting onto deep burn wounds whenever sufficient amounts of autograft skin are unavailable. Early excision of burned tissue and covering of the wound with deceased donor skin allograft has shortened hospitalization and decreased mortality more than has any other treatment.<sup>31</sup> A skin allograft provides temporary coverage and acts as a barrier against loss of water, electrolytes, protein, and heat. It reduces opportunities for the invasion of bacteria and speeds re-epithelialization. Skin allografts are replaced periodically until

the patient's vascular bed is reestablished. Skin allografts are also used for unhealed skin defects (decubitus ulcers, autograft skin sites, pedicle flap sites, and traumatically denuded areas).

After collection, fresh skin can be stored in medium at 1–10 °C for up to 14 days,<sup>5</sup> but fresh skin is seldom used today. Skin also can be frozen using a method that retains cell viability in order to improve availability. Because cell viability declines during refrigerated storage, results are best when cryopreservation is performed within 2–3 days after recovery. Cryopreserved skin can be prepared as strips (often 3-inch by 8-inch sections), either unmeshed or meshed (most commonly with a 1:1.5 expansion ratio, which triples the area that can be covered). The skin is then covered in fine-mesh gauze and laid flat, packaged, and then cryopreserved with glycerol or DMSO at a concentration of 10% or 15% as a cryoprotectant. Cryogenic damage is minimized by controlling the rate of freezing to between -1 and -5 °C/minute. Many tissue banks use a "heat sink" freezing method rather than one that employs computer-controlled freezing chambers. Heat sinks involve aluminum plates combined with styrofoam-insulated boxes; these are placed directly into a -70 °C mechanical freezer. This simple process provides a slow, controlled freezing rate that is acceptable for skin and that also maintains cellular viability.<sup>32</sup> AATB standards permit frozen storage in a mechanical freezer at -40 °C or colder, in the vapor phase of liquid nitrogen, or submerged in liquid nitrogen.<sup>5</sup> Cryopreserved skin allograft is usually transported from the tissue bank to the hospital with dry ice in order to maintain a frozen environment until use.

Skin for use in burn applications is generally not preserved by lyophilization because this method decreases clinical efficacy.

### Acellular dermal matrix

Although skin has historically been used only as a covering, decellularized skin offers the opportunities for use of a collagen matrix that can be implanted and remodeled within the site with the recipient's own cells, and can be either processed aseptically using chemicals or terminally sterilized using irradiation.<sup>33,34</sup> It is used for such applications as bladder suspension surgery, tendon repair, post-mastectomy breast reconstruction, oral reconstruction, and repair of large defects, such as postoperative hernias and dehisced wounds. Lyophilized (and prehydrated) acellular dermal matrix is available in several thicknesses for different applications, and can serve as a natural biological matrix for soft tissue augmentation in soft tissue defects and in periodontal peri-implant soft tissue management. Lyophilized skin is sometimes used by oral surgeons to cover oral mucous membrane defects and to speed re-epithelialization. Following hydration, lyophilized skin has multidirectional strength and can adapt to surface contours, and it is then resorbed over 4–6 months, depending on the site, defect size, patient age and health status, and the biomechanical load on the graft. Depending on processing method and packaging configuration, lyophilized skin can be stored as long as five years at ambient temperature or it may require refrigeration.<sup>2</sup>

### Ocular tissue

Cornea is one of the most frequently transplanted tissues; > 85,000 corneas were transplanted in the United States in 2019.<sup>4</sup> Corneal transplantation has become highly effective because of improvements in suture materials, surgical instruments and techniques, and medications to prevent and reverse rejection. It is considered a standard therapy for a variety of conditions. In the last 10 years, there has been a paradigm shift from full thickness keratoplasty to selective keratoplasty, where only the diseased layers of the cornea

are replaced. One such selective keratoplasty techniques is Descemet's stripping endothelial keratoplasty (DSEK), which transplants only the innermost portion of the cornea; the tissue adheres to the host cornea with the use of an air bubble. The benefits of this technique are a smaller, stronger wound with minimal disruption of the interior curvature of the cornea, resulting in faster recovery improved visual acuity, as well as a reduction in the occurrence of adverse effects such as graft rejection and vision threatening intraoperative and postoperative complications. As a consequence, DSEK for Fuchs endothelial dystrophy has become the preferred surgical therapy at much earlier stages of the disease, resulting in a resurgence of demand for cornea allografts. Currently, the most common indications for corneal transplantation are keratoconus, Fuchs dystrophy, postcataract surgery corneal edema, and corneal regrafting. Donor cells in the avascular full-thickness cornea graft enjoy long-term survival without the aid of histocompatibility matching because the recipient site is also almost completely avascular. Because of the avascularity of the cornea, routine immunosuppression is accomplished with topical corticosteroids. However, systemic immunosuppression may be used in conjunction with topical agents for high-risk cases. Some experts believe that the failure rate of 5–10% might be improved by HLA matching; recipients known to be sensitized to HLA antigens have rejection rates higher than nonsensitized recipients.<sup>35</sup> The possibility of alloimmunization is of particular concern in patients who are undergoing repeat grafting procedures because of graft failure or who have ocular infections, as the corneal rim may become quite vascularized. Sclera may be used in the repair of ocular defects, in orbital reconstruction following enucleation, and in some dental applications.<sup>36</sup>

Ocular tissue can be recovered by enucleation or by *in situ* excision of the cornea, with a rim of sclera. It is preferable that recovery be performed within 10 hours after death. The most common method of storage for the cornea today is with attached rim of sclera, at 4 °C in a modified tissue culture medium, based on that developed in 1974 by McCarey and Kaufman.<sup>37</sup> One example commonly used is Optisol-GS (Bausch & Lomb, Irvine, CA), which contains dextran (as an osmotic agent), chondroitin sulfate, gentamicin, and streptomycin. Storage of corneas in the medium, at 2–8 °C, can maintain endothelial viability for as long as 14 days and can maintain functional integrity for eutopic graft applications not requiring visual acuity for even longer storage periods.<sup>38</sup> Grafts are usually used within seven days. Although they have been treated with antibiotics, allograft corneas are not considered sterile. Rarely, corneas are frozen with cryoprotectants. Sclera are usually preserved in ≥70% ethyl alcohol; such a method yields a shelf life as long as two years.

