

## **Rossi's Principles of Transfusion Medicine**

# **Rossi's Principles of Transfusion Medicine**

## **Sixth Edition**

---

**Edited by**

### **Toby L. Simon, MD**

Senior Medical Director, Plasma and Plasma Safety, CSL Plasma, Boca Raton, FL, USA;  
and Clinical Professor of Pathology, University of New Mexico School of Medicine, Albuquerque, New Mexico, USA

### **Eric A. Gehrie, MD**

Executive Physician Director of Direct Patient Care and Emerging Cell and Gene Therapy Solutions, American Red Cross,  
Baltimore, Maryland, USA

### **Jeffrey McCullough, MD**

Professor Emeritus, University of Minnesota Medical School, Minneapolis, Minnesota, USA

### **John D. Roback, MD, PhD**

Professor of Pathology and Laboratory Medicine; Director, Center for Transfusion and Cellular Therapy,  
Department of Pathology & Laboratory Medicine, Emory University School of Medicine, Atlanta, Georgia, USA

### **Edward L. Snyder, MD, FACP**

Professor, Department of Laboratory Medicine, Yale University School of Medicine;  
Blood Bank/Apheresis Service, Yale-New Haven Hospital, New Haven, Connecticut, USA

*Limit of Liability/Disclaimer of Warranty*

The contents of this work are intended to further general scientific research, understanding, and discussion only and are not intended and should not be relied upon as recommending or promoting scientific method, diagnosis, or treatment by physicians for any particular patient. In view of ongoing research, equipment modifications, changes in governmental regulations, and the constant flow of information relating to the use of medicines, equipment, and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each medicine, equipment, or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. While the publisher and authors have used their best efforts in preparing this work, they make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation any implied warranties of merchantability or fitness for a particular purpose. No warranty may be created or extended by sales representatives, written sales materials or promotional statements for this work. The fact that an organization, website, or product is referred to in this work as a citation and/or potential source of further information does not mean that the publisher and authors endorse the information or services the organization, website, or product may provide or recommendations it may make. This work is sold with the understanding that the publisher is not engaged in rendering professional services. The advice and strategies contained herein may not be suitable for your situation. You should consult with a specialist where appropriate. Further, readers should be aware that websites listed in this work may have changed or disappeared between when this work was written and when it is read. Neither the publisher nor authors shall be liable for any loss of profit or any other commercial damages, including but not limited to special, incidental, consequential, or other damages.

*Library of Congress Cataloging-in-Publication Data*

Names: Simon, Toby L., editor. | Gehrie, Eric A., editor. | McCullough, Jeffrey, 1938- editor. | Roback, John D., 1961- editor. | Snyder, Edward L. (Edward Leonard), 1946- editor.

Title: Rossi's principles of transfusion medicine / edited by Toby L. Simon, Eric A. Gehrie, Jeffrey McCullough, John D. Roback, Edward L. Snyder.

Other titles: Principles of transfusion medicine

Description: Sixth edition. | Hoboken, NJ : John Wiley & Sons, Ltd, 2022.

Identifiers: LCCN 2021056451 (print) | LCCN 2021056452 (ebook) | ISBN 9781119719755 (cloth) | ISBN 9781119719786 (adobe pdf) | ISBN 9781119719793 (epub)

Subjects: MESH: Blood Transfusion | Blood Cells | Blood Grouping and Crossmatching | Transfusion Reaction

Classification: LCC RM171 (print) | LCC RM171 (ebook) | NLM WB 356 | DDC 615.3/9-dc23/eng/20220107

LC record available at <https://lccn.loc.gov/2021056451>

LC ebook record available at <https://lccn.loc.gov/2021056452>

Cover Design: Wiley

List of contributors, vii

Preface, x

List of abbreviations, xi

About the companion website, xxii

## Section I: Transfusion medicine from ancient times to the current pandemic

- 1** Transfusion in the new millennium, 3  
*Ennio C. Rossi and Toby L. Simon*

- 2** Disasters and the blood community (including COVID-19), 14  
*Ruth Sylvester and Louis M. Katz*

- 3** Responding to regulatory challenges during public health emergencies, 21  
*Peter W. Marks*

## Section II: Blood donation

- 4** Recruitment and screening of donors and the collection of blood, 27  
*Susan N. Rossmann, Mary Townsend, and Toby L. Simon*

- 5** Blood donor testing, 37  
*Nancy Van Buren and Jed B. Gorlin*

- 6** Acute adverse reactions after blood donation, 49  
*Anne F. Eder*

- 7** Chronic effects of blood and plasma donation, 56  
*Bryan R. Spencer and Toby L. Simon*

- 8** Global perspective: ensuring blood and blood product safety and availability through regulation and certification, 65  
*Eva D. Quinley*

## Section III: Blood groups and pretransfusion testing

- 9** Carbohydrate blood groups, 81  
*Laura Cooling*

- 10** Rh and LW blood group antigens, 100  
*Aline Flock, Don L. Siegel, and Connie M. Westhoff*

- 11** Other protein blood groups, 109  
*Jennifer Ricci Hagman and Jill R. Storry*

- 12** Immunohematology and compatibility testing, 118  
*Connie M. Westhoff and Lynsi Rahorst*

## Section IV: Blood components

### Part I: Red cells

- 13** Red blood cell production and kinetics, 133  
*Mark J. Koury and Lionel Blanc*

- 14** Red blood cell metabolism and preservation, 143  
*John R. Hess and Angelo D'Alessandro*

### Part II: Platelets

- 15** Platelet production and kinetics, 158  
*Thomas C. Binns, Christopher A. Tormey and Henry M. Rinder*
- 16** Platelet immunology and alloimmunization, 168  
*Cheryl L. Maier, Seema R. Patel, and H. Clifford Sullivan*
- 17** Preparation, preservation, and storage of platelet concentrates, 179  
*Moritz Stolla, Valery J. Li, and Johnathan P. Mack*

### Part III: White cells

- 18** Neutrophil production and kinetics: neutropenia and neutrophilia, 188  
*Lawrence Rice and Eric Salazar*
- 19** Granulocyte collection and transfusion, 194  
*Jenny Petkova, Corinne Goldberg, and Jeffrey McCullough*

### Part IV: Plasma

- 20** Composition of plasma, 200  
*Peter Hellstern*
- 21** Plasma and cryoprecipitate for transfusion, 209  
*Torunn Oveland Apelseth, Simon J. Stanworth, and Laura Green*
- 22** The purification of plasma proteins for therapeutic use, 216  
*Nathan Brinkman, Karl McCann, and Barry Gooch*
- 23** Immunoglobulin products, 236  
*Melvin Berger*

## Section V: Apheresis

- 24** Basic principles of apheresis and the collection of blood components by apheresis, 251  
*Edwin A. Burgstaler and Jeffrey L. Winters*
- 25** Therapeutic apheresis: plasma processing, 259  
*Patricia A. R. Brunner and Monica B. Pagano*
- 26** Therapeutic phlebotomy and cellular hemapheresis, 278  
*Patricia A. R. Brunner and Jeffrey A. Bailey*

## Section VI: Blood transfusion

- 27** Patient blood management, 293  
*Darrell J. Triulzi, Jansen N. Seheult, Mark H. Yazer, and Jonathan H. Waters*
- 28** Clinical and technical aspects of blood administration, 306  
*Edward S. Lee, Debra L. Mraz, and Edward L. Snyder*
- 29** Anemia and red blood cell transfusion, 314  
*Jeffrey L. Carson, Asher A. Mendelson, and Paul C. Hébert*

- 30** Sickle cell disease, thalassemia, and hereditary hemolytic anemias, 326  
*Ross M. Fasano, Emily Riehm Meier, and Satheesh Chonat*
- 31** Autoimmune hemolytic anemias and paroxysmal nocturnal hemoglobinuria, 346  
*Christopher A. Tormey and Alexa J. Siddon*
- 32** Hemolytic disease of the fetus and newborn, 364  
*Jennifer Webb, Wen Lu, and Meghan Delaney*
- 33** Obstetric transfusion practice, 373  
*James Sikora and John D. Roback*
- 34** Transfusion in infants and children, 381  
*Jeanne E. Hendrickson and Cassandra D. Josephson*
- 35** Thrombocytopenia and platelet transfusion, 392  
*Michael F. Murphy, Simon J. Stanworth, and Lise J Estcourt*
- 36** Management of immune-mediated thrombocytopenia, 402  
*Caroline Gabe, Donald M. Arnold, James W. Smith, and Theodore E. Warkentin*
- 37** Coagulation concentrates for inherited bleeding disorders, 424  
*Gary M. Woods and Robert F. Sidonio, Jr.*
- 38** Coagulation factor concentrates and pharmacologic therapies for acquired bleeding disorders, 443  
*Natalie Bayli and Ravi Sarode*
- 39** Perioperative transfusion practice, 453  
*Leanne Thalji, Allan M. Klompaas, Matthew A. Warner, Daryl J. Kor, and James R. Stubbs*
- 40** Transfusion therapy in the care of trauma and burn patients, 471  
*John R. Hess, Benjamin R. Huebner, Samuel P. Mandell and Eileen M. Bulger*
- 41** Transfusion support for the oncology patient, 482  
*Kristin M. Stendahl, Wade L. Schulz, and Edward L. Snyder*
- 42** Pathogen-reduced blood components and derivatives, 489  
*Edward S. Lee, Edward L. Snyder, and Jeffrey McCullough*
- 45** Transfusion transmission of parasites and prions, 523  
*Bryan R. Spencer and Paula P. Saá*
- 46** Bacterial contamination of blood components, 533  
*Evan M. Bloch, Richard J. Benjamin, and Sandra Ramirez-Arcos*
- 47** Hemolytic transfusion reactions, 543  
*Sandhya R. Panch and Celina Montemayor*
- 48** Nonhemolytic transfusion reactions, 553  
*Emmanuel A. Fadeyi and Gregory J. Pomper*
- 49** Transfusion-related acute lung injury and other respiratory-related transfusion reactions, 569  
*E. Alexander Dent and H. Clifford Sullivan*
- 50** Transfusion-associated graft-versus-host disease, 582  
*Eric A. Gehrie and Courtney E. Lawrence*
- 51** Transfusional iron overload, 587  
*Sujit Sheth*
- Section VIII: Cellular and tissue transplant technologies**
- 52** Hematopoietic growth factors, 601  
*David J. Kuter*
- 53** Hematopoietic stems cells and transplantation, 617  
*Garrett S. Booth*
- 54** HLA antigens, alleles, and antibodies, 624  
*Scott M. Krummey, Robert A. Bray, Howard M. Gebel, and H. Clifford Sullivan*
- 55** Chimeric antigen receptor T cells and other cellular immunotherapies, 633  
*Andrew D. Fesnak and Don L. Siegel*
- 56** Gene therapy applications to transfusion medicine, 642  
*Seena Tabibi, Eric A. Gehrie, Emanuela M. Bruscia, and Diane S. Krause*
- 57** Tissue engineering and regenerative medicine, 648  
*Cecilia Motta, Qi Xing, Cynthia Wilkins, and Julie Allickson*
- 58** Human tissue allografts: responsibilities in understanding the path from donor to recipient, 660  
*Cassandra D. Josephson and Matthew J. Kuehnert*
- Index, 674

# List of contributors

---

## **Julie Allickson**

Mayo Clinic, Center for Regenerative Medicine, Rochester, MN, USA

## **Torunn Oveland Apelseth**

Department of Immunology and Transfusion Medicine, Haukeland University Hospital, Bergen; and Norwegian Armed Forces Medical Services, Oslo, Norway

## **Donald M. Arnold**

Department of Medicine, Michael G. DeGroote School of Medicine, McMaster University, Hamilton, ON, Canada

## **Jeffrey A. Bailey**

Department of Pathology and Laboratory Medicine, Warren Alpert Medical School, Brown University, Providence, RI, USA

## **Natalie Bavli**

Department of Internal Medicine (Hematology/Oncology), University of Texas Southwestern, Dallas, TX, USA

## **Richard J. Benjamin**

Cerus, Concord, CA, USA and Department of Laboratory Medicine, Georgetown University Washington, DC, USA

## **Melvin Berger**

Departments of Pediatrics and Pathology, Case Western Reserve University, Cleveland, OH, USA

## **Thomas C. Binns**

Departments of Pathology and Laboratory Medicine, Yale School of Medicine and Yale New Haven Hospital, New Haven, CT, USA

## **Lionel Blanc**

Division of Pediatrics Hematology/Oncology, Cohen Children's Medical Center, Zucker School of Medicine at Hofstra/Northwell and Feinstein Institutes for Medical Research, Manhasset, NY, USA

## **Evan M. Bloch**

Division of Transfusion Medicine, Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

## **Garrett S. Booth**

Department of Pathology, Microbiology, and Immunology, Vanderbilt University Medical Center, Nashville, TN, USA

## **Robert A. Bray**

Department of Pathology, Emory University Hospital, Atlanta, GA, USA

## **Nathan Brinkman**

CSL Behring, Bradley, IL, USA

## **Patricia A. R. Brunker**

Blood Transfusion Service, Department of Pathology, Massachusetts General Hospital, Harvard University, Boston, MA, USA

## **Emanuela M. Bruscia**

Department of Pediatrics, Yale School of Medicine, Yale University, New Haven, CT, USA

## **Eileen M. Bulger**

Trauma Center, Department of Surgery, Harborview Medical Center, University of Washington, Seattle, WA, USA

## **Edwin A. Burgstaler**

Therapeutic Apheresis Treatment Unit, Mayo Clinic, Rochester, MN, USA

## **Jeffrey L. Carson**

Division of General Internal Medicine, Rutgers Biomedical Health Sciences, Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ, USA

## **Satheesh Chonat**

Aflac Cancer and Blood Disorders Center, Children's Healthcare of Atlanta, Department of Pediatrics, Emory University School of Medicine, Atlanta, GA, USA

## **Laura Cooling**

Department of Pathology, University of Michigan, Ann Arbor, MI, USA

## **Angelo D'Alessandro**

Department of Biochemistry and Molecular Genetics; and Metabolomics Core (SOM and Cancer Center), University of Colorado Denver–Anschutz Medical Campus, Aurora, CO, USA

## **Meghan Delaney**

Children's National Hospital, and Departments of Pediatrics and Pathology, The George Washington University School of Medicine and Health Sciences, Washington, DC, USA

## **E. Alexander Dent**

Department of Pathology and Laboratory Medicine, Emory University Hospital, Atlanta, GA, USA

## **Anne F. Eder**

Center for Biologics Evaluation and Research, Food and Drug Administration, Silver Spring, MD; and Georgetown University Medical Center, Washington, DC, USA

## **Lise J. Estcourt**

NHS Blood and Transplant, Department of Haematology, Oxford University Hospitals and University of Oxford, Oxford, UK

## **Emmanuel A. Fadeyi**

Department of Pathology, Wake Forest University School of Medicine, Winston-Salem, NC, USA

## **Ross M. Fasano**

# Preface

---

In 1983, the National Heart, Lung and Blood Institute (NHLBI) awarded five medical school faculty the first of what were to be a host of Transfusion Medicine Academic Awards. The purpose of the program was to enhance instruction in and exposure to the essential principles related to transfusion of blood into patients. This was considered a neglected area in medical education. Embedded in that decision was the idea that blood banking was part of a broader medical field now termed transfusion medicine.