### **Cardiac and vascular tissue**

Cardiac and vascular tissue includes heart valves, patches, and non-valved outflow tract arteries and vessels that can be used as conduits. Donor medical history requirements differ, so AATB has established separate standards for cardiac tissues and for vascular tissues.<sup>5</sup> Since their introduction decades ago, human heart valve allografts have been shown to be an alternative for patients needing heart valve replacement for whom mechanical and xenograft valves are contraindicated. Human heart valve allografts do not require recipient anticoagulation, have a lower incidence of thromboembolism, and appear relatively resistant to infection. After valve allograft transplantation, donor endothelium is not maintained, but donor fibroblasts may remain for an undetermined period. Because anticoagulation is unnecessary, human valve allografts are the graft

of choice for children, females of childbearing potential, and patients with cardiac infection in the aortic root. The use of allograft valves has been slowed, however, because implantation is more technically difficult compared to modern versions of stented prosthetic valves. In addition, their availability is limited, especially for pediatric use. Additionally, clinical results with transplantation of xenograft tissue valves have improved, although these are not available in the small sizes required by many pediatric patients.

Technical impediments have made it impossible to successfully produce man-made (either completely artificial or modified xenograft) replacement heart valves for use in neonates and other pediatric patients who require very small grafts. Only donated human heart valves from newborns or small children offer unobstructed blood flow through such a small annulus. Also, the tissue's pliability renders human allografts adaptable to the ingenuity of cardiothoracic surgeons who repair congenital defects by using allografts to replace underdeveloped or otherwise defective valves or outflow tracts, or to construct valves and tracts that may be absent.<sup>39</sup> Complex repairs may need to be staged over many years or may be only palliative. Demand for clinical use of nonvalved conduit sections of cardiac allografts (mostly from the main pulmonary artery and/or its branches) has shown superior results in use as treatment of defects of the right ventricular outflow tract.<sup>40</sup> On a global scale, the availability of cryopreserved pediatric allograft heart valves has historically been low and unable to meet demand.

To obtain cardiac allografts, hearts are recovered aseptically, immersed in a sterile isotonic solution within a sterile container, placed on wet ice, and transported expeditiously to a tissue processing facility. The pulmonic and aortic valves, along with their intact outflow tracts and/or small pieces of these conduits, are dissected free of the heart within 48 hours of donor asystole and then placed in tissue culture medium amended with a low-dose antibiotic cocktail. Studies demonstrate that cryopreservation of heart valves allow successful banking of valves of various sizes and types while retaining the intact matrix and having a low clinical incidence of valve degeneration, rupture, leaflet perforation, and valve-related death. For these reasons, human heart valves are generally cryopreserved,<sup>41</sup> with a method that includes an initial exposure to antibiotic solutions for 12–24 hours. Cryopreservation then follows, using a 10% DMSO solution tissue culture medium that is often amended with 10% fetal calf serum. Freezing is accomplished using a computer-assisted controlled rate of -1 °C/minute to -40 °C. Valves are generally stored in the vapor phase of liquid nitrogen. Theoretically, heart valves can be stored indefinitely in liquid nitrogen, although the nature of any deterioration during storage is not well characterized. The viability of cryopreserved connective tissue matrix cells is maintained, but at a lower level than that of fresh valves, and endothelial viability is lost. In addition, noncellular matrix elements are maintained.

The aorta and iliac arteries can be preserved using the same methods applied to heart valves. Frequently, the aortic arch is preserved with the aortic valve intact; such grafts are intended for transplantation as a valved conduit. Preservation and storage methods are similar to those for valves. Synthetic grafts are often the graft of choice, but such grafts may be less effective in an infected field. Aortoiliac arteries are used successfully as conduits in mycotic aneurysm repairs, when synthetic grafts have become infected, and for aortoenteric fistulas in an infected field.<sup>42</sup>

Arterial or venous segments of vascular organs may be recovered in order to provide a source of vascular "conduits" for use in organ transplants when the organ's attached vessels are damaged or

inadequate. Vascular conduits that have been recovered and transplanted under these conditions are not considered tissues under the FDA's human cells, tissues, or cellular or tissue-based products (HCT/Ps) rules, but they are regulated as organs under 42 CFR Part 121. Donor screening and testing, as well as labeling and storage requirements, are identical to those for donor organs specified in a federal contract with the Organ Procurement and Transplantation Network.

Autograft veins are used in cardiac and peripheral vascular bypass graft procedures whenever it is possible, but veins from deceased donors that have been recovered under aseptic conditions may be used for revascularization when autologous vein grafts are not available. Cryopreservation of allograft vessels is similar to that of cardiac allografts. Well-established tissue bank procedures are designed to retain venous endothelial cells during recovery, processing, and preservation, but these cells are rapidly sloughed off the lumen after the vein is transplanted into the high-pressure arterial system. Retention of endothelial cells during recovery and processing does aid, however, in reduction of the risk of thrombosis or failure after implantation through protection of the integrity of the vessel's basement membrane and acellular matrix.<sup>39</sup>

Although not proven to be necessary for successful clinical outcome or to prevent alloimmunization, ABO- and Rh-compatible allograft valves and vessel conduits are usually requested. One recent case series, involving limb salvage utilizing allograft saphenous veins, showed significantly better results in cases with ABO blood-type compatibility.<sup>43</sup> Some studies have shown that the use of these tissue allografts carry a risk of HLA antigen sensitization.<sup>44</sup>