Dr. Ennio C. Rossi was one of these first five awardees. At that time, he was a professor at Northwestern University School of Medicine in Chicago and director of its apheresis unit. Dr. Rossi was approached by Williams and Wilkins to put together a major textbook in this newly identified field of transfusion medicine. Dr. Rossi subsequently recruited two coeditors: Dr. Toby Simon, a board certified transfusion medicine physician who was also one of the first five NHLBI awardees, and Dr. Gerald Moss, a prominent surgeon who had notable research achievements in oxygen transport. Thus, the first edition of *Principles of Transfusion Medicine* was launched by two hematologists and a surgeon. After the second edition, Dr. Rossi retired and Dr. Toby Simon assumed the senior editor role. It was decided to add Dr. Rossi's name to the title in recognition of his conception of the role of the book and to establish continuity for subsequent editions. Sadly, Dr. Rossi passed away on September 3, 2021. We dedicate this book to his memory and quote as follows from the first two paragraphs of the Preface to the first edition published in 1991:

Blood transfusion is an essential part of medical care and indispensable for the support of increasingly more sophisticated surgery. In the past, transfusion decisions were simple because therapeutic options were few. Now, decisions are more complicated. Transplantation biology and immunohematology are tightly intertwined, and transplantation surgery is frequently contingent upon special transfusion support. Advances in the technology of plasma fractionation and apheresis now provide a broad array of services for a large variety of clinical problems. Balanced against these benefits are the risks of blood-transmitted diseases, which have been underscored in the public consciousness by the emergence of acquired immunodeficiency syndrome (AIDS). Autologous transfusion and products of genetic engineering, such as hematopoietic growth factors, are being made available to diminish the risk, albeit small, of transfusion-transmitted disease by homologous blood. As these and other innovations render transfusion therapy more complex, blood banking has developed a clinical arm, transfusion medicine, to deal with these complexities.

*Principles of Transfusion Medicine* will attempt to define the proper use of blood in clinical care. It is intended for the clinicians who prescribe blood, for the students who expect to enter clinical practice, for the scientists, physicians, nurses, technologists, and others who ensure the quality of our blood services. Many diverse sciences are applied to the preparation of blood for transfusion, and virtually all medical and surgical specialties must employ transfusion, from time to time, in care of their patients. For this reason, transfusion medicine is, of necessity, multidisciplinary.

In preparation of this sixth edition, we have also been challenged by a pandemic. In response to this pandemic, two chapters in the

early part of the book have been added, detailing how our specialty responded to the emergency and the lessons learned. In addition, we have chapters focusing on other "megatrends": the application of molecular biology to the basics of matching donor and recipient, the use of apheresis to support new cellular approaches to cancer, the application of pathogen reduction for blood safety, the growth in plasma fractionation to meet the growing use of immune globulin preparations and other plasma-derived derivatives, as well as new approaches to support patients with massive bleeding, coagulopathy, and malignancy.

When the first edition was published, the transition away from whole blood to components and from cold-stored platelets to room-temperature stored platelets was nearly complete. Now we are seeing a reverse trend with recognition of potential benefits for the bleeding patient when treated with whole blood and cold-stored platelets. In the period since 1991, hemophilia care has gone from blood components such as cryoprecipitate, to plasma-derived factor concentrates, to recombinant products, to nonreplacement recombinant treatments, and finally to gene therapy to correct the defect that causes the disease. This is but one example of the evolution of the broader field of transfusion medicine we are capturing in this new sixth edition. We have assembled chapters and authors to guide the reader in understanding the changes that are occurring. At the same time, we have retained a significant amount of still-relevant material from earlier editions.

Contributors for this edition have once again been drawn from various scientific, medical, and surgical disciplines. Thus, this book encompasses topics including encouraging and managing donors, collecting and preserving donated blood, and matching each component to the appropriate recipient, based on the patient's clinical needs. The text also extends these concepts to tissue and goes beyond the field's basic tenets to address new applications.

We can think of no better way to honor Dr. Rossi's legacy than to present a sixth edition that blends transfusion science with clinical medicine, thus facilitating the thoughtful and measured prescription of blood, blood components, and their alternatives. Both the laboratory practice of blood banking and the clinical practice of transfusion medicine remain as important as ever. We proudly attribute the long-term influence of this field to its early leaders, who organized the discipline of transfusion medicine for success by anticipating future practice. We thank our new and returning contributors and the editorial staff at Wiley Blackwell for making possible a sixth edition of *Rossi's Principles of Transfusion Medicine* in this new pandemic-influenced world of transfusion practice.

# List of abbreviations

---

2RBC	double red cell collection	AHG	antihuman globulin
3-PCC / 3F-PCC	three-factor nonactivated prothrombin complex concentrate	AHPI	antihuman polyclonal immunoglobulin
4-PCC / 4F-PCC	four-factor nonactivated prothrombin complex concentrate	AHSP	alpha-hemoglobin stabilizing protein
A3GALT2	isogloboside synthase	AHTR	acute hemophilic transfusion reaction
A4GALT1	PIP <sub>K</sub> synthase	aHUS	atypical hemolytic-uremic syndrome
AA	aplastic anemia	AIDS	acquired immune deficiency syndrome
AABB	Association for the Advancement of Blood and Biotherapies (previously: American Association of Blood Banks)	AIHA	autoimmune hemolytic anemia
AAP	American Academy of Pediatrics	AIS	absent iron stores
aAPC	artificial antigen presenting cell	AKI	acute kidney injury
AATB	American Association of Tissue Banks	ALAS2	5-aminolevulinic acid synthase
AAV	adeno-associated virus	ALI	acute lung injury
AAV	ANCA-associated vasculitis	ALL	acute lymphoblastic leukemia
Ab	antibody	ALT	alanine transferase
ABC	America's Blood Centers	AML	acute myelogenous leukemia
ABC/EBA	America's Blood Centers/European Blood Alliance	AMP	adenosine monophosphate
ABE	acute bilirubin encephalopathy	AMPD	adenosine monophosphate deaminase
ACCP	American College of Chest Physicians	AMR	antibody-mediated rejection
ACD	acid citrate dextrose solution	AMR	Ashwell-Morell receptor
ACD-A	acid-citrate-dextrose formula A	aMSCs	adipose tissue-derived mesenchymal stem cells
ACE	angiotensin-converting enzyme	ANC	absolute neutrophil count
ACEI	angiotensin-converting enzyme inhibitor	ANCA	antineutrophil cytoplasmic antibodies
ACh	acetylcholine	ANG1	angiopoietin 1
AChE	acetylcholinesterase	ANH	acute nonvolemic hemodilution
AChR	acetylcholine receptor	ANK1	ankyrin
ACI	anemia of chronic inflammation	anti-GBM	anti-glomerular basement membrane antibody
ACKR1	atypical chemokine receptor 1	anti-Gov	anti-HPA-15 antibody
ACOG	American College of Obstetricians and Gynecologists	anti-TPO	antithyroid peroxidase
ACS	acute chest syndrome	ANXA2	annexin 2
ACT	activated clotting time	APC	antigen-presenting cell
ADA	adenosine deaminase	aPCC	activated prothrombin complex concentrate
ADCC	antibody-dependent cellular cytotoxicity	APCs	antigen-presenting cells
ADEM	acute disseminated encephalomyelitis	API	alpha <sub>1</sub> -proteinase inhibitor
ADF	actin depolymerizing factor	APS	antiphospholipid antibody syndrome
aDHQ	Abbreviated Donor History Questionnaire	aPTT	activated partial thromboplastin time
ADORA2b	Adenosine interactions with the receptor A2B	AQP1	aquaporin-1
ADP	adenosine diphosphate	AQP3	aquaporin-3
ADSC	adipose-derived stem cell	AQP4-IgG	aquaporin-4 immunoglobulin G antibodies
AECII	alveolar epithelial type cells of the upper airway II	ARC	absolute reticulocyte count
AF	atrial fibrillation	ARDS	acute respiratory distress syndrome
AFSC	amniotic fluid-derived stem cells	ARDS	adult respiratory distress syndrome
AGM	aortogonadomesonephros	ARIPI	Age of Red Blood Cells in Premature Infants Study
AHF	antihemophilic factor	ART	antiretroviral therapy
		AS	additive solution
		ASA	American Society of Anesthesiologists
		ASFA	American Society for Apheresis
		ASH	American society of Hematology
		ASO	antisense oligonucleotides

ASP	antibody-specific prediction	BPAC	FDA Blood Products Advisory Committee
ASPEN	association of sickle cell priapism, exchange transfusion and neurological events	BPD	bronchopulmonary dysplasia
ASRI	American Society for Reproductive Immunology	BRN	World Health Organization Blood Regulators Network
ASSC	acute splenic sequestration crisis	BSA	body surface area
ASTCT	American Society for Transplantation and Cellular Therapy	BSE	bovine spongiform encephalopathy
AT	antithrombin	BSS	Bernard Soulier syndrome
ATF4	activating transcription factor 4	BT	bleeding time
ATG	antithymocyte globulin	BTHC	butyryl-tri-hexyl citrate
ATIII	antithrombin III	BVDV	bovine viral diarrhea virus
ATL	adult T-cell leukemia and lymphoma	C/EBP $\alpha$	CCAAT/enhancer binding protein $\alpha$
ATP	adenosine 5prime*-triphosphate	CAAR	chimeric auto antigen receptor
ATRs	allergic transfusion reactions	CABG	coronary artery bypass graft
ATS	American Thoracic Society	CAD	cold agglutinin disease
AUC	area under the ROC curve	CAEV	arthritis-encephalitis virus of goats
AUG	Augustine blood group	CAFC	cobblestone area-forming cell
AvWWS / AVWS	acquired von Willebrand syndromex	CALR	calreticulin
B-ALL	B-cell acute lymphoblastic leukemia	cAMP	cyclic adenosine monophosphate
B-CAM	basal cell adhesion molecule	CAP	College of American Pathologists
B-CAM/LU	Basal Cell Adhesion Molecule-Lutheran antigen	CAPS	catastrophic antiphospholipid syndrome
B3GALNT1	P synthase	CAR	chimeric antigen receptor
B19V	parvovirus B19	CAR-T cell	CXCL12 abundant reticular (cell)
BAGP	bicarbonate, adenine, glucose, and phosphate	CARS	T cell expressing a chimeric antigen receptor
BART	Blood Conservation Using Antifibrinolytics in a Randomized Trial	CASI	compensatory anti-inflammatory response syndrome
BasoEB	basophilic erythroblast	CASPR2	computer-assisted self-interview
BB/TS	Blood Bank/Transfusion Medicine standards	CBC	contactin-associated protein-2
BC method	buffy-coat method	CBER	complete blood count
BCEs	blood collection establishments	CBF	Center for Biologics Evaluation and Research
BCMA	B cell maturation antigen	CBS	cerebral blood flow
BCSH	British Committee for Standards in Hematology	CCAD	Canadian Blood Services
BCT	blood component therapy	ccc-DNA	Central Cardiac Audit Database
BDD	B-domain-deleted	CCI	covalently closed circular DNA
BECS	blood establishment computer software	CCP	corrected count increment
BELIEVE	An Efficacy and Safety Study of Luspatercept Versus Placebo in Adults Who Require Regular Red Blood Cell Transfusions Due to Beta Thalassemia	CCPD	convalescent Covid plasma
BEN	benign ethnic neutropenia	CDA	complement control protein domain
BFU-Es	burst-forming units-erythroid	CCAD	congenital dyserythropoietic anemia
BFU-MK	burst-forming units-megakaryocyte	CDR	Centers for Disease Control and Prevention
BiKE	bispecific killer engager	CDER	complement-dependent cytotoxicity
BIND	bilirubin-induced neurotoxicity	CD-P-TS	Center for Drug Evaluation and Research
BloodNet	Pediatric Critical Care Blood Research Network	CDR	European Committee on Blood Transfusion
BM-MSCs	bone marrow-derived mesenchymal stem cells	CDRH	complementarity-determining region
BMD	Becker muscular dystrophy	CDSS	Center for Devices and Radiologic Health
BMI	body mass index	CERA	clinical decision support systems
BMP	bone morphogenetic protein	CFB	polyethylene glycol-conjugated recombinant
BMSC	bone marrow stem cell	cffDNA	human erythropoietin
BMT	bone marrow transplantation	CFH	complement factor B
BNP	B-type natriuretic peptide	CFI	cell-free fetal DNA
BOS	bronchiolitis obliterans syndrome	CFR	complement factor H
BP	blood pressure	CFU-Es	complement factor I
		CFU-GM	US Code of Federal Regulations
		CFU-MK	colony-forming units-erythroid
		CGD	progenitor cells with the capacity to generate neutrophils in vitro
		cGMP	colony-forming units-megakaryocyte
		cGMP	chronic granulomatous disease
		CH2-THF	current good manufacturing practice
			cyclic guanosine monophosphate
			methylenetetrahydrofolate

CH3-THF	methyltetrahydrofolate	CREG	cross-reactive group
CHAPS	3-[(3-Cholamidopropyl)dimethylammonio]-1-propanesulfonate	CRISPR	clustered regularly interspaced short palindromic repeat
	hydrate	CRM	cross-reactive material
CHCM	cell hemoglobin concentration mean	CRPS	chronic regional pain syndrome
CHIKV	chikungunya virus	CRPS II	chronic regional pain syndrome type 2
CHILL REDS-III	Comparison of Donation History and Iron Levels in Teenage Blood Donors	CRRT	continuous renal replacement therapy
ChLIA	chemiluminescent immunoassays	CRS	cytokine release syndrome
CHMP	Committee for Medicinal Products for Human Use	CS	caesarean section
CHO-THF	formyltetrahydrofolate	CSF	cyclosporine
CHOP	Study of Cyclophosphamide, Hydroxydaunorubicin, Oncovin, Prednisone	CT	circulating steel factor
CHR	cellular hemoglobin in reticulocytes	CTA	computerized tomography
CI	confidence interval	CTCL	cancer-testis antigen
CIBMTR	Center for International Blood and Marrow Transplant Research	CTL	cutaneous T-cell lymphoma
CIDP	chronic inflammatory demyelinating polyradiculoneuropathy	CTL2	cytotoxic T-cell
CIT	chemotherapy-induced thrombocytopenia	CTLA-4	choline transporter-like 2 protein
CJD	Creutzfeldt–Jakob disease	CTT	cytotoxic T lymphocyte-associated protein 4
CKD	chronic kidney disease	cTTP	chronic transfusion therapy
CLET	cultured limbal epithelial transplantation	CVAD	congenital thrombotic thrombocytopenic purpura
CLIA	chemiluminescent immunoassay	CVCs	central venous access device
CLIA	Clinical Laboratory Improvement Act	CWD	central venous catheters
CLL	chronic lymphoid leukemia	CXCL12	chronic wasting disease
CM	carboxymethyl	CY	stromal-cell derived factor 1
CM-HUS	complement-mediated hemolytic-uremic syndrome	DAF	cyclophosphamide
CM-TMA	complement-mediated thrombotic microangiopathy	DAH	decay accelerating factor
CMIAs	chemiluminescent microparticle immunoassays	DAMPs	diffuse alveolar hemorrhage
CML	chronic myelogenous leukemia	DARC	damage-associated pattern molecules
CMP	common myeloid precursor	DART	Duffy antigen receptor for chemokines
CMQCC	California maternal quality care collaboration	DAT	Danish Registration of Transfusion Accidents
CMS	Centers for Medicare and Medicaid Services	dATP	direct antiglobulin test
CMV	cytomegalovirus	DBA	deoxy adenosine triphosphate
CNS	central nervous system	DBCD	Diamond–Blackfan anemia
CNSHA	chronic nonspherocytic hemolytic anemia	DBM	Division of Blood Components and Devices
COBLT	Cord Blood Transplant (study)	DC	demineralized bone matrix
CoE	Council of Europe	DCASGPR	dendritic cell
COM	All Common Checklist	DCM	dendritic cell asialoglycoprotein receptor
COOP	continuity of operations plans	DCs	dilated cardiomyopathy
COX2	cyclooxygenase 2	DD	dendritic cells
CP2D	citrate phosphate double dextrose	DDAVP	D-dimers
CPB	cardiopulmonary bypass	DEA	desmopressin
CPD	citrate–phosphate–dextrose	DEAE	diethyleneamine
CPDA	citrate–phosphate–dextrose–adenine	DEC	diethylaminoethyl
CPDA-1	citrate phosphate dextrose adenine	dECM	diethylcarbamazine
CPOE	computerized physician order entry systems	DEHP	decellularised extracellular matrix
CPRA	calculated panel-reactive antibody tests	DEM	diethylhexyl phthalate
CPSI	Canadian Patient Safety Institute	DETTD	Donor Educational Materials
CQ	clindamycin and quinine	DF	Division of Emerging and Transfusion Transmitted Diseases
CR	complete response	DFO	dengue fever
CR1	complement receptor 1	DFP	deferoxamine B mesylate
CRASH-2	Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage trial	DFPP	deferiprone
		DFSD	double-membrane filtration plasmapheresis
		DFX	dry fibrin sealant dressing
		dGTP	deferasirox
		DHF	deoxy guanine triphosphate
		DHFR	dihydrofolate
		DHQ	dihydrofolate reductase
		DHS	Donor History Questionnaire
			Department of Homeland Security

DHSt	dehydrated stomatocytosis	EPO-a	erythropoietin alpha
DHTF	Donor History Task Force	EPO-R	erythropoietin receptor
DHTRs	delayed hemolytic transfusion reactions	ePTFE	expanded polytetrafluoroethylene
DIC	disseminated intravascular coagulation	ERFE	erythroferrone
DIIHA	drug-induced immune hemolytic anemia	ERMAP	erythrocyte membrane-associated protein
DITP	drug-induced immune thrombocytopenic purpura	ESAs	erythropoietin-stimulating agents
DLIs	donor lymphocyte infusions	ESC	embryonic stem cell
DMD	Duchenne muscular dystrophy	ESF	Emergency Support Functions (NRF)
DMH/DHA	dorsomedial nucleus/dorsal area	ESRD	end-stage renal disease
DMS	demarcation membrane system	ET	essential thrombocythemia
DMSO	dimethyl sulfoxide	ETTNO	Effect of Transfusion Thresholds on Neurocognitive Outcomes of extremely low birth weight infants Trial
DOACs	direct oral anticoagulants	EU	European Union
DOT	Department of Transportation	EUHASS	European Hemophilia Safety Surveillance
2,3-DPG	2,3-diphosphoglycerate	EV	extracellular vesicles
DSAs	donor-specific antibodies	EVA	ethylene vinyl acetate
DSBs	double-stranded breaks	EXM	electronic crossmatch
dsDNA	double-stranded DNA	EXT	extreme thrombocytosis
DSEK	Descemet's stripping endothelial keratoplasty	FACT	Foundation for the Accreditation of Cellular Therapy
DSGG	disialogalactosylgloboside	FADH	reduced flavin adenine dinucleotide
dsRNA	double-stranded RNA	FAST	focused ultrasonographic survey for trauma
DSS	decision support system	FBS	fetal blood sampling
DSTR	delayed serologic transfusion reaction	FC	fibrinogen concentrates
DTT	dithiothreitol	fCJD	familial Creutzfeldt–Jacob disease
DVT	deep vein thrombosis	FCR	fraction of cells remaining
EACA	$\epsilon$ -aminocaproic acid	FcRn	neonatal Fc receptor
EBA	European Blood Alliance	FDA	United States Food and Drug Administration
EBI	erythroblastic island	FDAAAA	Food and Drug Administration Amendments Act
EBV	Epstein–Barr virus	FDAMA	Food and Drug Administration Modernization Act
EC	endothelial cells	FDASIA	Food and Drug Administration Safety and Innovation Act
ECBS	Expert Committee on Biological Standardization	FDC	follicular dendritic cell
ECG	electrocardiogram	FDCA	Food, Drug, and Cosmetic Act
ECM	extracellular matrix	FDCs	follicular dendritic cells
ECMO	extracorporeal membrane oxygenation	FDP	fibrin degradation product
ECP	extracorporeal photopheresis	FEIBA	factor VIII inhibitory bypass activity
ECV	extracorporeal volume	FEMA	Federal Emergency Management Agency
EDQM	European Directorate for the Quality of Medicines	FEP	free erythrocyte protoporphyrin
EDTA	ethylenediaminetetraacetic acid	FFI	fatal familial insomnia
EEA	European Economic Area	FFP	fresh frozen plasma
EFIC	exception from informed consent	FGS	focal glomerulosclerosis
EGC	endothelial glycocalyx	FH	familial hypercholesterolemia
EGPA	eosinophilic granulomatosis with polyangiitis	FL	Flt3-ligand
EIA	enzyme immuno(sorbent) assay	FLAER	fluorescent aerolysin
EIAV	infectious anemia virus of horses	FLIPID	Ferritin Levels in Plasma Donors study
ELBW	extremely low birthweight	FMH	fetal–maternal hemorrhage
ELISA	enzyme-linked immunosorbent assay	FNAIT	fetal/neonatal alloimmune thrombocytopenia
EMA	European Medicines Agency	FNHTR	febrile nonhemolytic transfusion reaction
EMAs	emergency management agencies	FOCUS	Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair study
EMCV	encephalomyocarditis virus	FSFI	Female Sexual Function Index
EMP3	epithelial membrane protein 3	FSGS	focal segmental glomerulosclerosis
EMP	Embden–Meyerhof–Parnas pathway	FSPT	filtered sunlight phototherapy
EMP	erythroblast–macrophage protein		
ENT1	equilibrative nucleoside transporter 1		
EP	European Pharmacopoeia		
EP3Rs	prostaglandin EP3 receptors		
EPO	erythropoietin		

FT/RA	first-time and reactivated (donors)	HbC	hemoglobin C
FTA-ABS	fluorescent <i>Treponema pallidum</i> antibody absorption	HBc	hepatitis B core
G-CSF	granulocyte colony-stimulating factor	HBcAg	hepatitis B core antigen
G6PD	glucose-6-phosphate dehydrogenase	HbD	hemoglobin D
GABA	$\gamma$ -amino butyric acid	HbE	hemoglobin E
GAD-65	65-kD isoform of glutamic acid decarboxylase	HBeAg	hepatitis B e antigen
GAG	glycoslyaminoglycan	HbF	fetal hemoglobin
Gal	$\beta$ -galactose	HBOCs	hemoglobin-based oxygen carriers
GalNAc	<i>n</i> -acetylgalactosamine	HbS	hemoglobin S
GATA1	GATA-binding factor 1	HBSAg	hepatitis B virus surface antigen
GBM	glomerular basement membrane	HBV	hepatitis B virus
GBS	Guillain–Barré syndrome	HCEC	human corneal endothelial cell
GDF	growth differential factor	HCT	hematopoietic cell transplant
GDP	guanosine diphosphate	HCT/P	human cells, tissues, and cellular and tissue-based product
GEF-H1	guanine nucleotide exchange factor H1	HCV	hepatitis C virus
GEMM-CFC	granulocyte-erythroid-macrophage-megakaryocyte colony-forming cells	HDFN	hemolytic disease of the fetus and newborn
GEN	Laboratory General Checklist	HDI	human development index
GFI1	growth factor interdependent 1	HDIVIG	high-dose intravenous immunoglobulin
GI	gastrointestinal	HDL	high-density lipoprotein
GLUT1	glucose transporter 1	HDN	hemolytic disease of the fetus and newborn
GM-CSF	granulocyte macrophage colony-stimulating factor	HDR	homology-directed repair
GMP	good manufacturing practice	HDV	hepatitis D virus
GP	glycoprotein	HE	hereditary elliptocytosis
GPA	glycophorin A	HEIRS	REDS-III Hemoglobin and Iron Recovery Study
GPA	granulomatosis with polyangiitis	HELLP (syndrome)	hemolysis, elevated liver enzymes, and low platelets
GPB	glycophorin B	HEMPAS	Hereditary erythroblastic multinuclearity with positive acidified serum lysis test
GPC	glycophorin C	HES	hydroxyethyl starch human
GPCR	guanine nucleotide-binding protein-coupled receptor	hESC	human embryonic stem cell
GPD	glycophorin D	HEV	hepatitis E virus
GPI	glycosylphosphatidylinositol	HFMEA	Healthcare Failure Mode and Effect Analysis
GPS	Goodpasture syndrome	Hgb	hemoglobin
GPVI	Glycoprotein VI (platelet)	hGH	human growth hormone
GPX4	glutathione peroxidase 4	HH	hereditary hemochromatosis
GRADE	Grading of Recommendations Assessment, Development and Evaluation	HHV	human herpesvirus
GSH	glutathione	HIC	hydrophobic interaction chromatography
GSL	glycospingolipid	HIF	hypoxia-inducible transcription factor
GSS	Gerstmann–Straussler–Scheinker disease	HIF-PHDs	hypoxia-inducible transcription factor
GT	gestational thrombocytopenia	HIPA	prolyl hydroxylases
GT6	glycosyltransferase family 6	HIT	heparin-induced platelet activation assay
GTA	A-transferase	HIV	heparin-induced thrombocytopenia
GTB	B-transferase	HLA	human immunodeficiency virus
GTP	guanosine triphosphate	HLH	human leukocyte antigen
GTX	granulocyte transfusions	HMW	hemophagocytic lymphohistiocytosis
GVHD	graft-versus-host disease	HMWK	high molecular weight
GVL	graft-versus-leukemia	HNA	high-molecular-weight kininogen
GWA	genome-wide association	HNA-3	human neutrophil antigen
HA	hyaluronic acid	HO1	human neutrophil antigen 3
HA	hydroxyapatite	HPAs	heme oxygenase-1
HAA	hospital-acquired anemia	HPC	human platelet antigens
HAART	highly active antiretroviral therapy	HPCT	hematopoietic progenitor cell
HAV	hepatitis A virus	HPP	hematopoietic progenitor cell
HB-PAN	hepatitis B-associated polyarteritis nodosa	HPV	transplantation
HbAA	normal hemoglobin A	HR	hereditary pyropoikilocytosis
HbAS	hemoglobin A sickle	HRI	human papilloma virus
			hazard ratio
			heme-regulated inhibitor

HRP	histidine-rich protein 2	IPF	immature platelet fraction
HSC	hematopoietic stem cells	IPFA	International Plasma Fractionation Association
HSCT	hematopoietic stem cell transplantation	iPSC	induced pluripotent stem cell
HSV	herpes simplex virus	IPSS	International Prognostic Scoring System
HTA	health technology assessment	IQPP	International Quality Plasma Program
HTLV	human T-cell lymphotropic virus	IR	interventional radiologists
HTR	hemolytic transfusion reaction	IRE	iron-responsive element
hUCMScs	human umbilical cord mesenchymal stem cells	IRP	iron regulatory protein
HUS	hemolytic-uremic syndrome	ISBT	International Society of Blood Transfusion
HVM	handheld vital microscopy	ISTARE	International Surveillance Database for Transfusion Adverse Reactions and Events
hWJCs	Wharton's jelly-derived mesenchymal stem cells	ISTH	International Society on Thrombosis and Hemostasis
HX	hereditary xerocytosis	IT	information technology
%HYPOm	percentage of hypochromic mature red blood cells	ITAC	Inpatient Treatment With Anti-Coronavirus
%HYPOR	percentage of hypochromic red blood cells	ITI	Immunoglobulin Trial
IA-HUS	infection-associated hemolytic-uremic syndrome	ITP	immune tolerance induction
IAP	integrin-associated protein	iTTP	immune thrombocytopenic purpura
IAT	indirect antiglobulin test	IV	immune thrombotic thrombocytopenic purpura
IBCT	incorrect blood component transfused	IVC	intravenous
IBR	intraoperative blood recovery	IVD	inferior vena cava
IC	informed consent	IVIG / IVIg	in vitro diagnostic devices
ICAM4	interstitial cell adhesion molecule-4	JAK2	intravenous immunoglobulin
ICCBBA	International Council for Commonality in Blood Banking Automation	KIR	Janus kinase 2
ICH	International Conference on Harmonization (of Technical Requirements)	KLF-1	killer immunoglobulin-like receptor
ICH	intracranial hemorrhage	LacCer	Krppel-like factor-1
iCJD	iatrogenic Creutzfeldt-Jakob disease	LAD	lactosylceramide
ICU	intensive care unit	LAG3	leukocyte adhesion deficiency
ID NAT	individual nucleic acid test	LAK	lymphocyte-activation gene 3
IDA	iron-deficiency anemia	LCL	lymphokine-activated killer
IDE	iron-deficient erythropoiesis	LCMV	lymphoblastoid line
IDH1	isocitrate dehydrogenase 1	LCR	lymphatic choriomeningitis
IDSA	Infectious Disease Society of America	LCT	locus control region
IDT	individual testing	LDH	lymphocytotoxicity
IE	ineffective erythropoiesis	LDL	lactate dehydrogenase
IFA	immunofluorescence assay	LEMS	low-density lipoprotein
IFAT	immunofluorescent antibody test	LESC	Lambert-Eaton myasthenic syndrome
IFN	interferon	LF	limbal epithelial stem cell
IG/ Ig	immunoglobulin	LFI	low ferritin
IgA	immunoglobulin A	LGI1	lateral flow immunoassay
IGF-1-R	insulin-like growth factor 1 receptor	LGL	leucine-rich glioma inactivated 1
IGF1	insulin-like growth factor-1	LHDAg	large granular lymphocyte
IgG	immunoglobulin G	LHR	long hepatitis D antigen
IgM	immunoglobulin M	LIA	long homologous repeat
IgSF	immunoglobulin superfamily	LIC	latex-enhanced immunoturbidimetric assay
IHD	incorporating isovolemic hemodilution (red cell exchange)	LIF	liver iron concentration
IHN	International Hemovigilance Network	LISS	leukemia inhibitory factor
IL	interleukin	LKE	low ionic strength solution
IM	intramuscular	LMAN	luke antigen on erythrocytes
IMP	inosine monophosphate	LMO2	lectin mannose binding
IND	individual donor	LMW	Lim domain partner of TAL1
IND	investigational new drug	LMWH	low molecular weight
iNKT	invariant natural killer T cell	lncRNAs	low molecular weight heparin
INR	international normalized ratio	LP	long noncoding RNAs
IPC	immature platelet count	LPI	liquid plasma
IPD	individual-patient data	LPS	labile plasma iron
		LR	lipopolysaccharide
		LRP4	leukocyte reduction / leukoreduced
			lipoprotein receptor-related protein 4

LSC	limbal stem cell	MOG	myelin oligodendrocyte glycoprotein
LTA	lipoteichoic acid	8-MOP	8-methyoxyxpsoralen
LTOWB	low-titer group O whole blood	MPA	microscopic polyangiitis
LVDS	large volume delayed sampling	MPO	myeloperoxidase
LVEF	left ventricular ejection fraction	MPP	multipotent progenitor
Mab	monoclonal antibody	MPV	mean platelet volume
MAC	membrane attack complex	MR	magnetic resonance
McC	McCoy antigen	MRI	magnetic resonance imaging
MACE	modified capture enzyme-linked immuno-sorbent assay	mRNA	messenger ribonucleic acid
MAG	myelin-associated glycoprotein	MS	multiple sclerosis
MAHA	microangiopathic hemolytic anemia	MSC	mesenchymal stem (stromal) cell
MAIPA	monoclonal antibody-specific immobilization of platelet antigens	MSM	men who have sex with men
MAP	mean arterial pressure	MTP	massive transfusion protocol
MAPK	mitogen-activated protein kinase	MTX	methotrexate
MART	melanoma antigen recognized by T cells	MuSK	muscle-specific kinase
MATTERs	Military Application of Tranexamic acid in Trauma Emergency Resuscitation study	MVM	minute virus of mice
MB	methylene blue	NAAT	nucleic acid amplification testing
MBFs	microaggregate blood filters	NACSSG	National Acute Chest Syndrome Study Group
MBG	Marburg virus	NAD	nicotinamide adenine dinucleotide
MBP	myelin basic protein	NADH	reduced nicotinamide adenine dinucleotide
MCA	middle cerebral arteries	NADP	nicotinamide adenine dinucleotide
MCFD	multiple coagulation factor deficiency gene	NADPH	phosphate
MCH	mean cell hemoglobin	NAIT	reduced nicotinamide adenine dinucleotide
MCHC	mean corpuscular hemoglobin concentration	NAITP	phosphate
MCP	macrophage chemoattractant protein	NANB	neonatal alloimmune thrombocytopenia
MCV	mean corpuscular volume	NAPTT	neonatal alloimmune thrombocytopenic purpura
MDDS	Medical Device Data Systems	NAT	non-A, non-B hepatitis
MDH1	malate dehydrogenase 1	NATA	non-activated partial thromboplastin time
MDL	Medication Deferral List	NBCUS	nucleic acid testing
MDS	myelodysplastic syndrome	NCAAs	Network for Advancement of Transfusion Alternatives
MECOM	MDS1 and EV11 complex locus protein	NCI	National Blood Collection and Utilization Survey
MEDALIST	A Study of Luspatercept to Treat Anemia Due to Very Low, Low, or Intermediate Risk Myelodysplastic Syndromes	NDDR	national competent authorities
MEHP	mono(2-ethylhexyl) phthalate	NDI	National Cancer Institute
MEP	megakaryocytic-erythroid progenitor	NDMA	National Donor Deferral Registry
MET	mesenchymal–epithelial transition	NEC	neurodevelopmental impairment
MFI	mean fluorescence intensity	NETs	nitrosodimethylamine
MGSA	melanocyte growth-stimulating activity	NF- $\kappa$ B	necrotizing enterocolitis
MGUS	monoclonal gammopathy of undetermined significance	NFE2	neutrophil extracellular traps
MHA-TP	Microhemagglutination Assay for <i>Treponema pallidum</i>	NGC	nuclear factor $\kappa$ B
MHC	major histocompatibility complex	NGS	nuclear factor, erythroid 2
MIRL	membrane inhibitor of reactive lysis	NHLBI	nerve guidance conduits
miRNA	micro RNA	NHS	next-generation sequencing
MK	megakaryocyte	NHSBT	National Heart, Lung, and Blood Institute
MKL	myocardin-like transcription factors	NHSN	National Health Service (UK)
MLR	mixed lymphocyte reaction	NIBSC	National Health System Blood and Transplant Service
MM	multiple myeloma	NICU	National Healthcare Safety Network
MMN	multifocal motor neuropathy	NIH	National Institute of Biological Standards and Control
MMP	matrix metalloproteinase	NIRS	neonatal intensive care unit
MMR	Measles, mumps, and rubella vaccination	NK	National Institutes of Health
MnPO	median preoptic area	NMDAR	near-infrared spectroscopy
MoAbs	monoclonal antibodies	NMDP	natural killer