### **Peripheral nerves**

Fresh autografts of peripheral sensory nerves are used in nerve repair, but this practice is hampered by collection morbidity and resulting limitations on the amount of autologous nerve tissue that can be made available. Although allografts ideally might repair peripheral nerve defects without requiring the sacrifice of the patient's own nerve, frozen, irradiated, and lyophilized allografts have not functioned well. New animal studies using nerve allografts cold-preserved for seven weeks have shown promising results, as have cultured Schwann cells added into synthetic conduits.<sup>45</sup> Axogen, Inc. (Alachua, FL), has developed a thermally decellularized nerve allograft scaffold called Avance that is treated with chondroitinase in order to degrade chondroitin sulfate proteoglycan. Such grafts have been shown to inhibit both aberrant growth and retrograde regeneration in the absence of any immunosuppressive therapy. Animal studies employing such an approach demonstrated enhancement of nerve regeneration. The first human Avance nerve allograft was implanted in 2007 into a 38-year-old man who had suffered a traumatic facial nerve injury; a single nerve allograft was used to connect the severed facial nerve root to three nerve branches. The surgeons informally reported that the graft's handling characteristics were superior to those of autograft tissue.<sup>2</sup>

### **Extraembryonic tissue preservation and transplantation**

Extraembryonic tissues that have been used occasionally for transplantation include the amnion and the umbilical vein. Amnion, which is the smooth, slippery, glistening membrane lining the fluid-filled space surrounding the fetus, has been used as a covering for nonhealing chronic leg ulcers, burns, and raw surfaces following mastectomy, and in major oral cavity reconstruction and vaginoplasty. Amnion has also been used as a pelvic peritoneum substitute following pelvic exenteration and as a source of replacement enzymes

for infants with inborn errors of metabolism.<sup>46</sup> Most of the fetal amnion is covered on the maternal side by the chorion, a slightly roughened membrane. Amnion is collected under sterile conditions during cesarean section. The amnion's epithelium and basement membrane can be separated by blunt dissection from the underlying chorion immediately after collection or after temporary storage. The amnion is then cryopreserved or lyophilized. Human umbilical vein allografts previously were used occasionally as vascular substitutes to provide venous access for hemodialysis or as an arterial bypass graft, but such allografts proved to be inferior to saphenous vein autografts. Such umbilical vein grafts are no longer available, following application of FDA device manufacturing requirements to their recovery and processing.

### **Tissue autograft collection, storage, and use**

Tissue autografts, tissue recovered from a patient's own body, are utilized in many surgical reconstruction procedures. Autologous grafts have certain benefits and costs to the recipient when compared to use of tissue allografts. Some benefits ascribed to autografts include faster incorporation/healing and relative safety from transmission of viral disease or immunologic rejection.<sup>47</sup> Conversely, certain costs include morbidity associated with an additional surgical procedure, as well as pain and potential surgical-site infection. Further, the tissue integrity and quantity of autologous tissue may not be adequate for the intended use, and the removal of the patient's tissue may adversely affect function at the site of removal from which it was extracted.

FDA has exempted, with a few exceptions, the collection, storage, and use of autologous tissues. These require that the autograft (1) must be used in the *same surgical procedure* and (2) must be *minimally manipulated*.<sup>48</sup>

The same FDA rule applies to surgical procedures such as removal of the tissue and subsequent use within the same individual within a single operation or a staged follow-up surgery, where removal and implantation may be separated by several days but are technically considered part of the same surgical procedure. The following include examples of types of procedures: skin grafting, coronary artery bypass surgery utilizing autologous vessels, cranioplasty, and parathyroidectomy with implantation.<sup>47</sup>

Minimal manipulation allows exceptions for tissues that are maintained in their original form and include steps such as rinsing, cleansing, sizing, and shaping. A facility that removes the autologous tissue, which is intended to be shipped to a different facility for autologous use, does not qualify for the FDA exemption except under limited circumstances in order to accommodate the medical needs of an individual patient, which commonly occurs with cranial-flaps removed at one facility and the return of the flap to the patient occurs at another facility.<sup>48</sup> Contraindication to autograft use is in the context of patients with systemic infections or if the tissue is in close proximity to an area of infection. Autografts may be stored at the medical facility where they are collected or with same organization off-site.<sup>47</sup>

### **Oversight, tracking, and traceability of human tissues**

#### **Oversight**

With the rapid growth of all areas of tissue banking, there has been an increasing need for accountability and for measures that ensure that safe, quality tissues are recovered, processed, and available for

clinical use. Quality improvement can be affected through voluntary standards, and most tissue banks have incorporated the achievement of high standards into their goals. The American Association of Tissue Banks (AATB) has established comprehensive standards for donor screening, recovery, and processing of musculoskeletal, cardiac, vascular, and skin tissues, birth tissue, and reproductive cells.<sup>5</sup> Additionally, the standards contain institutional requirements; descriptions of required functional components of a tissue bank; requirements for construction and management of records and development of procedures; requirements for donor authorization and informed consent, tissue labeling, storage, and release; expectations for handling adverse outcomes, investigations, and tissue recalls; requirements for establishment of a quality program; specifications for equipment and facilities; and guidelines for tissue dispensing services and tissue distribution intermediaries. AATB's *Standards for Tissue Banking* are consulted not only by tissue bankers, but also by end-user health-care facilities, other standard-setting organizations, and regulators worldwide. Best practice for checking a tissue bank's accreditation status is to perform an accredited bank search on the AATB website ([www.aatb.org](http://www.aatb.org)).