# **Transfusion medicine from ancient times to the current pandemic**

## CHAPTER 1

# Transfusion in the new millennium

Ennio C. Rossi<sup>1</sup> & Toby L. Simon<sup>2</sup>

<sup>1</sup>Northwestern University School of Medicine (deceased), Chicago, IL, USA

<sup>2</sup>CSL Plasma, Boca Raton, FL, USA; and Department of Pathology, University of New Mexico School of Medicine, Albuquerque, NM, USA

Prehistoric man left drawings of himself pierced by arrows.<sup>1</sup> This means he was as aware of blood as he was of his own limbs. The flint implements he used as tools and weapons distinguished him from other creatures and contributed to the violence of his era. As he hunted food and fought enemies, he observed bleeding and the properties of blood. A cut, received or inflicted, yielded a vivid red color. If the cut was shallow, there was little blood. But if the cut was deep, a red torrent flowing from the stricken victim quickly led to death, with shed blood congealed and darkening in the sun. Fatal hemorrhage was commonplace. Nonetheless, the sight must have been fearful and possibly existential as life flowed red out of the body of an enemy or a wounded animal.<sup>2</sup> It is no wonder, then, that at the dawn of recorded history, blood was already celebrated in religious rites and rituals as a life-giving force.

The cultural expressions of primitive and ancient societies, although separated by time or space, can be strikingly similar. Whether these expressions emerged independently or were diffused about the world by unknown voyagers will probably always remain clouded in mystery.<sup>2</sup> Nonetheless, there is a common thread in the ancient rituals that celebrate blood as a mystical vital principle. In Leviticus 17:11, “the life of the flesh is in the blood,” and the Chinese Neiching (circa 1000 BCE) claims the blood contains the soul.<sup>2</sup> Pre-Columbian North American Indians bled their bodies “of its greatest power” as self-punishment,<sup>3</sup> Egyptians took blood baths as a recuperative measure, and Romans drank the blood of fallen gladiators in an effort to cure epilepsy.<sup>4</sup>

The Romans also practiced a ceremony called taurobolium—a blood bath for spiritual restoration. A citizen seeking spiritual rebirth descended into a pit or *fossa sanguinis*. Above him on a platform, a priest sacrificed a bull, and the animal’s blood cascaded down in a shower upon the beneficiary. Then, in a powerful visual image, the subject emerged up from the other end of the pit, covered with blood and reborn.<sup>1</sup>

The legend of Medea and Aeson taken from Ovid’s *Metamorphoses* and quoted in Bulfinch’s *Mythology*<sup>5</sup> also ascribed rejuvenating powers to blood. Jason asked Medea to “take some years off his life and add them to those of his father Aeson.” Medea, however, pursued an alternative course. She prepared a cauldron with the blood of a sacrificed black sheep. To this, she added magic herbs, hoarfrost gathered by moonlight, the entrails of a wolf, and many other things “without a name.” The boiling cauldron was stirred

with a withered olive branch, which became green and full of leaves and young olives when it was withdrawn. Seeing that all was ready,

Medea cut the throat of the old man and let out all his blood, and poured into his mouth and into his wound the juices of her cauldron. As soon as he had imbibed them, his hair and beard laid by their whiteness and assumed the blackness of youth; his paleness and emaciation were gone; his veins were full of blood, his limbs of vigour and robustness. Aeson is amazed at himself and remembers that such as he now is, he was in his youthful days, 40 years before.

This legend seems to echo the apocryphal story of Pope Innocent VIII, who is said to have received the blood of three young boys in 1492 while on his deathbed. As the story goes, a physician attempted to save the pope’s life by using blood drawn from three boys 10 years of age, all of whom died soon thereafter. Some nineteenth-century versions of this tale suggest the blood was transfused. However, earlier renditions more plausibly suggest that the blood was intended for a potion to be taken by mouth. In any event, there is no evidence the pope actually received any blood in any form.<sup>6,7</sup>

The folklore that flowed with blood was not accompanied by a great deal of accurate information. The ancient Greeks believed that blood formed in the heart and passed through the veins to the rest of the body, where it was consumed. Arteries were part of an independent system transporting air from the lungs. Although Erasistratos (circa 270 BCE) had imagined the heart as a pump, his idea was ahead of its time. As long as veins and arteries were dead-end channels transporting blood and air, there was little need for a pump in the system. Although Galen (131–201 CE) finally proved that arteries contain blood, communication with the venous system was not suspected. Blood, formed in the liver, merely passed through the blood vessels and heart on its way to the periphery.<sup>1</sup> These teachings remained in place for 1400 years until they were swept away in 1628 by Harvey’s discovery of the circulation.

The realization that blood moved in a circulating stream opened the way to experiments on vascular infusion. In 1642, George von Wahnrendorff injected wine<sup>8</sup>—and, in 1656, Christopher Wren and Robert Boyle injected opium and other drugs<sup>9</sup>—intravenously into dogs. The latter studies, performed at Oxford, were the inspiration for Richard Lower’s experiments in animal transfusion.

## The first animal transfusion

Richard Lower (1631–1691) was a student at Oxford when Christopher Wren and Robert Boyle began their experiments on infusion. In due course, Lower joined their scientific group and studied the intravenous injection of opiates, emetics, and other substances into living animals.<sup>10</sup> In time, the transfusion of blood itself became the objective. The announcement of the first successful transfusion, performed by Richard Lower at Oxford in February 1665, was published on November 19, 1666, in the *Philosophical Transactions of the Royal Society* in a short notation titled, “The Success of the Experiment of Transfusing the Blood of One Animal into Another.”<sup>11</sup> The entire notation is as follows:<sup>11</sup>

This experiment, hitherto look'd upon to be of an almost insurmountable difficulty, hath been of late very successfully perform'd not only at Oxford, by the directions of that expert anatomist Dr. Lower, but also in London, by order of the R. Society, at their publick meeting in Gresham Colledge: the Description of the particulars whereof, and the Method of Operation is referred to the next opportunity.

The December 17, 1666, issue of the *Transactions* contained the full description as promised.<sup>12</sup> It was taken from a letter<sup>13</sup> written by Lower to Robert Boyle on July 6, 1666, in which Lower described direct transfusion from the carotid artery of one dog to the jugular vein of another. After describing the insertion of quills into the blood vessels of the donor and recipient dogs, Lower wrote:<sup>13</sup>

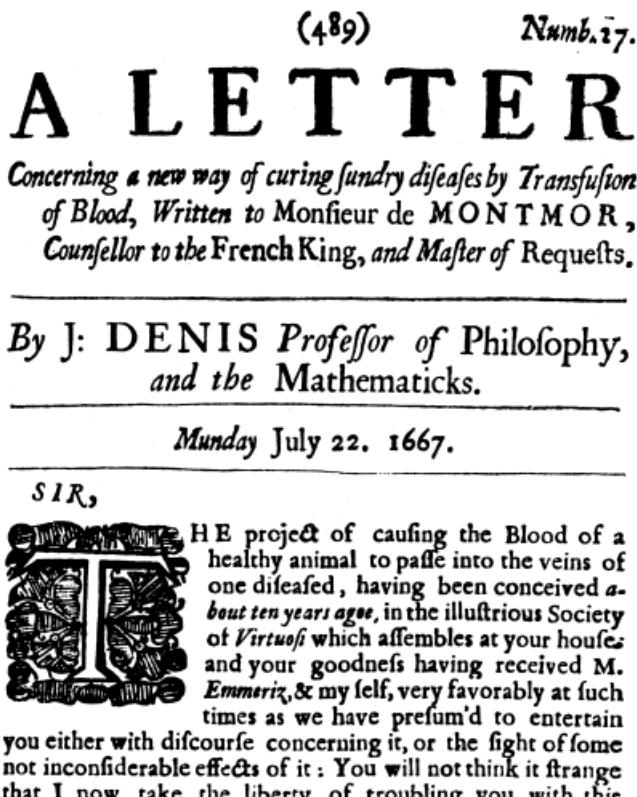

When you have done this you may lay the dogs on their side and fasten them densely together as best you may to insure the connection of the two quills. Quickly tighten the noose around the neck of the receiving animal as in venesection, or at all events compress the vein on the opposite side of the neck with your finger, then take out the stopper and open the upper jugular quill so that while the foreign blood is flowing into the lower quill, the animal's own blood flows out from the upper into suitable receptacles—until at last the second animal, amid howls, faintings, and spasms, finally loses its life together with its vital fluid.

When the tragedy is over, take both quills out of the jugular vein of the surviving animal, tie tightly with the former slipknots, and divide the vein. After the vessel has been divided, sew up the skin, slacken the cords binding the dog, and let it jump down from the table. It shakes itself a little, as though aroused from sleep, and runs away lively and strong, more active and vigorous perhaps, with the blood of its fellow than its own.

These studies inevitably led to the transfusion of animal blood to humans. In England, this occurred on November 23, 1667, when Lower and Edmund King transfused sheep blood into a man named Arthur Coga.<sup>14</sup> Described by Samuel Pepys as “a little frantic,” Coga was paid 20 shillings to accept this transfusion, with the expectation that it might have a beneficial “cooling” effect. One week later, Coga appeared before the Society and claimed to be a new man, although Pepys concluded he was “cracked a little in the head.”<sup>15</sup> However, this was not the first transfusion performed in a human. The credit for that accomplishment belongs to Jean-Baptiste Denis (1635–1704), who had performed the first human transfusion several months earlier in Paris.

## The first animal-to-human transfusion

The founding of the Royal Society in London in 1662 was followed in 1666 by the establishment of the Academie des Sciences in Paris under the patronage of King Louis XIV. The new Academie reviewed the English reports on transfusion with great interest. Denis probably read of Lower’s experiments in the *Journal des Savants* on January 31, 1667, and he began his own studies approximately one month later.<sup>15,16</sup> The first human transfusion was

**Figure 1.1** The first human transfusion. Source: Denis (1967).<sup>17</sup> Figure 01, p 01 / With permission of The Royal Society.

then performed on June 15, 1667, when Denis administered the blood of a lamb to a 15-year-old boy (Figure 1.1).

Although discovery of the circulation had suggested the idea of transfusion, indications for the procedure remained uninformed. Transfusion was still thought to alter behavior and possibly achieve rejuvenation. The blood of young dogs made old dogs seem frisky; the blood of lions was proposed as a cure for cowardice; and, five months later, Arthur Coga would receive a transfusion of sheep blood because of its presumed “cooling” effect. Denis used animal blood for transfusion because he thought it was “less full of impurities”<sup>17</sup>:

Sadness, Envy, Anger, Melancholy, Disquiet and generally all the Passions, are as so many causes which trouble the life of man, and corrupt the whole substance of the blood: Whereas the life of Brutes is much more regular, and less subject to all these miseries.

It is thus ironic that the symptoms of the first transfusion recipient may have been explained in part by profound anemia; the single transfusion of lamb blood may have produced temporary amelioration owing to increased oxygen transport. Denis described the case as follows:<sup>17</sup>

On the 15 of this Moneth, we hapned upon a Youth aged between 15 and 16 years, who had for above two moneths bin tormented with a contumacious and violent fever, which obliged his Physitians to bleed him 20 times, in order to asswage the excessive heat.

Before this disease, he was not observed to be of a lumpish dull spirit, his memory was happy enough, and he seem'd cheerful and nimble enough in body; but since the violence of this fever, his wit seem'd wholly sunk, his memory perfectly lost, and his body so heavy and drowsie that he was not fit for anything. I beheld him fall asleep as he sate at dinner, as he was eating his Breakfast, and in all occurrences where men seem most unlikely to sleep. If he went to bed at nine of the clock in the Evening, he needed to be wakened several times before he could be got to rise by nine the next morning, and he pass'd the rest of the day in an incredible stupidity.

I attributed all these changes to the great evacuations of blood, the Physitians had been oblig'd to make for saving his life.

Three ounces of the boy's blood were exchanged for 9 ounces of lamb arterial blood. Several hours later the boy arose, and "for the rest of the day, he spent it with much more liveliness than ordinary." Thus, the first human transfusion, which was heterologous, was accomplished without any evident unfavorable effect.

This report stimulated a firestorm of controversy over priority of discovery.<sup>18,19</sup> The letter by Denis was published in the *Transactions* on July 22, 1667, while the editor, Henry Oldenburg, was imprisoned in the Tower of London. Oldenburg, following some critical comments concerning the Anglo-Dutch War then in progress (1665–1667), had been arrested under a warrant issued on June 20, 1667. After his release two months later, Oldenburg returned to his editorial post and found the letter published in his absence. He took offense at Denis's opening statement, which claimed that the French had conceived of transfusion "about ten years ago, in the illustrious Society of Virtuosi" (Figure 1.1). This seemed to deny the English contributions to the field. Oldenburg cited these omissions in an issue of the *Transactions* published September 23, 1667, "for the Months of July, August, and September." By numbering this issue 27 and beginning pagination with 489, Oldenburg attempted to suppress the letter by Denis.<sup>18</sup> However, as is evident, this did not ultimately succeed. Nonetheless, subsequent events created even greater difficulties for Denis.

Although the first two subjects who underwent transfusion by Denis were not adversely affected, the third and fourth recipients died. The death of the third subject was easily attributable to other causes. However, the fourth case initiated a sequence of events that put an end to transfusion for 150 years.

Anthony du Mauroy was a 34-year-old man who suffered from intermittent bouts of maniacal behavior. On December 19, 1667, Denis and his assistant Paul Emmerez removed 10 ounces of the man's blood and replaced it with 5 or 6 ounces of blood from the femoral artery of a calf. Failing to note any apparent improvement, they repeated the transfusion 2 days later. After the second transfusion, du Mauroy experienced a classic transfusion reaction:<sup>20</sup>

His pulse rose presently, and soon after we observ'd a plentiful sweat over all his face. His pulse varied extremely at this instant, and he complain'd of great pains in his kidneys and that he was not well in his stomach.

Du Mauroy fell asleep at about 10 o'clock in the evening. He awoke the following morning and "made a great glass full of urine, of a color as black, as if it had been mixed with the soot of chimneys."<sup>20</sup> Two months later, the patient again became maniacal, and his wife again sought transfusion therapy. Denis was reluctant but finally gave in to her urgings. However, the transfusion could not be accomplished, and du Mauroy died the next evening.

The physicians of Paris strongly disapproved of the experiments in transfusion. Three of them approached du Mauroy's widow and encouraged her to lodge a malpractice complaint against Denis. She instead went to Denis and attempted to extort money from him in return for her silence. Denis refused and filed a complaint before

the Lieutenant in Criminal Causes. During the subsequent hearing, evidence was introduced to indicate that Madame du Mauroy had poisoned her husband with arsenic. In a judgment handed down at the Chatelet in Paris on April 17, 1668, Denis was exonerated, and the woman was held for trial. The court also stipulated "that for the future no transfusion should be made upon any human body but by the approbation of the Physicians of the Parisian Faculty."<sup>21</sup> At this point, transfusion research went into decline, and within 10 years it was prohibited in both France and England.

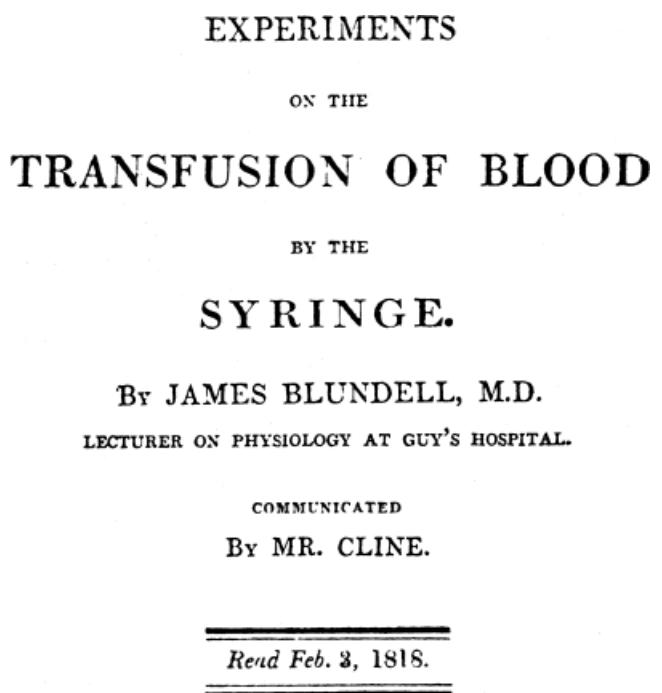

## The beginnings of modern transfusion

After the edict that ended transfusion in the seventeenth century, the technique lay dormant for 150 years. Stimulated by earlier experiments by Leacock, transfusion was "resuscitated" and placed on a rational basis by James Blundell (1790–1877), a London obstetrician who had received his medical degree from the University of Edinburgh.<sup>22</sup> Soon after graduation, Blundell accepted a post in physiology and midwifery at Guy's Hospital. It was there that he began the experiments on transfusion that led to its rebirth. The frequency of postpartum hemorrhage and death troubled Blundell. In 1818, he wrote:<sup>23</sup>

A few months ago I was requested to visit a woman who was sinking under uterine hemorrhage. . . . Her fate was decided, and notwithstanding every exertion of the medical attendants, she died in the course of two hours.

Reflecting afterwards on this melancholy scene . . . I could not forbear considering, that the patient might very probably have been saved by transfusion; and that . . . the vessels might have been replenished by means of the syringe with facility and promptitude.

This opening statement introduced Blundell's epoch-making study titled "Experiments on the Transfusion of Blood by the Syringe"<sup>23</sup> (see Figure 1.2). Blundell described in detail a series

**Figure 1.2** The beginnings of modern transfusion. Source: Blundell (1818).<sup>23</sup> Figure 01, p 01 / With permission of The Royal Society of Medicine.

of animal experiments. He demonstrated that a syringe could be used effectively to perform transfusion, that the lethal effects of arterial exsanguination could be reversed by the transfusion of either venous or arterial blood, and that the injection of 5 drams (20 cc) of air into the veins of a small dog was not fatal but transfusion across species ultimately was lethal to the recipient.<sup>23</sup> Thus, Blundell was the first to clearly state that only human blood should be used for human transfusion. The latter conclusion was confirmed in France by Dumas and Prevost, who demonstrated that the infusion of heterologous blood into an exsanguinated animal produced only temporary improvement and was followed by death within six days.<sup>24</sup> These scientific studies provided the basis for Blundell's subsequent efforts in clinical transfusion.

The first well-documented transfusion with human blood took place on September 26, 1818.<sup>25</sup> The patient was an extremely emaciated man in his mid-thirties who had pyloric obstruction caused by carcinoma. He received 12 to 14 ounces of blood in the course of 30 or 40 minutes. Despite initial apparent improvement, the patient died two days later. Transfusion in the treatment of women with postpartum hemorrhage was more successful. In all, Blundell performed 10 transfusions, of which 5 were successful. Three of the unsuccessful transfusions were performed on moribund patients, the fourth was performed on a patient with puerperal sepsis, and the fifth was performed on the aforementioned patient with terminal carcinoma. Four of the successful transfusions were given for postpartum hemorrhage, and the fifth was administered to a boy who bled after amputation.<sup>22</sup> Blundell also devised various instruments for the performance of transfusion. They included an "impellor," which collected blood in a warmed cup and "impelled" the blood into the recipient via an attached syringe, and a "gravitator"<sup>26</sup> (Figure 1.3), which received blood and delivered it by gravity through a long vertical cannula.

The writings of Blundell provided evidence against the use of animal blood in humans and established rational indications for transfusion. However, the gravitator (Figure 1.3) graphically demonstrated the technical problems that remained to be solved. Blood from the donor, typically the patient's husband, flowed into a funnel-like device and down a flexible cannula into the patient's vein "with as little exposure as possible to air, cold, and inanimate surface."<sup>25</sup> The amount of blood transfused was estimated from the amount spilled into the apparatus by the donor. In this clinical atmosphere, charged with apprehension and anxiety, the amount of blood issuing from a donor easily could be overstated. Clotting within the apparatus then ensured that only a portion of that blood actually reached the patient. Thus, the amount of blood actually transfused may have been seriously overestimated. This may explain the apparent absence of transfusion reactions. Alternatively, reactions may have been unrecognized. Patients who underwent transfusion frequently were agonal. As Blundell stated, "It seems right, as the operation now stands, to confine transfusion to the first class of cases only, namely, those in which there seems to be no hope for the patient, unless blood can be thrown into the veins."<sup>26</sup> Under these circumstances, "symptoms" associated with an "unsuccessful" transfusion might be ascribed to the agonal state rather than the transfusion itself. For a time, the problem of coagulation during transfusion was circumvented by the use of defibrinated blood. This undoubtedly increased the amount of blood actually transfused. However, there were numerous deaths. Interestingly, these deaths were attributed to intravascular coagulation when in actuality they

### OBSERVATIONS

ON

### TRANSFUSION OF BLOOD.

BY DR. BLUNDELL.

*With a Description of his Gravitator.\**

STATES of the body really requiring the infusion of blood into the veins are probably rare; yet we sometimes meet with cases in which the patient must die unless such operation can be performed; and still more frequently with cases which seem to require a supply of blood, in order to prevent the ill health which usually arises from large losses of the vital fluid, even when they do not prove fatal.

\* The instrument is manufactured by Messrs. Maw, 55, Aldermanbury.

In the present state of our knowledge respecting the operation, although it has not been clearly shown to have proved fatal in any one instance, yet not to mention possible, though unknown risks, inflammation of the arm has certainly been produced by it on one or two occasions; and therefore it seems right, as the operation now stands, to confine transfusion to the first class of cases only, namely, those in which there seems to be no hope for the patient, unless blood can be thrown into the veins.

The object of the Gravitator is, to give help in this last extremity, by transmitting the blood in a regulated stream from one individual to another, with as little exposure as may be to air, cold, and inanimate surface; ordinary venesection being the only operation performed on the person who emits the blood; and the insertion of a small tube into the vein usually laid open in bleeding, being all the operation which it is necessary to execute on the person who receives it.

The following plate represents the whole apparatus connected for use and in action:—

Tab. I.

were probably fatal hemolytic reactions caused by the infusion of incompatible blood.<sup>27</sup>

Transfusion at the end of the nineteenth century, therefore, was neither safe nor efficient. The following description, written in 1884, illustrates this point:<sup>28</sup>

Students, with smiling faces, are rapidly leaving the theatre of one of our metropolitan hospitals. The most brilliant operator of the day has just performed immediate transfusion with the greatest success. By means of a very beautiful instrument, the most complex and ingenious that modern science has yet produced, a skilful surgeon has transfused half a pint, or perhaps a pint, of blood from a healthy individual to a fellow creature profoundly collapsed from the effects of severe hemorrhage. Some little difficulty was experienced prior to the operation, as one of the many stop-cocks of the transfusion apparatus was found to work stiffly; but this error was quickly rectified by a mechanic in attendance. Towards the close of the operation the blood-donor, a powerful and heavy young man, swooned. Two porters carried him on a stretcher into an adjoining room.

In the latter half of the nineteenth century, there were many attempts to render transfusion a more predictable and less arduous procedure. In 1869, Braxton-Hicks,<sup>29</sup> using blood anticoagulated with phosphate solutions, performed a number of transfusions on women with obstetric bleeding. Many of the

patients were in extremis and ultimately all died. Unfortunately, a detailed description of terminal symptoms was not provided.<sup>29</sup> Some investigators attempted to rejuvenate animal-to-human transfusion, and Oscar Hasse persisted in this approach despite disastrous results. Studies by Emil Ponfick and by Leonard Landois finally put an end to this practice. Ponfick, in carefully controlled studies, confirmed the lethality of heterologous transfusion and identified the resulting hemoglobinuria along with its donor erythrocyte source. Landois documented the poor results of animal-to-human transfusion and demonstrated the lysis of sheep erythrocytes by human serum in vitro.<sup>8</sup>

Frustration with blood as a transfusion product led to even more bizarre innovations. From 1873 to 1880, cow, goat, and even human milk was transfused as a blood substitute.<sup>30</sup> The rationale derived from an earlier suggestion that the fat particles of milk could be converted into blood cells. Milk transfusion was particularly popular in the United States,<sup>30</sup> where the practice of animal-to-human transfusion was recorded as late as 1890.<sup>31</sup> Fortunately, these astonishing practices were discontinued when saline solutions were introduced as "a life-saving measure" and "a substitute for the transfusion of blood."<sup>32</sup> A passage from an article written by Bull in 1884<sup>32</sup> is particularly instructive:

The danger from loss of blood, even to two-thirds of its whole volume, lies in the disturbed relationship between the calibre of the vessels and the quantity of the blood contained therein, and not in the diminished number of red blood-corpuscles; and . . . This danger concerns the volume of the injected fluids also, it being a matter of indifference whether they be albuminous or containing blood corpuscles or not.

Mercifully, volume replacement with saline solutions deflected attention from the unpredictable and still dangerous practice of blood transfusion. Accordingly, transfusions were abandoned until interest was rekindled by the scientific and technical advances of the early twentieth century.

### The twentieth century

The twentieth century was ushered in by a truly monumental discovery. In 1900, Karl Landsteiner (1868–1943) observed that the sera of some persons agglutinated the red blood cells of others. This study, published in 1901 in the *Wiener Klinische Wochenschrift*<sup>33</sup> (Figure 1.4), showed for the first time the cellular differences in individuals from the same species. In his article, Landsteiner wrote:<sup>34</sup>

In a number of cases (Group A) the serum reacts on the corpuscles of another group (B), but not, however, on those of group A, while, again, the corpuscles of A will be influenced likewise by serum B. The serum of the third group (C) agglutinates the corpuscles of A and B, while the corpuscles of C will not be influenced by the sera of A and B. The corpuscles are naturally apparently insensitive to the agglutinins which exist in the same serum.

menschlichen Blutes.

Von Dr. Karl Landsteiner, Assistenten am pathologisch-anatomischen  
Institute.

Figure 1.4 Landsteiner's description of blood groups. Source: Landsteiner (1901).<sup>33</sup> With permission of ScienceOpen.

With the identification of blood groups A, B, and C (subsequently renamed group O) by Landsteiner and of group AB by Decastello and Sturli,<sup>35</sup> the stage was set for the performance of safe transfusion. For this work, Landsteiner somewhat belatedly received the Nobel Prize in 1930. But even that high recognition does not adequately express the true magnitude of Landsteiner's discovery. His work was like a burst of light in a darkened room. He gave us our first glimpse of immunohematology and transplantation biology and provided the tools for important discoveries in genetics, anthropology, and forensic medicine. Viewed from this perspective, the identification of human blood groups is one of only a few scientific discoveries of the twentieth century that changed all of our lives.<sup>34</sup> Yet the translation of Landsteiner's discovery into transfusion practice took many years.

At the turn of the twentieth century, the effective transfer of blood from one person to another remained a formidable task. Clotting, still uncontrolled, quickly occluded transfusion devices and frustrated most efforts. In 1901, the methods used in transfusion were too primitive to demonstrate the importance of Landsteiner's discovery. Indeed, the study of in vitro red cell agglutination may have seemed rather remote from the technical problems that demanded attention. An intermediate step was needed before the importance of Landsteiner's breakthrough could be perceived and the appropriate changes could be incorporated into practice. This process was initiated by Alexis Carrel (1873–1944), another Nobel laureate, who developed a surgical procedure that allowed direct transfusion through an arteriovenous anastomosis. Carrel<sup>36</sup> introduced the technique of end-to-end vascular anastomosis with triple-threaded suture material. This procedure brought the ends of vessels in close apposition and preserved luminal continuity, thus avoiding leakage or thrombosis. This technique paved the way for successful organ transplantation and brought Carrel the Nobel Prize in 1912. It was also adapted by Carrel<sup>37</sup> and others<sup>38,39</sup> to the performance of transfusion. Crile<sup>38</sup> introduced the use of a metal tube to facilitate placement of sutures, and Bernheim<sup>39</sup> used a two-piece cannula to unite the artery to the vein (Figure 1.5). Because all of these procedures usually culminated in the sacrifice of the two vessels, they were not performed frequently. Direct transfusion was also fraught with danger. In a passage written two decades later, the procedure was recalled in the following manner:<sup>40</sup>

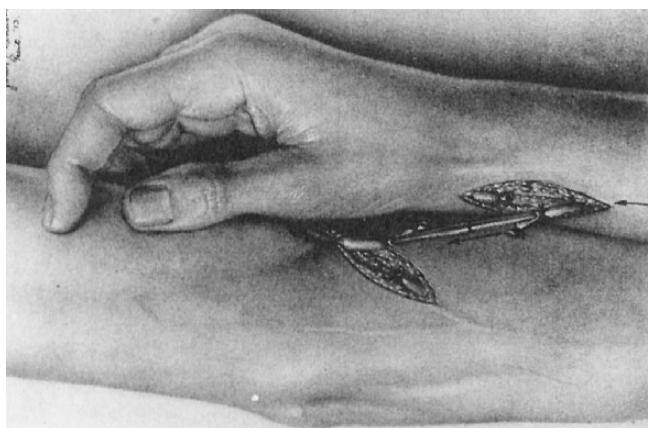

Figure 1.5 Direct transfusion by means of arteriovenous anastomosis through the two-pieced cannula of Bernheim. Source: Bernheim (1917).<sup>39</sup> With permission of J. B. Lippincott & Company.

## A CASE OF FATAL HEMOLYSIS FOLLOWING DIRECT TRANSFUSION OF BLOOD BY ARTERIOVENOUS ANASTOMOSIS.\*

The direct artery to vein anastomosis was the best method available but was often very difficult or even unsuccessful. And, what was almost as bad, one never knew how much blood one had transfused at any moment or when to stop (unless the donor collapsed). (I remember one such collapse in which the donor almost died—and the surgeon needed to be revived.)

Despite these many difficulties, direct transfusion through an arteriovenous anastomosis for the first time efficiently transferred blood from one person to another. The process also disclosed fatal hemolytic reactions that were undeniably caused by transfusion<sup>41</sup> (Figure 1.6). However, the relation of these fatal reactions to Landsteiner's discovery was not recognized until Reuben Ottenberg (1882–1959) demonstrated the importance of compatibility testing.