AABB *Standards for Blood Banks and Transfusion Services*<sup>49</sup> address tissue inspection, handling, storage, preparation and dispensing, handling adverse events, and recordkeeping, which must provide traceability to each recipient or other disposition. The Joint Commission has standards for storage and issuance of tissue for hospitals and ambulatory surgery centers. These standards apply to bone, tendon, fascia, and cartilage, as well as cellular tissues of both human and animal (xenograft) origin. The standards address key functions, including the need to develop procedures for tissue acquisition and storage, recordkeeping and tracking, and follow-up of adverse events and suspected allograft-caused infections, which must be reported to the tissue bank from which the tissue was obtained. Similar to federal regulations and AATB *Standards*, the minimal record retention period is specified to be 10 years from the date of transplantation, distribution, other disposition, or expiration, whichever is latest. The College of American Pathologists' Laboratory Accreditation Program's Transfusion Medicine Checklist also includes several questions on storage and issuance of tissues, including accountability; procedures for proper storage, handling, in accordance with the source facility's directions; procedures for investigating recipient infections and adverse events, and handling look-back notifications from a supplier; and recordkeeping, which allow for tracking from donor to recipient and vice versa.

FDA authority to create and "enforce regulations necessary to prevent the introduction, transmission, or spread of communicable diseases between the States or from foreign countries into the States" under section 361(a) of the US Public Health Service Act (42 USC 264) applies to human tissue intended for transplantation. Formal enforcement policy and regulations did not exist until 14 December 1993 (codified in 21 CFR Parts 16 and 1270), when the "Interim Rule: Human Tissue Intended for Transplantation," which required donor screening, infectious disease testing and record-keeping "to prevent transmission of infectious diseases through human tissue used in transplantation," was adopted in response to reports of HIV transmission by human tissue and of potentially unsafe bone imported into the United States.<sup>50</sup>

These regulations were supplanted by a series of federal regulations, published in stages, first announced in the Proposed Approach to the Regulation of Cellular and Tissue-Based Products in March 1997.<sup>51</sup> A final rule, "Human Cells, Tissues, and Cellular and Tissue-Based Products: Establishment Registration and

Listing," published in January 2001, required organizations that are engaged in tissue recovery, donor qualification, tissue processing, and/or tissue-related laboratory testing to register as a tissue establishment with the FDA. The rule (21 CFR Part 1271) became effective for all tissue banks on 29 March 2004.

A final rule, "Eligibility Determination for Donors of Human Cells, Tissues, and Cellular and Tissue-Based Products," published on 25 May 2004, set forth donor eligibility requirements, including health history screening and laboratory testing. Another final rule, "Current Good Tissue Practice for Human Cell, Tissue and Cellular and Tissue-Based Product Establishments; Inspection and Enforcement," published on November 24, 2004, established elements of good tissue practice, analogous to good manufacturing practice for blood banks. Both rules became effective from 25 May 2005.<sup>48</sup>

In addition to requirements for establishment registration, donor eligibility screening and testing, and good tissue practice, the regulations set forth requirements for adverse reaction reporting and also define inspection and recall authority. To improve tissue safety and surveillance, the FDA Current Good Tissue Practice Rule, effective from 25 May 2005, requires that tissue establishments report infectious adverse events after allograft transplantation to the FDA through its MedWatch adverse event reporting system. More than half of the reports filed by tissue banks have been flagged to indicate possible recall of tissue(s). Of these flagged reports, the majority pertained to acceptance of ineligible donors for whom one or more components of the donor qualification process was not performed or was insufficiently documented. The FDA also encourages health-care professionals, patients, and consumers to voluntarily report tissue adverse reactions through the MedWatch system (see <http://www.fda.gov/Safety/MedWatch>).<sup>2</sup>

## Donation tracking

Each tissue bank assigns identification for each individual tissue, but assigned numbers are often unique only for the tissue bank issuing them. Because a typical numbering system is often based on year followed by sequence of recovery, numbers assigned between tissue banks may overlap so that tissues may have the same number from the same donor between tissue banks, which may create confusion and redundancy.<sup>52</sup> Systems using bar codes feature standardized approaches to numbering, may contain more details about the tissue (e.g., tissue processor, product description, and unique tissue identifier), and allow for health-care facilities to read the code. FDA requires use of coding to identify tissues but is agnostic on what coding system to use. Thus, coding used for tissues is fragmented in the United States. Apart from individual tissue bank coding, standardized systems include ISBT-128, GS-1, and HIBCC. However, ISBT-128 is the only major coding system designed specifically for biologics and is recognized by WHO as the sole global standard for the identification of medical products of human origin.<sup>53</sup> GS-1 is more commonly used in hospitals and more optimized for devices and other items with manufactured lots.<sup>54</sup>

The Veterans Affairs department has attempted to improve tissue tracking in their facilities, and now require their vendors to have ISBT-128 coding on tissues through the Strategic Acquisition Center. An OIG report outlines the challenges faced by tissue tracking in VA health-care facilities.<sup>55</sup>

The lack of donor identifier can be challenging in the event of a recall, when rapid confirmation on the location and implant status of tissue from the same donor or same processing period is paramount. This has been a barrier in past public health investigations.<sup>56</sup>

Currently, “tissue trace cards” are issued by processors to confirm that a tissue was implanted, with patient and surgeon information written onto the document and voluntarily sent back to the processor. However, there is no requirement that a standardized set of information be placed into the patient medical record.

An attempt was made to create a system for tracking and reporting of adverse events through a common donor identifier and monitoring of outcomes from the same donor (Transplantation Transmission Sentinel Network, a cooperative agreement between UNOS and CDC), but the project did not advance beyond the pilot phase.<sup>57</sup>

### Hospital-based tissue services

Hospital transfusion services have been greatly affected by transplantation, and have encountered new and increased demands for services. This stems from The Joint Commission requiring organizations to assign oversight responsibility for their tissue transplantation program, use standardized procedures in tissue handling, maintain traceability of all tissues, and have a process for investigating and reporting adverse events.<sup>58</sup>

Hence, the hospital transfusion service has become involved in transplantation in several ways, including (1) providing traditional blood components; (2) providing new or special blood components; (3) taking responsibility for tissue acquisition, storage, distribution, and tracking; and (4) providing specialized services. For organ transplants, the major demand is for traditional blood components, although special preparation may be required.