Ottenberg's interest in transfusion began in 1906 while he was an intern at German (now Lenox Hill) Hospital in New York. There, Ottenberg learned of Landsteiner's discovery and in 1907 began pretransfusion compatibility testing.<sup>42</sup> Ottenberg accepted an appointment at Mount Sinai Hospital the next year and continued his studies on transfusion. In 1913, Ottenberg published the report that conclusively demonstrated the importance of preliminary blood testing for the prevention of transfusion "accidents"<sup>43</sup> (Figure 1.7). This was not Ottenberg's only contribution. He observed the Mendelian inheritance of blood groups,<sup>44</sup> and he was the first to recognize the relative unimportance of donor

## ACCIDENTS IN TRANSFUSION

THEIR PREVENTION BY PRELIMINARY BLOOD EXAMINATION: BASED ON AN EXPERIENCE OF ONE HUNDRED TWENTY-EIGHT TRANSFUSIONS \*

REUBEN OTTENBERG, M.D.

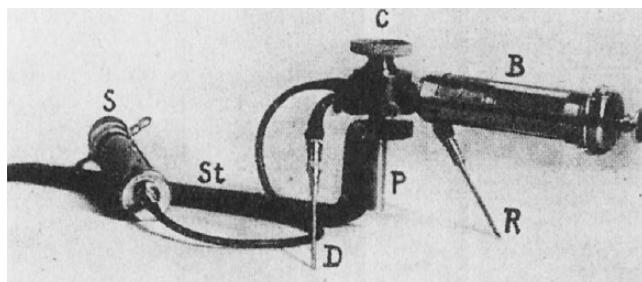

AND

DAVID J. KALISKI, M.D.

NEW YORK

Accidents following transfusion have been sufficiently frequent to make many medical men hesitate to advise transfusion, except in desperate cases. It has been our opinion since we began making observations on this question in 1908 that such accidents could be prevented by careful preliminary tests, leading to the exclusion of agglutinative or hemolytic donors. Our observations on over 125 cases have confirmed this view and we believe that untoward symptoms can be prevented with absolute certainty.

**Figure 1.7** Report of the importance of testing before transfusion. Source: Ottenberg and Kaliski (1913).<sup>43</sup> Figure 01, p 01 / With permission of American Medical Association.

antibodies and consequently the "universal" utility of type O blood donors.<sup>45</sup>

Further advances in immunohematology were to occur in succeeding decades. The M, N, and P systems were described in the period between 1927 and 1947.<sup>46</sup> The Rh system was discovered in connection with an unusual transfusion reaction. In 1939, Levine and Stetson<sup>47</sup> described an immediate reaction in a group O woman who had received her husband's group O blood soon after delivery of a stillborn fetus with erythroblastosis. This sequence of events suggested that the infant had inherited a red cell agglutininogen from the father that was foreign to the mother. At about the same time, Landsteiner and Wiener<sup>48</sup> harvested a rhesus monkey red cell antibody from immunized guinea pigs and rabbits. This antibody agglutinated 85% of human red cell samples (Rh-positive) and left 15% (Rh-negative) unaffected. When the experimentally induced antibody was tested in parallel with the serum from Levine's patient, a similar positive and negative distribution was observed, and the Rh system had been discovered. Other red cell antigen systems were subsequently described, but when Rh immunoglobulin was introduced as a preventive measure for hemolytic disease of the newborn, it became one of the major public health advances of the century.

Despite the introduction of compatibility testing by Ottenberg, transfusion could not be performed frequently as long as arteriovenous anastomosis remained the procedure of choice. Using this method, Ottenberg needed five years (Figure 1.7) to accumulate the 128 transfusions he reported in his study on pretransfusion testing.<sup>43</sup> New techniques, such as Unger's two-syringe method introduced in 1915<sup>49</sup> (Figure 1.8), eventually put an end to transfusion by means of arteriovenous anastomosis. However, transfusions did not become commonplace until anticoagulants were developed and direct methods of transfusion were rendered obsolete.

## Anticoagulants, the blood bank, and component therapy

The anticoagulant action of sodium citrate completely transformed the practice of transfusion. Early reports from Belgium<sup>50</sup> and Argentina<sup>51</sup> were followed by the work of Lewisohn<sup>52</sup> that established the optimal citrate concentration for anticoagulation. The work of Weil<sup>53</sup> then demonstrated the feasibility of refrigerated storage. Subsequently, Rous and Turner<sup>54</sup> developed the anticoagulant solution that was used during World War I.<sup>55</sup> Despite its very large volume, this solution remained the anticoagulant of choice until World War II, when Loutit and Mollison<sup>56</sup> developed an acid-citrate-dextrose (ACD) solution. Used in a ratio of 70 mL ACD to 450 mL blood, ACD provided 3–4 weeks of preservation of a more concentrated red

cell infusion. Thus, the two world wars were the stimuli for the development of citrate anticoagulants and the introduction of indirect transfusion.<sup>46</sup> For the first time, the donation process could be separated, in time and place, from the actual transfusion. Blood drawn and set aside now awaited the emergence of systems of storage and distribution. Again, it was the provision of medical support during armed conflict that stimulated these developments.

A blood transfusion service, organized by the Republican Army during the Spanish Civil War (1936–1939), collected 9000 L of blood in citrate-dextrose anticoagulant for the treatment of battle casualties.<sup>57</sup> At about that same time, Fantus<sup>58</sup> began operation of the first hospital blood bank at Cook County Hospital in Chicago. His interest had been stimulated by Yudin's report<sup>59</sup> on the use of cadaveric blood in Russia. Apart from certain scruples attached to the use of cadaveric blood, Fantus reasoned that a transfusion service based on such a limited source of supply would be impractical. Accordingly, he established the principle of a "blood bank" from which blood could be withdrawn, provided it had previously been deposited. As Fantus<sup>58</sup> himself stated, "[J]ust as one cannot draw money from a bank unless one has deposited some, so the blood preservation department cannot supply blood unless as much comes in as goes out. The term 'blood bank' is not a mere metaphor." The development of anticoagulants and the concept of blood banks provided an infrastructure upon which a more elaborate blood services organization could be built. World War II was the catalyst for these further developments.

At the beginning of World War II, blood procurement programs were greatly expanded.<sup>46</sup> In Great Britain, an efficient system had been developed through the organization of regional centers. When the war started, these centers, already in place, were able to increase their level of operation. In the United States, the use of plasma in the management of shock had led to the development of plasma collection facilities.<sup>60</sup> The efficient long-term storage of plasma had been further facilitated by the process of lyophilization developed by Flosdorf and Mudd and the introduction of ABO-independent "universal" plasma produced by pooling several thousand units of plasma.<sup>61</sup> In 1940, the United States organized a program for the collection of blood and the shipment of plasma to Europe. The American Red Cross, through its local chapters, participated in the project, which collected 13 million units by the end of the war.<sup>46</sup>

The national program of the American Red Cross ceased at the end of the war. However, many of the local chapters continued to help recruit donors for local blood banks, and in 1948, the first regional Red Cross blood center was begun in Rochester, New York. By 1949–1950 in the United States, the blood procurement system included 1500 hospital blood banks, 1100 of which performed all blood bank functions. There were 46 nonhospital blood banks and 31 Red Cross regional blood centers. By 1962, these numbers had grown to 4400 hospital blood banks, 123 nonhospital blood banks, and 55 American Red Cross regional blood centers, and the number of units collected had grown to between 5 and 6 million per year.<sup>62</sup>

During this time, blood was collected through steel needles and rubber tubing into rubber-stoppered bottles. After washing and resterilization, the materials were reused. On occasion, "vacuum bottles" were used to speed up the collection. However, the high incidence of pyrogenic reactions soon led to the development of disposable plastic blood collection equipment.

In a classic article written in 1952, Walter and Murphy<sup>63</sup> described a closed, gravity technique for whole blood preservation. They used a laminar flow phlebotomy needle, an interval donor tube, and a collapsible bag of polyvinyl resin designed so that the unit could be

assembled and ready for use after sterilization with steam. The polyvinyl resin was chemically inert to biologic fluids and nonirritating to tissue. Soon thereafter, Gibson *et al.*<sup>64</sup> demonstrated that plastic systems were more flexible and allowed removal of plasma after sedimentation or centrifugation. In time, glass was replaced with plastic, and component therapy began to emerge. This development was enhanced by the US military's need to reduce the weight and breakage of blood bottles during shipment in the Korean War.

Component and derivative therapy began during World War II, when Edwin J. Cohn and his collaborators developed the cold ethanol method of plasma fractionation.<sup>65</sup> As a result of their work, albumin, globulin, and fibrinogen became available for clinical use. As plastic equipment replaced glass, component separation became a more widespread practice, and the introduction of automated cell separators provided even greater capabilities in this area.

Clotting factor concentrates for the treatment of patients with hemophilia, and other hemorrhagic disorders were also developed during the postwar era. Although antihemophilic globulin had been described in 1937,<sup>66</sup> unconcentrated plasma was the only therapeutic material until Pool discovered that Factor VIII could be harvested in the cryoprecipitable fraction of blood.<sup>67</sup> This resulted in the development of cryoprecipitate, which was introduced in 1965 for the management of hemophilia. Pool showed that cryoprecipitate could be made in a closed-bag system and urged its harvest from as many donations as possible. The development of cryoprecipitate and other concentrates was the dawn of a golden age in the care of patients with hemophilia. Self-infusion programs, made possible by technologic advances in plasma fractionation, allowed early therapy and greatly reduced disability and unemployment. This golden age came abruptly to an end with the appearance of the AIDS virus.

### Transfusion in the age of technology

In contrast to the long ledger of lives lost in previous centuries because of the lack of blood, transfusion in the twentieth century saved countless lives. In 1937, during those early halcyon days of transfusion, Ottenberg wrote:<sup>40</sup>

Today transfusion has become so safe and so easy to do that it is seldom omitted in any case in which it may be of benefit. Indeed the chief problem it presents is the finding of the large sums of money needed for the professional donors who now provide most of the blood.

It is ironic that Ottenberg's statement should refer to paid donors and foreshadow difficulties yet to come. However, experience to that point had not revealed the problem of viral disease transmission. More transfusions would have to be administered before that problem would be perceived.

After the introduction of anticoagulants, blood transfusions were given in progressively increasing numbers. At Mount Sinai Hospital in New York, the number of blood transfusions administered between 1923 and 1953 increased 20-fold<sup>68,69</sup> (Table 1.1). This increase was particularly notable after the establishment of blood banks. It was during this period that Beeson wrote his classic description of transfusion-transmitted hepatitis.<sup>70</sup> He had been alerted to the problem by the outbreaks of jaundice that followed inoculation programs with human serum during World War II. Thus, blood transfusion entered a new era. Blood components not only saved lives but also transmitted disease. The discovery of the Australian antigen<sup>71</sup> and the subsequent definition of hepatitis A virus and B virus (HBV) still left residual non-A and non-B diseases,<sup>72</sup> a gap that has been largely filled by the discovery of the

hepatitis C virus (HCV).<sup>73</sup> However, it was the outbreak of AIDS that galvanized public attention to blood transfusion.

The AIDS epidemic was first recognized in the United States, and the first case of AIDS associated with transfusion was observed in a 20-month-old infant.<sup>74</sup> Subsequently, the suspicion that AIDS could be transmitted by means of transfusion was confirmed.<sup>75</sup>

The human immunodeficiency virus (HIV) was identified,<sup>76</sup> and an effective test to detect the HIV antibody was developed.<sup>76</sup>

## Concern for blood safety

Since 1943, transfusion therapy has been shadowed by the specter of disease transmission. In that year, Beeson described post-transfusion hepatitis and unveiled a problem that has grown with time. As transfusion increased, so did disease transmission. In 1962, the connection between paid donations and post-transfusion hepatitis was made.<sup>77</sup> A decade later, the National Blood Policy mandated a voluntary donation system in the United States. And yet, blood usage continued to increase.

Concern about post-transfusion hepatitis was not sufficient to decrease the number of transfusions. Although the use of whole blood declined as blood components became more popular, total blood use in the United States doubled between 1971 and 1980

(Table 1.2).<sup>78–85</sup> This pattern changed as the emergence of AIDS exposed all segments of society to a revealing light.

AIDS probably arose in Africa in the 1960s and spread quietly for years before it was detected. By 1980, an estimated 100,000 persons were infected, and by 1981, when the first cases were reported, a worldwide pandemic lay just beneath the surface. The initial response of the public and officials seemed trifling and insufficient as the outbreak grew to proportions few had foreseen. Criticism was levied against the news media for initially ignoring the story, the government for delay in acknowledging the problem, gay civil rights groups for resistance to epidemiologic measures, research scientists for unseemly competition, blood services for delayed response in a time of crisis, and the US Food and Drug Administration (FDA) for inadequate regulatory activity. Historians with the perspective of time will determine whether there really were more villains than the virus itself.<sup>89</sup>

The realization that transfusion can transmit an almost invariably fatal disease had a chilling effect on the public. Two major changes in blood services have occurred in the aftermath of the AIDS epidemic. The FDA, using pharmaceutical manufacturing criteria not “tailored to . . . blood banks,” became more aggressive in regulatory actions against blood collection establishments.<sup>90</sup> And, finally, blood use moderated for approximately 10 years. Through the 1980s and early 1990s, red cell and plasma transfusion peaked and began to stabilize (Table 1.2). Only platelet use and human progenitor cell transplantation, driven by the demands of cancer chemotherapy, continued to increase.<sup>78–85</sup> Educational programs to encourage judicious use of blood have been initiated, and they have been favorably received by practicing physicians. Use of red cells and plasma fell from 2008 to 2011. This was a combined impact of the great recession reducing healthcare utilization and the widespread use of patient blood management programs intended to reduce blood transfusion. This represents the first time since the end of the Second World War that the growth in transfusion of blood products in the United States and other developed countries stopped and was reversed for a sustained period.

Relentless public pressure for a “zero-risk” blood supply resulted in dividends through continued scientific and technologic improvements. Enhanced sensitivity and better use of serologic testing, along with improved scrutiny of donors, resulted in major reductions in risk of transmitted disease by the mid-1990s.<sup>91</sup> Discovery that pools of units subjected to nucleic acid testing almost closed the window for HIV and HCV virus resulted in the application of this testing for both whole blood and plasma donations beginning between 1998 and 2000.<sup>91,92</sup> This, combined with virus reduction and inactivation of the final product, resulted in plasma derivatives that have not transmitted AIDS or hepatitis since 1994.<sup>93</sup> For whole blood and platelet components, risks have become low. Pathogen reduction has driven the risks lower for plasma and platelets, and very low for plasma-derived therapies such as immune globulin.

With the reduction in the risk of viral transmission, the focus in the developed world has shifted to transfusion-related acute lung injury (TRALI)—possibly from recipient-directed leukocyte antibodies and lipid mediators in transfused plasma—and bacterial infection primarily occurring in room-temperature stored platelets. In order to make incremental gains against these risks, the use of male plasma only and the culture of platelets before they are released have been implemented. The 2011 blood utilization survey indicated a 28.8% reduction in TRALI, suggesting a significant breakthrough with regard to this risk.<sup>85</sup> Geographic exclusions have been aimed at reducing the potential for variant

Creutzfeldt–Jakob disease (vCJD) transmission by transfusion, although in the United States such occurrence seems highly unlikely. In many countries, universal leukocyte reduction has been a response to the vCJD risk. Ironically, universal application of leukocyte reduction is probably ineffective for vCJD but has stimulated controversy over its use for preventing other problems.<sup>94</sup>

Finally, focus on the understanding, management, and prevention of medical errors in general might lead to progress against remaining nemesis hemolytic transfusion reactions caused by mis-transfusion. Bar code technology at the bedside, commonly applied to prevent errors in medication administration, has shown efficacy in reducing transfusion errors.<sup>95</sup> Radiofrequency identification shows further promise in error-prone situations such as operating rooms.<sup>96</sup> Transfusion safety officers and hemovigilance systems are other initiatives that have been instituted.

“Zero risk” has still not been achieved. Emerging global infections such as West Nile virus, Chagas disease, and Chikungunya virus remain future potential threats and have encouraged further test development and implementation of strategies for pathogen reduction.

## Current status

As shown in Figure 1.9, there is a complex sequence of events that occurs today between recruitment of the donor and the final hemovigilance and quality reviews. In the developed world, increasing sophistication of methods to ensure safety and availability increased the cost of blood components to hospitals up to 2013 when a leukocyte-reduced red cell in the United States cost hospitals a mean of \$228, an apheresis platelet unit \$557, a unit of fresh frozen plasma \$63.<sup>98</sup> Blood usage, as measured by a national utilization study, peaked in 2008 before the financial crisis. It then began a steady, slow decline. The latest survey available of the 2017 utilization suggested the decline had slowed.<sup>88</sup> During this time, pathogen reduction began to be introduced. In addition, new data suggested cold-stored platelets might be superior to room-temperature stored platelets in some situations because of better immediate function, and whole blood became preferred by some centers for trauma and other massively bleeding patients. This was a “back to the 1970s” scenario. Thus, new complexities were introduced into the blood operations which had simplified in the 1980s and 1990s to component preparation to red cells and plasma for either transfusion or further manufacture into derivatives with platelets predominantly

**Figure 1.9** The blood donation and transfusion chain: from donor arm to patient vein. (2015).<sup>97</sup> Reproduced with permission of Lippincott, Williams & Wilkins.

from apheresis. It is not clear where blood utilization is headed in a postpandemic world.

In the developed world, no cost has usually been spared in meeting public demands for blood safety. In the underdeveloped world, the picture is quite different. The greatest blood need is for women hemorrhaging during childbirth, infants and children with anemia caused by malaria, and victims of trauma. In 80 of 172 countries responding to a World Health Organization (WHO) survey, less than 1% of the population donate blood. In sub-Saharan Africa, fewer than 3 million units of blood are collected annually for a population of more than 700 million. Of the 148 countries reporting data to WHO, 41 are unable to screen for minimum safety (HIV, HBV, HCV, and syphilis). WHO estimates that unsafe blood in these countries results in 16 million new infections with HBV, 5 million with HCV, and 160,000 with HIV each year (accounting for 5–10% of the world's HIV infections). Fortunately, there is progress in some nations in achieving an all-volunteer supply and minimum screening. Thus, there are two drastically different pictures of blood safety and availability worldwide.<sup>99</sup>

## Organization of blood services in the United States

Blood collection for transfusion in the United States is accomplished by an eclectic system that has evolved since World War II. Close to half of the blood for transfusion in the United States has historically been collected by the American Red Cross ([www.redcross.org](http://www.redcross.org)). Community blood centers were established nationwide in areas where the Red Cross did not operate. Most of these non-profit collection agencies are now loosely affiliated with a trade organization known as America's Blood Centers. In recent years, consolidation among regional blood centers has been driven by the impact of reduced transfusions on the blood center business model. This has added several larger national blood programs independent of the American Red Cross such as Vitalant, Versiti, New York Blood Center Enterprises, and OneBlood.

Many blood centers are affiliated with national blood banking organizations, including AABB (founded in 1947—see [www.aabb.org](http://www.aabb.org)). The “voluntary” standards set by the AABB are so well regarded that these often become the standard of care in North America and in other areas of the world, even without government regulatory intervention.

Many hospitals have found it impractical to maintain hospital-based collections. Although hospital-based collection still exists in the United States, the increasing cost, external regulation, shortage of medical technologists, and variable supply and demand have progressively shifted collection activities to blood centers. However, the proportion of blood collected by hospitals in 2011 remained relatively constant when compared to 2004 (6.6 vs 6.4%, respectively).<sup>100,101</sup> Even hospitals that collect their own blood usually do not perform donor testing, and out of necessity they maintain a supplemental blood contract with the local blood supplier. The US Department of Defense continues to operate an independent blood services organization for its hospitals as well as its military mission.

Blood components collected for transfusion in the United States are from volunteer donors; in contrast, most plasma for further manufacture into plasma-derived therapies also known as plasma-derived medicinal products (PDMPs) is collected from paid donors in commercial centers.

## Organization of blood services outside the United States

Most high-income countries have adequate blood services, maintaining a full range of donor screening and quality assurance procedures, while producing most of the components needed in the region. However, there exist a wide variety of dissimilar organizational structures that are successful in meeting the transfusion needs of areas served. These models can be centralized or decentralized, governmental, military, private, hospital based, or mixed. For the most part, the local transfusion system reflects the administrative system of each country. For instance, in countries that have strong governmental control, there is often a centralized transfusion system operated by government-run institutions. The World Health Organization (WHO) encourages strong governmental leadership in establishing national transfusion networks.<sup>102</sup> Many countries outside the United States have instituted national blood programs. Overall, the provision of blood services worldwide is heterogeneous and varies with historical development, the socioeconomic development of the region, and the influence of national scientific and political factors.<sup>102</sup>

Donor recruitment is sometimes performed externally to the blood collection agencies. Recruitment is sometimes carried out by independent organizations that have a special relationship with the procurement agency, such as a country's national Red Cross. The International Federation of Blood Donor Organizations was established in 1955 as a support network for donor recruitment ([www.fiods-ifbdo.org](http://www.fiods-ifbdo.org)). Seventy-two nations participate, although there is a notable absence of many English-speaking countries. The goal of the organization is member state self-sufficiency in blood from voluntary, unpaid blood donors, while also improving safety and, in turn, confidence in the national blood supplies by developing minimum standards for donations, inspection, and quality assurance.

In 1975, the 28th World Health Assembly passed a resolution recognizing the value of voluntary blood donation and called on member states to promote national blood transfusion services based on voluntary unpaid donations.<sup>102</sup> Voluntary donation has been a goal for some time as it is perceived as a safer alternative. In 2002, the European Union approved legislation that established comprehensive standards for blood products that included a requirement for voluntary donation.<sup>102</sup> The WHO Global Database on Blood Safety 2011 report presents data from 164 countries representing 92% of the global population.<sup>103</sup> It shows that half of the global blood collection occurs in high-income countries, home to only 15% of the world population. Global blood donations from voluntary unpaid donors increased from 2004 to 2012. Seventy-three countries collect over 90% of their blood supply from voluntary unpaid blood donors. However, 72 countries collect more than 50% of their blood supply from family/replacement or paid donors. Around 1.5 million donations intended for transfusion were collected from paid donors.<sup>104</sup> Nevertheless, countries are increasingly moving toward voluntary blood donation.

WHO recommends that, at minimum, all blood for transfusion should be screened for HIV, hepatitis B, hepatitis C, and syphilis. Twenty-five countries are not able to screen all donated blood for one or more of these infections. Irregular supply of test kits is one of the most commonly reported barriers to screening.<sup>100</sup> Yet, even in countries that are able to screen all of their blood, the risk of transfusion-transmitted infections (TTIs) varies. The prevalence of TTIs in blood donations in high-income countries is considerably lower than in low- and middle-income countries.<sup>4</sup> External quality control assessment is often lacking: whereas 97% of blood-screening

laboratories in high-income countries are monitored, only 33% of middle-income and 16% of low-income countries have external quality assessment.<sup>104</sup>

There is still heterogeneity in the practices that are taken for granted as mandatory in North America, even among the most effective blood services. For instance, in Norway, nucleic acid testing for HIV is not performed on repeat blood donors due to the low incidence in the recruited donor population and the effectiveness of the serological screening.

Low- and middle-income countries often struggle to provide the same level of safety as high-income countries with established blood procurement systems. The costs of procurement and testing of the blood are often prohibitive. For instance, in sub-Saharan Africa, although blood transfusion has a long history,<sup>105</sup> collection services are fragmented. Blood is sometimes in short supply, and safety seldom can be guaranteed.<sup>4</sup>

Some high-income countries such as the United States have implemented a “precautionary principle” that has meant extreme costs for marginal added safety when measured by standards such as quality-adjusted life-years.<sup>106</sup> Many countries simply do not have resources to implement this strategy, even if it were medically justified. In stark contrast to the precautionary principle, blood in some parts of the world is still transfused without testing. In addition, when testing can be done, there may not be resources to notify and counsel donors about positive test results, such as HIV. This provides an opportunity for the world community to make a great impact on global health through collaboration and collegiality. In response, WHO established the Global Collaboration for Blood Safety in 1994, a voluntary partnership of organizations, institutions, associations, agencies, and experts that are concerned with the safety and availability of blood. Many of these functions are now carried out by the WHO Global Blood Safety Network and the WHO Global Forum for Blood Safety (<http://www.who.int/bloodsafety/collaboration/en/>).

Even in the developed world, availability has been a challenge in the past.<sup>107</sup> A clear need is for more group O red cells; populations of non-European ethnicity generally have an increased proportion of group O.<sup>108</sup>

Another approach to maintain adequate availability is to control usage by ensuring that blood is used appropriately. Some US blood centers have been successful in bringing their transfusion medicine expertise into the patient care setting by providing transfusion services to hospitals. The model in Seattle, Washington, has operated for decades.<sup>109,110</sup> In the United Kingdom, liaison systems for blood centers to hospitals employing web-based technology for supply chain management have been introduced.<sup>111,112</sup> In Denmark, success has been reported using the Thromboelastograph (Haemoscope, Niles, IL) hemostatic system to manage coagulopathy in conjunction with treating physicians—something also done in many US hospitals.<sup>113</sup> Other point-of-care tests to assess the state of the coagulation system and tissue oxygenation could also result in more accurately targeted component transfusion. Transfusion medicine specialists in hospitals—whether from pathology groups, blood center staff, or other areas such as anesthesiology or hematology—are critical to the successful use of blood transfusion in patient care. Today, patient blood management has become a new standard for assuring transfusion as indicated based on best evidence. This has significantly reduced blood utilization in developed countries and has been supported by indications that restrictive blood transfusion strategy does not impair outcomes in most cases, although certain subsets of patients such as cancer patients might require a higher

hemoglobin threshold.<sup>114,115</sup> At the same time, the treatment of trauma is returning to what is in effect whole blood for massive bleeding by administering plasma and platelets in proportion to red cells early in the care of victims.<sup>116</sup>

Although some advances in transfusion medicine at the end of the last millennium have been difficult to implement, such as the use of hemoglobin solutions, the field has continued to advance into new areas of stem cell biology, regenerative medicine, and cord blood banking. In addition, transfusion medicine specialists increasingly function in collaboration with surgeons, oncologists, and hematologists in treating the acutely ill patient with complex medical problems. With all the added sophistication, the optimal hemoglobin and platelet triggers and endpoints for transfusion remain unsettled. Clinicians are less likely to use oxygenation transport endpoints to determine the need for red cell transfusion but are beginning to look for other means to assess tissue oxygenation. If a patient's hemoglobin is too high (even when below normal), complications such as thromboembolism can result. Too low an endpoint exposes some patients to the risk of tissue hypoxia. The clearest trend has been away from autologous transfusion, although some medical centers seek bloodless medicine and surgery combining pharmacotherapy (mainly erythropoietin and iron), blood recovery and reinfusion, and conservative triggers and endpoints.<sup>117</sup> More conservative triggers and endpoints for platelet transfusion are becoming accepted, but approaches to alloimmunized patients and bacterial contamination are still in question.<sup>118</sup> Also debatable is whether transfusion, through some poorly quantifiable mechanism such as immunomodulation, confers a poorer prognosis on acutely ill patients.<sup>114</sup>

The COVID-19 pandemic challenged the blood supply in the United States and throughout the world. Blood centers adjusted by increasing collection of convalescent plasma and decreasing other collections to match reduced demand for routine transfusions. As the developed world began to exit the pandemic, demand for convalescent plasma was replaced by demand for routine transfusions leading to shortages. The emergence from the pandemic thus revealed issues with blood supply chain, as it did for other needs. An analysis in the United States suggests the need for stronger national policies, attention to structural issues in the supply chain, and better integration with national and global emergency preparedness efforts.<sup>119</sup>

From ancient times into the new millennium, blood has been a substance that fascinates mankind. Despite unresolved controversies, blood transfusion remains of critical importance in the care of sick patients throughout the world.

## CHAPTER 2

# Disasters and the blood community (including COVID-19)

Ruth Sylvester<sup>1</sup> & Louis M. Katz<sup>2</sup>

<sup>1</sup>USAF (ret), Omaha, NE, USA

<sup>2</sup>ImpactLife Blood Services, Davenport, IA and Medicine and Infectious Diseases, Roy and Lucille Carver College of Medicine, University of Iowa, Iowa City, IA, USA

This chapter is an attempt to explain and link the reader to the resources available to guide the development of an organization wide disaster preparedness process. As such, it is not all inclusive. Given the recent history of abundant catastrophes ranging from earthquakes and tsunamis, extreme weather events and most recently the COVID-19 pandemic, most facilities should already have undertaken this activity, and this information may function as a checklist to be sure that critical elements have all been addressed. Issues presented by the COVID-19 pandemic will be discussed as well.

Disaster preparedness, emergency response, and disaster risk reduction are all terms referring to the process of preparing for and responding to a disaster. These are defined by the World Health Organization as “an occurrence that disrupts the normal functioning of a community or society and causes a level of suffering (human, material, economic, or environmental) that exceeds the capacity of adjustment of the affected community.”<sup>1</sup> Disasters vary in size, and what is a disaster in one area may not be in another. A blood collection facility in Iowa’s tornado alley will have a different list of priorities to confront than one in the hurricane prone Gulf Coast locale or in California near the San Andreas fault. Disasters can be natural events such as earthquakes, weather related like hurricanes or tornadoes or man-made, for example, bombs, industrial accidents, or mass shootings. They can be internal to an organization, the crash of critical IT infrastructure, or external, responding to a mass shooting incident in a center’s or hospital’s service region. Anything that overwhelms local capacity can be considered a disaster.<sup>2</sup>

Management focus has grown from only responding when an event happens to reducing the potential for and impact of disasters. Using a process approach, disaster management addresses the entire cycle from planning, response, and recovery followed by learning from the experience and modifying plans accordingly. We will discuss strategies herein, but tactical and procedural resources relevant to the blood community can be found in the AABB Disaster Operations Handbook.<sup>3</sup>

Transfusion services rarely stand-alone but are generally a component of a hospital or medical complex. As such, transfusion services do not generally develop disaster plans in isolation, rather they contribute to the overall facility’s planning activities. Regardless, it is critical to ensure blood needs, and support are included in all disaster-planning activities.

## Background

Disaster management encompasses pre-event planning, response, and recovery phases. Planning is by nature iterative with improvement dependent on simulations and especially on learning from prior events.<sup>4</sup> The cycle of disaster management includes four functional areas: mitigation, preparedness, response, and recovery. Each should be included in an organization’s disaster planning activities.

*Mitigation* efforts are those that prospectively limit the damage an unpredictable event can cause. Accordingly, preparation for disasters begins with a thorough risk assessment.<sup>5</sup> Risk is the potential for losses (physical, economic, and social) associated with a hazard and can be defined in terms of estimated probability and frequency, causative factors, and locations or areas affected. Such a risk assessment serves to identify the known risks to and vulnerabilities of one’s physical plant, personnel, and operations, and evaluates the likelihood and damage potentials for each threat. Potential internal disasters include fires, flooding from burst water pipes, workplace violence, and hazardous spills. External includes earthquakes, wild-fires, pandemics, hurricanes, and mass casualty incidents. Resources are available to assist in identifying known risks and threats in various countries around the world and can be used in this endeavor.<sup>3,6</sup>

Risks should be eliminated or controlled where possible. This may include adjustments to plant and property design. These initiatives range from site locations to building or retrofitting physical structures to protect employees and assets with redesigns to evolving building codes, flood plain analyses, storm shelters, redundant data pathways, and communications systems. Smaller actions can reduce loss or injury (e.g., securing bookshelves or file cabinets to a wall). All such interventions can contribute to the protection of both physical resources and human capital.

*Preparedness* addresses risks that cannot be minimized by mitigation alone through planning and testing those plans. These efforts should focus on people, assets, and organizational systems that can be affected by different threats. Plans should include actions required if an event directly affects the organization as well as responses needed in support of disasters in the local/regional area. How an organization responds to a mass shooting within the facility versus one in the local area are different and plans must account for both. Finally, plans are words on paper, and staff must be trained on them with simulations and drills. It is the reinforcement from

repetition that hones leader's and staff's ability to think and react quickly during unexpected occurrences during a disaster.

*Response* occurs during the event(s) and is essentially putting predeveloped plans into effect and adjusting the plan to facts on the ground. These are time-sensitive action steps taken by the staff to protect life and property, ensure ongoing safety, and to stabilize operations. These will always involve communication with leadership, staff, "customers" (broadly defined) and often the media, and operational adjustments to maintain the ability to collect process, distribute, and transfuse blood products.