FDA regulations pertaining to tissue (see below) cover donor selection and testing, tissue recovery, processing, storage, labeling, and distribution to the “consignee.”<sup>48</sup> The consignee can be a distributor, a surgeon in a hospital operating room, a dentist in his or her office, or a designated individual or department in a hospital or other health-care institution. Tissue “banks” that are located in hospitals are not regulated by the FDA if they serve only to store and dispense tissues provided by comprehensive tissue banks or distributors. A hospital tissue service can be centralized in a support area for the operating suite, hospital central supply service, or hospital transfusion service.

Alternatively, tissues can be handled using a decentralized system and be ordered, received, and stored by each functional area of the hospital in which they are used. However, in the absence of centralization, records of storage and recipient identification may be inadequate. In one case involving an HIV-infected donor, the recipients of five of the tissues could not be identified from hospital records. Other examples of inadequate traceability exist.<sup>59</sup> The Joint Commission standard<sup>58</sup> on recordkeeping and traceability of tissues, College of American Pathologists Transfusion Medicine Checklist,<sup>60</sup> and AABB Standards for Blood Banks and Transfusion Services<sup>49</sup> require that the institutions’ records permit tracing of any tissue from the donor or source facility to all recipients or other final tissue disposition. However, the New York State is the only government regulatory agency that requires tracking of tissues to the recipients with records kept separate from patient charts.

The hospital transfusion service has the capacity, experience, and skills to act as a central depot and distribution point for all human tissue and to ensure that storage, issuance, and disposition records are maintained. Functions include allograft selection; vendor qualification and price negotiation; receipt of tissues, including inspection and accessioning; proper storage; inventory control; issuance; and recordkeeping, which must ensure traceability to recipient or other disposition; promotion of tissue recipient informed consent;

and assurance that allograft tissue preparation steps (i.e. instructions for use) are followed and documented.<sup>61</sup> Recordkeeping, especially if barcodes are used in the laboratory, is complicated by the fact that barcodes are not yet standardized among tissue banks, although adoption of ISBT 128 labeling standards has been suggested.<sup>62</sup> An additional challenge is that some tissues are produced in lots or batches, so each individual unit may not carry a unique identifier. Effective development of such tissue storage and distribution services takes time and relies on good relationships and communications with both operating room staff who will handle tissues and the surgeons who use them.<sup>61</sup>

A transfusion service operating as a central tissue repository and dispensing service may also be called upon to manage autologous tissues, such as calvaria (skull bone flaps), bone, skin, and parathyroid gland. Such tissues may require preparation and packaging before storage. Testing is not required, but careful labeling and recordkeeping are essential. Such tissues may ultimately be reimplanted in the original location (e.g., calvaria) or in a heterotopic location (e.g., limbs for parathyroid gland). It is prudent to establish time limits for storage either on an individual basis as specified by the surgeon or on a generalized basis because stored tissues may not be claimed if the tissue was not needed because the patient died or for other reasons. The tissue dispensing service may also be called upon to package tissues in an appropriate, qualified, properly labeled transport container for transport to another institution.<sup>61</sup>

### Quality and safety measures

Unlike the system implemented for organ procurement, tissue banking is not formally organized based on defined geographic areas, and there is direct competition between tissue banks for processing. Both non-profit and for-profit tissue organizations exist, including over 120 tissue establishments accredited by AATB.<sup>3</sup> The vast majority of tissue recovered in the US is performed by organ procurement organizations for distribution by tissue processors (referred to as tissue banks). Processors independently perform donor eligibility assessment, even if the recovery partner has already performed such steps. Eye banks are organized in a separate system, and approximately 69 organizations are accredited by the Eye Bank Association of America.<sup>4</sup> Although in the past a number of blood centers have provided tissue processing and banking, few have continued to offer these combined services.

Procedures to assure high-quality and safe allografts are guided by national professional standards set by organizations such as AATB, EBAA, AABB, and the American Society for Reproductive Medicine. Some states require additional standards.<sup>63</sup>

Tissue donors are carefully evaluated to assess for both safety and quality. This assessment is performed through information obtained (1) during interviews with family members, significant others, and health-care providers; (2) available medical records; (3) findings on physical assessment; (4) results of autopsy, including toxicology, if performed; and (5) results of laboratory tests for infectious diseases.

General donor eligibility criteria include the absence of significant infection or sepsis, and any evidence of risk factors for a list of conditions FDA terms “relevant communicable disease agents or diseases (RCDADs).<sup>64</sup> This requires evaluation for disease conditions such as HIV, hepatitis B, and hepatitis C, which have been known to be transmitted through tissue transplantation, and may be a risk despite laboratory test screening, particularly for acute infection. In an effort to improve the uniformity of the donor history, a standardized questionnaire has been developed by multiple

organizations collaboratively, led by AATB.<sup>65</sup> Physical assessment seeks evidence consistent with risk for infectious diseases or quality of the tissues being recovered.

Beyond FDA guidance and voluntary organizational standards, many tissue processors have criteria above and beyond the minimum to address both safety (e.g., history of malignancy) and quality (e.g., advanced age, history of autoimmune disease, organ failure, and long-term diabetes). Donors of reproductive tissue are additionally screened for inherited diseases. Placental tissues are specifically screened for history of genital infections such as HPV. Both placental and dermis tissues may be rejected if discolored by meconium or bilirubin, respectively.

Tissues are collected aseptically in an operating room, autopsy room, or other suitable locations where aseptic recovery can be performed. Recovery methods are described in AATB guidance.<sup>5</sup> Tissues are cultured by swabbing directly or through a sample of transport solution. There may also be additional cultures done during processing and after processing to provide evidence of sterility.

Infectious disease laboratory testing is performed where screening of serum or plasma samples has specifically been approved for cadaveric tissue donation (Table 58.3). Laboratory methods include the use of antibody, antigen, and nucleic acid testing. The list of required tests is relatively small, and some are done only seasonally (WNV), while screening may depend on travel history (Zika, CJD). Hemodilution may be an issue for laboratory sensitivity if the donor was heavily transfused. In addition, the testing of post-mortem samples may be complicated by hemolysis or presence of inhibiting factors that can cause false-positive results in some assays. Tests on living donors are subject to different issues and must be performed as close to recovery as possible to avoid false-negative results.

### Tissue processing

A variety of methods, including chemical treatments and irradiation, have been used to reduce or eliminate pathogens in tissue intended for transplantation.<sup>2</sup> Tissue sterilization is defined as the killing or elimination of all micro-organisms from allograft tissue, whereas disinfection refers to the removal of microbial contamination. Sterility assurance level (SAL) is the probability that an individual device, dose, or unit is nonsterile (i.e., one or more viable micro-organisms being present) after it has been exposed to a validated sterilization process. SAL is generally applied only to the level of possible contamination with bacteria or parasites, and does not include viruses or prions. Furthermore, standard terminal

sterilization does not substantially affect viability of prions. In contrast to log reduction of viruses determined in assessments of virus reduction methods, SAL is an absolute determined by the ability of the method to eradicate or reduce micro-organisms, the susceptibility of organisms that may be present to the sterilization method applied, and the maximal bioburden that could occur in the initial material. For example, an SAL of  $10^{-6}$  means that there is less than a 1 in 1,000,000 chance of a viable micro-organism remaining after the sterilization procedure. The FDA requires that medical devices be sterilized using a method validated to achieve an SAL of  $10^{-6}$ . A medical device derived from or that includes a biological product component must also meet an SAL of  $10^{-6}$  if it is to be labeled sterile. Human tissue is different from a device in terms of its ability to withstand harsh processing methods. The initial bioburden, which may be high in some tissues, also must be considered. Many tissues are unable to withstand the harsh treatment needed to achieve a more restrictive SAL without an impairment of tissue function. Such tissues may not then be labeled as sterile.

The complex physical structures and density of musculoskeletal tissues pose challenges for adequate penetration of antimicrobial agents to eradicate micro-organisms. Allografts will not tolerate methods usually applied to metal and plastic medical devices because such treatment would impair the mechanical and biologic properties necessary for clinical utility. As an alternative, sterilization of tissues has been accomplished by several methods, including heat, chemicals, ethylene oxide gas, supercritical CO<sub>2</sub>, and gamma or electron beam irradiation. However, not all of these methods have adequate tissue penetration. Some tissues are treated with antibiotics *in vitro* before storage, but this treatment decontaminates only the surface and may be effective against bacteria only.

A variety of methods, including chemical treatments and irradiation, have been used to reduce or eliminate pathogens in tissue intended for transplantation.

First introduced over 40 years ago,  $\gamma$ -irradiation of bone is still used widely, usually employing a cobalt-60 source. The  $\gamma$ -rays penetrate bone effectively and work by generating free radicals, which may have adverse effects on collagen and limit utility in soft tissues unless performed in a controlled dose fashion at ultralow temperature. The minimal bacteriocidal level of  $\gamma$ -irradiation is 10–20 kGy (1 kGy = 100,000 rad).

Concerns about pathogen transmission and the limitations of irradiation, especially for soft tissues, have prompted improvements in sterilization methods and in the validation of these methods. It should be noted that FDA does not have a standard for tissue processing or sterilization for HCT/Ps, but simply requires that tissue processors have a validated reproducible method for ensuring prevention of transmission of relevant communicable diseases as outlined in guidance.

A number of proprietary chemical-based processing methods have been developed with aims of effectively penetrating tissues and reducing, killing, or inactivating micro-organisms and viruses without unacceptable adverse effects on the tissue's biomechanical properties. Additionally, for use in transplantation, the agents must either be able to be effectively removed or be nontoxic. All methods in current use are applied only to tissue from donors who have met stringent criteria for medical history and behavioral risk assessment, as well as negative results on infectious disease marker testing.

### Need for surveillance

Despite a careful donor selection process, the risk of donor-to-recipient transmission of viral, bacterial, fungal, and prion diseases

**Table 58.3** Relevant Communicable Disease Agents or Diseases (RCDAD) for Human Cells, Tissues, and Cellular and Tissue-Based Products (HCT/Ps)

HIV*
Hepatitis B virus*
Hepatitis C virus*
Transmissible spongiform encephalopathies, including Creutzfeldt–Jakob disease
<i>Treponema pallidum</i> (syphilis)*
HTLV-I, II* (for leukocyte-rich cells or tissues only)
<i>Chlamydia trachomatis</i> * (for reproductive cells or tissues only)
<i>Neisseria gonorrhoeae</i> * (for reproductive cells or tissues only)

cannot be completely eliminated (Table 58.4).<sup>15,66</sup> Because of the sheer number of tissues recovered from one donor, the consequences of transmission from an infected donor are amplified in this setting, similar to processed plasma donors, with many products recovered from a single donor. However, unlike plasma, tissues recovered from the same donor may be processed differently, leading to different risks of transmission. Transmitted infections can occur despite both a robust evaluation of donor history and laboratory testing, particularly for any grafts with minimal processing or containing viable cells.

Serology (antibody testing) was the first laboratory screening tool developed to detect donor infection, but has limited sensitivity in the early phase of incubation due to the “window period” in detection. HIV was the first well-publicized example of laboratory failure due to the window period of antibody. In 1985, 48 organ or tissue recipients received an organ or tissue from a single donor who, although without apparent risk for HIV infection according to medical history, proved to have been recently infected with HIV and in the window period before HIV-1 antibody could be detected by the assays in use at the time (October 1985).<sup>66</sup> All four organ recipients became infected with HIV, but the majority of tissue recipients did not. Whole unprocessed frozen bone did transmit HIV to three recipients, whereas bone from which the marrow had been removed did not; transplanted corneas, lyophilized soft tissue, and  $\gamma$ -irradiated dura mater also did not transmit the virus. In addition, this case additionally served to highlight vulnerabilities associated with inadequate disposition records, given that six recipients could not be identified from hospital records.

The window period of serology remained an ongoing challenge in the setting of acute infection of the donor. In 2002, tissue from a man with no identifiable infectious disease risk by history or physical examination, and a negative test for anti-HCV, was found to have transmitted HCV to recipients.<sup>67</sup> All organ recipients who could subsequently be tested were found to be infected with HCV. Among 32 tissue recipients, five probable cases occurred: one of two saphenous vein recipients, one of three tendon recipients, and

three of three recipients of tendon with bone allografts. No cases occurred in recipients of skin, cornea, or irradiated bone. All eight recipients whose infection was linked to the transplant were determined to be infected with the same HCV genotype. With the implementation of nucleic acid testing, first for HIV and HCV, and then for HBV, the current risk of viral transmission is thought to be exceedingly low.<sup>68,69</sup> A combination of stringent donor selection, testing strategies that now include both antibody and NAT, and processing methods now in use that reduce the risk for tissues, particularly for those forms not requiring viable cells, transmission risk is as low as it has ever been.

Since the implementation of NAT for tissue donor screening, there has been one high profile transmission of HCV in 2011. The HCV positive donor, which was not detected due to a testing error, transmitted the virus to two organ recipients (a third having been infected with HCV previously). A total of 44 tissue grafts were recovered, with 16 grafts, including 15 musculoskeletal tissues and 1 cardiovascular patch, transplanted. The cardiovascular patch transmitted HCV, which was the only tissue not treated with chemicals or by irradiation.<sup>70</sup>

West Nile virus has been transmitted through organ transplantation and blood transfusion,<sup>71</sup> but transmission through tissue has not been recognized. *Trypanosoma cruzi*, the etiologic agent of Chagas’ disease, has been transmitted through solid organs but transmission of parasitic diseases through vascular tissue allografts has not been reported, but is considered to be possible, particularly for minimally processed grafts.<sup>72</sup>

One poorly understood risk in the solid organ transplant setting is when arteries or veins are recovered from a different donor than a recovered organ, and may be used for a transplant, particularly liver, if the donor and/or recipient vessels are damaged or insufficient. Although such vessel grafts associated with organ transplantation are not considered regulated HCT/Ps by the FDA, such grafts caused documented transmission of rabies in 2004, and have been implicated in hepatitis B and C transmission.<sup>73,74</sup>

Transmission of malignancy via tissue transplantation has not been reported, but is thought to be possible, particularly in fresh, minimally processed grafts with viable cells, where infectious disease transmission has been recognized, such as fresh femoral head collected during hip arthroplasty.<sup>15</sup>

Although most disease transmission reported has involved deceased donors, infectious diseases can also be transmitted through transplantation of tissue from living donors. Cases are well documented in the semen banking arena with a variety of agents and diseases having been transmitted to semen recipients. Human immunodeficiency virus type 1 (HIV-1) has been transmitted both by unrelated donors and from husband to wife. This virus has the greatest number of reports of transmission. Hepatitis B virus (HBV), gonorrhea, *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Trichomonas vaginalis*, *Chlamydia trachomatis*, group B *Streptococcus*, and herpes simplex virus type 2 (HSV-2) have also been reported. Transmission of HCV and human T-cell lymphotropic virus type 1 (HTLV-1) is likely, and the transmission of cytomegalovirus, human papilloma virus (HPV), and syphilis is a possibility.<sup>75</sup>

Transmission of bacteria is a known risk of tissue transplantation. Bacteria can be present in the donor, either as a normal occurrence or as the result of a disease process or medical intervention.<sup>15</sup> Resuscitation efforts can increase the dispersion of such organisms. In addition, “agonal bacteremia” is a well-known process whereby endogenous bacteria, such as normal intestinal flora, begin to

disperse throughout the body after cessation of cardiopulmonary functions, as the putrefaction process begins. This process is accelerated in persons with sepsis, rhabdomyolysis, or drug overdose before death.<sup>15</sup> Bacteria can be introduced during tissue recovery; during processing, whether through cross contamination, insufficient aseptic technique, or contaminated chemicals or solutions; or even during packaging. Some tissues, including ocular tissue, epidermis, and semen, are inherently not sterile even if collected aseptically.

At particular risk for transmission of bacteria are tendon allografts used in orthopedics because these cannot be subjected to extensive processing if their mechanical properties are to be preserved. In 2001, a 23-year-old man was found to have died from *Clostridium sordellii* sepsis following receipt of a femoral condyle allograft. An extensive investigation identified 14 patients who had received allografts between 1998 and 2002 and who developed postoperative infections with *Clostridium* species.<sup>15,76</sup> The tissues were derived from nine donors, but all were prepared by the same processor, and investigation identified several factors that could have contributed to the infections. Although the tissues were cultured, they had already been suspended in antimicrobial solutions, likely leading to false-negative results. Additionally, for two of the donors, including the donor of the tissue that was implicated in the fatal case, the interval between death and refrigeration of the body (19 hours for the donor in the fatal case) exceeded the industry's voluntary standards at the time of 15 hours maximum without refrigeration of the deceased donor. This likely permitted excessive bacterial proliferation prior to tissue recovery. In addition, tissue was processed aseptically without the use of terminal sterilization, and the processing methods used had not been validated. Human error can also lead to release of contaminated tissues. In one case, a technician failed to follow standard procedures, resulting in release of tissue labeled as having been subjected to irradiation when, in fact, no irradiation had occurred.<sup>77</sup> Although a wound infection in a tissue recipient, or even disseminated bacteremia, does not necessarily implicate the donor tissue, any unusual organism or cluster of infections associated with grafts recovered from the same donor should be investigated promptly. Site infections are a well-known risk of many surgical procedures and can result from the use of contaminated solutions or equipment insufficiently sterilized between procedures.<sup>78</sup>

Placental tissues are increasingly used in a variety of settings as a wound covering and undergo a wide range of processing, from minimal to sterilized through chemical or radiologic means. In 2017, *Mycoplasma hominis* was documented to be transmitted through a minimally processed amniotic product. After a report of a cluster of surgical site infections associated with the use of a common product, an investigation revealed *M. hominis* infections confirmed in 2 recipients of implants out of 14 patients, and 2 unopened vials of the amniotic product that were cultured also grew the organism. Sequences were identical in isolates from these two unopened vials and patient cultures. Also commented on was the lack of a standardized system to track tissue products in health-care facilities, limiting the ability of public health agencies to respond to outbreaks and investigate other adverse events associated with these products.<sup>79</sup>

### **Adverse event monitoring—role of the hospital-based tissue bank**

Inherent risk of human-derived medical products, such as tissue allografts, must be balanced with the clinical benefits when transplantation of tissue is undertaken. Rarely, human tissue allografts

have transmitted disease by bacteria, viruses, and fungi, and prion disease (dura mater only). Other risks are noninfectious in nature and may pertain to the integrity of the graft itself or processing done after recovery resulting in structural weakness that can lead to an unsuccessful outcome.

Hospital-based tissue services are required, by the TJC to have procedures to investigate, in an acceptable timeframe, any adverse outcome suspected to be caused by a tissue allograft. Furthermore, once an investigation begins at the hospital, it is incumbent upon the hospital, under TJC standards, to immediately report allograft-transmitted infections and other severe adverse events that may have occurred to the tissue supplier.

Surgeons and end users play a critical role in identifying allograft-associated adverse outcomes and must notify the hospital-based tissue service immediately when they suspect such events. Prompt adverse event reporting aids the hospital-based tissue service to investigate the root cause, report the issue to the tissue supplier, and implement corrective action, including quarantine of any other suspect allografts. In addition, tissue-associated adverse events may also be voluntarily reported via MedWatch to the FDA, but the reporting person should be aware that FDA regulation is focused on if an infection is suspected to have been caused by the tissue allograft not on a graft integrity adverse event. Cooperation is key between the hospital-based tissue service, clinicians, and the tissue supplier when investigating adverse events. Reporting the serial number of the graft with the report is critical for further investigation by the tissue bank. The hospital infection-control department or an infectious disease specialist should be linked via protocol and/or procedure to this process. The earlier the notification, the better this can help prevent complications in other potential recipients of allografts implicated by this same donor or other tissue donors.<sup>47</sup>

Another requirement is via state health departments that have lists of communicable diseases that must be reported when they are newly diagnosed. Examples consist of new diagnoses of HIV or viral hepatitis in a tissue allograft recipient where the allograft is suspected as a possible source. Additionally, it is suggested that an epidemiologic investigation may be necessary to trace the tissue allograft to determine the source of the recipient's infection.<sup>47</sup> One resource that contains a database of notable infectious disease transmission and process errors has been developed by the World Health Organization and the Italian National Transplant Centre as its collaborating center.<sup>80</sup> The website features a searchable website that allows for review of the spectrum of adverse events that can occur from transfusion and transplantation, including infectious diseases transmitted through tissue transplantation, and details on risk factors and outcomes.

### **Recalls and look-back investigations**

Suppliers notify hospital-based tissue banks about product recalls and market withdrawals (i.e., field action) when tissues are deemed, by their criteria, compromised. This may encompass, tissue suppliers sequestering tissue in inventory not yet distributed, recall of all tissues belonging to a specific donor or lot, or direct notification to a hospital of a specific affected allograft received. The recall nature usually dictates next steps, but customarily the hospital would first quarantine allografts in inventory (if not yet implanted), identify recipients (if already implanted), and/or notify the transplanting surgeon(s) of the hospital-based tissue service notification. The responsibility of the surgeon would be to evaluate the circumstances and notify, if appropriate, each recipient receiving a recalled or withdrawn tissue graft.

A look-back investigation is when a tissue donor is discovered after donation of tissue to have a communicable disease that is known to be transmitted by tissue graft transplantation. The type of infections include, but are not limited to, HIV, human T-cell lymphotropic virus type I or II, HBV, and HCV. Tissue graft infectious transmission is an uncommon occurrence, but requires investigation, or other communicable disease known to be transmitted by tissue grafts.<sup>47</sup>

### **Reimbursement**

Reimbursement for tissue transplantation is similar to that for blood transfusion. The tissue bank recovers expenses through a service fee (per tissue) billed to the hospital. This service fee includes such costs as services rendered by the organ/tissue recovery agency; recovery supplies and logistical support of the recovery agent that may be provided by the tissue processor; the tissue processor's operating costs associated with processing, storage, and distribution, as well as research and development; and overhead costs incurred with support of all operations. Health-care insurance carriers reimburse hospitals for most tissue service fees. Current procedural terminology codes specific to allograft transplantation procedures are available and used routinely.<sup>2</sup>

### **Conclusion**

Tissue donation is a gift, and those who donate must be honored for this act of altruism through responsible stewardship. Part of honoring and respecting donors is to ensure there is safety and quality applied to the process of tissue recovery, processing, packaging, and implantation of the various types of tissues to maximally benefit multiple recipients. From donor to recipient, the stewardship of this process lies in a path from the tissue suppliers to health-care providers, connected by the hospital-based tissue bank. Medical directors in both arenas must continue to ensure that processes, as described in this chapter, are in place to have reliable traceability and trackability from tissue recovery to implantation, allowing rapid feedback to the tissue supplier in case there is a problem with

that tissue. Infectious and noninfectious hazards are critically important to report and trace as they may impact multiple recipients, and the more robust the system of traceability, the more rapidly affected tissue can be located and assessed. Human tissue has the potential to save and heal millions of lives each year, when recovered, processed, tracked, and used in a responsible way.