Effective response strategies center on a formal incident command process<sup>7</sup> using defined processes and procedures under explicitly assigned scopes of responsibility based on subject matter expertise. Clear lines of authority are obviously needed. These should be practiced during drills and suitable for immediate implementation any time of the day or night. Written checklists drafted using the outputs of the risk assessment process are an example of "job aids" that can be useful for an incident command group to avoid missing important tasks during simulations or actual disaster responses when time may be of the essence. Such documents were prepared at AABB (formerly the American Association of Blood Banks) starting in 2005 for an anticipated influenza pandemic and are available for modification.<sup>8</sup>

Recovery refers to efforts to return toward normal operations and to evaluate the response for lessons learned and begins after the initial response has been initiated. Restoring and preserving critical systems to maintain business operations (e.g., communications, water, power, sewage, and data) must be prioritized. Once systems and normal operations are restored, the final step of the disaster management cycle begins with an honest, thorough analysis of the event, actions taken, and challenges encountered. Such critical self-review is imperative to learn lessons that

will allow organizations to prevent recurrences and improve future disaster responses.

An important detail in disaster response is the contemporaneous recording of all actions and decisions made as events unfold to enable accurate reconstruction of the real-time evolution of a disaster in the future. It is virtually impossible to remember after the fact all details that occur in the rapidly changing environment of an unfolding catastrophe. While everyone should be encouraged to keep notes and all notes made should be retained and used in the reconstruction of the event, organizations should assign recording responsibility to ensure completion of the task. This will assist in after action reporting, analysis, and identifying lessons learned.

## Organization for emergency operations

National governmental authorities generally have agencies responsible for the coordination of disaster planning and response in their respective countries. Important exemplars of international sources of information and training on disaster planning and emergency operations are provided in Table 2.1.

It is important for incident command staff to understand where their organization fits in the disaster management framework among the multiple levels of governmental and nongovernmental organizations (NGOs) to ensure effective coordination during an event or drill.

In the United States, the Department of Homeland Security (DHS) and its Federal Emergency Management Agency (FEMA) are responsible for developing rules and guidelines for responding to emergencies and coordinating any national response when necessary. DHS and FEMA get their statutory authority to respond to disasters from the Robert T. Stafford Disaster Relief and Emergency Assistance Act (the "Stafford Act") signed into law in 1988.<sup>9</sup>

The National Response Framework (NRF) “is a guide to how the nation responds to all types of disasters and emergencies. It is built on scalable, flexible, and adaptable concepts that align key roles and responsibilities.<sup>10</sup> The NRF is composed of 15 Emergency Support Functions (ESF) that group resources into functional areas. Blood is specifically covered under the medical and public health section.<sup>11</sup> Blood collection and hospital facilities must be familiar with the language contained in the NRF in order to request and receive assistance during major disaster declarations.

The AABB Interorganizational Task Force on Domestic Disasters and Acts of Terrorism (Task Force) was formed in 2002 to provide specific support to blood collection and transfusion facilities during major emergencies integrating with the NRF and other cross-disciplinary systems. Blood centers and hospital facilities should review the AABB Disaster Operations Handbook and be familiar with how to contact the Task Force during emergencies.<sup>3</sup>

Disasters are inherently *local* events requiring individuals, local organizations, NGOs, and authorities to work together. The lynchpin to any disaster response will be local emergency management agencies (EMAs) that include public health, police, fire, and ambulance services that will coordinate the response. State, territorial, and national support systems are in place to support local plans, with development and training and with response when localities are overwhelmed. It is imperative that blood centers and transfusion services be familiar with and participate with local EMAs as blood support is key to minimizing morbidity and mortality of injuries.

## Planning for blood and transfusion in disasters

Blood collection and distribution systems vary by country, some centralized, others dispersed. In the United States, blood is collected in regional blood centers where it is tested, processed, labeled, and stored. Other countries centralize different aspects of the process. The process can take anywhere from 24 to 72 hours to complete depending on national regulations and local operations. Blood is then distributed to intermediate hubs or directly to hospitals for use in patient care. Complex distribution systems heavily rely on robust communication and information systems, transportation and logistics support, and critical utilities such as fuel and electricity. EMA personnel are generally not familiar with how blood collection, processing, and distribution work, and often make assumptions that blood is always available. It is incumbent upon blood center and hospital transfusion service personnel to continually educate EMAs on how the local blood supply works, the average general inventory on hand, and what is required for resupply.

Most mass casualty events and disasters do not seriously stress blood supplies or distribution systems.<sup>12</sup> Needs are met via established inventories and relationships with regional and national colleagues. Those relationships need to be established before an event occurs, but organizations like the AABB task force can facilitate the availability of blood products needed, including urgent transportation requirements where disruptions to usual routes have occurred.

The public/donor response to disasters can be overwhelming and if not controlled can lead to overcollection, the eventual outdate of some blood products, and medium-term donor unavailability while they are deferred awaiting the passage of minimum interdonation intervals.<sup>13</sup> Controlling this generous and understandable donor response is difficult but can benefit from having template messages ready in advance and disseminated early via all

available routes, including and especially social media. Securing the cooperation of EMAs and the media in their dissemination is pivotal. Unified messages about need, or lack thereof, at all levels are critical (local, regional, and national) and should address some minimum elements including a situation report regarding supply and demand with a clear “ask”—e.g., delay donation to the recovery period or a “donate now” ask that specifies what is needed, where and when.

Disasters from the use of biologic, chemical, or nuclear agents may result in widespread donor deferrals and in the potential quarantine of blood components already in the manufacturing process or storage until the nature and effect of the agent can be determined. Radiologic attacks may dramatically increase the demand for platelets, other blood products, or stem cells for weeks or months following an event.

The COVID pandemic saw immediate decreases in blood use as elective medical care was delayed, followed by excess demand when care returned suddenly toward normal at the end of the first wave in the US (Personal communication from Basavaraju S, CDC Office of Blood Organs and Other tissue Safety, March 8, 2021).

Staff absenteeism and donor shortages develop as individuals are unable to travel to work, become ill, need to stay home to take care of loved ones, face quarantine, or fear exposure to a pathogen in public places. Careful consideration of who can and how they will work from home is critical. Those who must be physically present to collect, process, and distribute blood must be made to feel secure at work. At collection facilities during the SARS-CoV-2 pandemic, many clerical and administrative tasks were transitioned to remote systems. A variety of physical interventions recommended by public health, including physical and social distancing, and installing or making available physical barriers and personal protective equipment both for staff and donors, were adapted to collection and manufacturing operations, and to transfusion service environments.

These same considerations may disrupt just-in-time supply chains and the availability of critical supplies as manufacturers face the same difficulties as collection facilities and hospitals.<sup>14</sup> Due diligence during the selection and qualification of vendors of critical supplies requires careful consideration of their disaster planning in support of an uninterrupted flow of goods. This includes, importantly, the companies that develop, install, maintain, and upgrade the information technology resources the blood community relies upon in the highly regulated environment of transfusion medicine, up to and including complete duplication of all applications and archives at a “hardened” remote site.

Hospitals and collection facilities need crisis standards of care that include blood triage to optimize blood use during a severe shortage.<sup>15</sup> It is critical that these be sufficiently detailed to apply both conservative transfusion thresholds for multiple products and clinical scenarios and decisions to curtail blood-intensive nonurgent services and to allocate scarce components at need, be available, and regularly reviewed in advance of a severe disaster. Blood centers should work with their hospital customers to ensure that they have triage plans in place to avoid making collection facility medical personnel, remote from the bedside, responsible for rationing. The Minnesota Department of Health has developed an exemplary menu of materials for hospitals preparing to respond to disasters. They include clinical guidelines that will be useful to assist healthcare facilities in planning for events that would overwhelm the system’s resources, including blood and blood components.<sup>16</sup>

Certain disasters may affect a blood collector's ability to collect and process blood before, during, and after an event. For instance, as a hurricane approaches, a blood collector may suspend collections for a few days before and after the storm has passed, losing expected collections. Elective surgeries typically are postponed during the same period, alleviating the strain on blood availability. However, lessons learned from previous disasters indicate that blood collection and transfusion facilities should prepare for the potential acute shortage of blood components in the days following a hurricane-type event, with special attention given to the supply of platelets. Accordingly, collection facilities should work to augment supplies before a predictable hazard (e.g., hurricane or severe winter storm) and plan for a managed donor surge as the threat recedes. The AABB Disaster Task Force or analogous organizations can provide for support if routine supply channels are inadequate to bolster supplies.

## Continuity of operations plans

Disaster planning is an essential element of a successful business.<sup>17</sup> Accrediting organizations, such as AABB, the College of American Pathologists (CAP), and The Joint Commission (TJC), require participating organizations to have an emergency plan. Planning for responding to a disaster is an iterative process. Plans can have various names, but one commonly accepted term is a continuity of operations plan (COOP). Such a plan is best developed by a cross-functional team representing the major areas within the organization. Coordination with key suppliers and customers is essential to ensure their plans integrate with those of the planning entity. Hospital-based blood bank and transfusion service planning may be subsumed in an overall hospital or department effort but must be reviewed by subject matter experts to be certain that issues specific to blood and transfusion are recognized and attended to.

Once a plan is drafted, it must be validated, the staff trained, and the strategy practiced. It must be reviewed frequently, annually at a minimum, revised, and the process must be repeated. Plans are based on assumptions and are only as good as those assumptions and the experiences of the people writing them. It is the process of testing the plans, either through simulation or during actual events, that provides the necessary challenges to identify shortfalls in the plan. No plan will include all potential scenarios that can occur as each disaster can be unique. Key elements for consideration to include in a COOP are outlined in Table 2.2.

**Table 2.2** Elements Critical for Inclusion in a Continuity of Operations Plan: Minimal Elements of a COOP.

Element	Purpose
Essential Functions	Identify functions needed for business continuity. They are the essential functions that must continue. The most basic functions include: <ul style="list-style-type: none"> <li>• <i>Blood Center:</i> Procurement and storage of blood and blood components, transportation to hospitals. Collection and testing can be interrupted, but the supply of blood to customers is essential.</li> <li>• <i>Hospitals:</i> Receive, store, and transfuse blood to appropriate patients.</li> </ul>
Chain of Command	Leadership is critical to successful control and direction during an emergency. Organizations must have clearly defined and communicated primary and alternative chains of decision-making authority.
COOP Decision Trees	Flow charts and decision trees listing options for various scenarios to guide leaders during emergency operations.

**Table 2.2** (Continued)

Element	Purpose
Emergency Communications	Effective communications are vital during a disaster. Communication failures are the most cited lesson from all disasters. The ability to communicate with staff, EMAs, customers, suppliers, donors, community, and media all must be maintained. Redundant modes of communication should be planned on and tested periodically.
Staffing	Staff are vulnerable to local events and risks. Critical staff/essential personnel responsibilities should be identified, and personnel occupying those positions should be informed. Cross-training to protect essential operations during staff shortages can be considered. Additional contingency staff (volunteers, retirees, etc.) should be identified and trained periodically. Staff should be encouraged to complete family preparedness plans.
Key Contacts	A contact list for both internal and external key personnel should be maintained. It should be available both electronically and as hard copy.
Logistics	Plans are needed to ensure critical supplies, and equipment required to perform essential functions remain available. Identify and validate alternative sources of essential supplies as primary sources may be unavailable as a result of the disaster.
Transportation	Transportation has repeatedly proven vulnerable during past disasters due to a myriad of causes (e.g., flooding, fuel shortages, and road blockages). During the COVID pandemic, routine commercial flights were reduced suddenly and without warning. Coordination with local EMAs or national organizations may be necessary to ensure the delivery of blood, samples, and supplies.
Alternate Facilities	Identify alternative facilities that can be used to continue operations or safeguard equipment pending recovery.
Security and Safety	Plans to secure facilities, fleet, staff, information systems, fuel, and hazardous waste. Additional consideration should be given to the potential for large crowds at collection sites following large mass casualty events. Coordination with local EMAs and insurance companies is suggested.
Vital Records	Protection of essential records is critical in the highly regulated field of blood. Records related to the safety and availability of blood, human resource files, legal records, and financial records are critical to business continuity.
Insurance	Adequate insurance is essential to survive disasters, both property and liability. Business interruption insurance should also be considered.
Cash Reserves	Cash reserves, equal to several months of operating expenses, should be accrued to ensure the survivability of the business until normal operations can be resumed.
Human Resources	Consideration should be given to alternative work options that may be required during a disaster such as shelter in place, work from home, salary, and benefit continuation. Predisaster consideration of such possibilities allows for thorough evaluation.
Utilities	Basic utility services such as water, sewer, power, fuel, telecommunications, and Internet can be vulnerable particularly in weather-related events. Contingency plans for their priority availability based on the nature of the blood community mission should be made with service providers.
Media Communications	Creation and dissemination of clear messaging about the status of local and national blood supplies is critical. Media spokespersons should be preidentified and trained in risk and emergency communication anticipating media interactions. Resources are available on effectively communicating with the media (CDC, 2018) (CFRC, 2020).

## Regulatory considerations in disasters

The blood community is highly regulated worldwide and even slight changes to processes and procedures can have far-reaching effects for facilities and patients, especially during an emergency. Blood collection and transfusion facilities must address regulatory impacts as part of their disaster planning.

## National authority

Most countries have a national authority with overall responsibility for the safety of health care delivery often called the Ministry of Health or Department of Health. Within these organizations will be an agency responsible for the safety of blood and blood components. In the United States, this agency is the Food and Drug Administration (FDA). FDA's Center for Biologics Evaluation and Research (CBER) has the primary responsibility to ensure the safety, purity, and potency of biologic products, which includes blood and blood components.<sup>18</sup> Consideration must be given to the regulations and requirements of the relevant national regulatory agencies when developing emergency response plans. Such regulatory considerations during disasters generally fall into the following three categories.

## Determination of the acceptability of components in available inventory

Written emergency procedures at centers and hospitals should address emergency power and temperature and other environmental monitoring during storage. For example, the impact on acceptability of temperature excursions (either high or low) should be identified as well as any other effects, such as exposure to smoke or water. Consideration should also be given to unprecedented emergencies that may affect blood, such as a radiologic event or exposure to a biologic or chemical agent. Components potentially exposed in an event may require quarantine for a determination of component suitability.<sup>19</sup> When the safety, purity, or potency of a component is in question, the appropriate regulatory agencies should be consulted. An exception or variance may be needed to use such components in certain situations, especially when clinically important shortages are extant. The resources from the AABB Disaster Task Force can be a useful intermediary of such questions.<sup>3</sup>

Blood released for use during a disaster should generally be compliant with applicable regulations and standards, including quality control and testing for infectious diseases. Exceptions may be needed if blood supplies are exhausted, resupply is not possible, and blood is needed immediately to save lives. Appropriate samples should be retained for retrospective testing as soon as conditions permit. Documentation of the circumstances is essential, and hospitals and physicians should be notified about any normal processing steps that have not been completed on the blood.

In extreme circumstances, national regulatory authorities may issue emergency guidance to help ensure an adequate blood supply. For example, on September 11, 2001, following the terrorist attacks on the United States that shut down commercial air travel, the FDA issued "Policy Statement on Urgent Collection, Shipment, and Use of Whole Blood and Blood Components Intended for Transfusion to Address Blood Supply Needs in the Current Disaster Situation" (this document is no longer available on the FDA website). Likewise, some donor eligibility requirements were amended during the recent SARS-CoV-2 pandemic, especially those regarding the deferral of men who have had sex with men and for reducing the risk from malaria and from variant Creutzfeldt-Jakob disease to transfusion recipients. While these changes had long been advocated by blood collectors and were under reconsideration by FDA, the revisions were expedited early in the COVID pandemic to address potential blood shortages.<sup>20</sup>

Disasters can affect donor eligibility, particularly emergencies involving infectious diseases or hazardous chemicals. These agents should be evaluated for (1) their potential to harm to recipients and (2) potential for an asymptomatic interval of infectivity or toxicity

after exposure but before or after any donor illness that would allow collection of an unsafe donation. If an agent is suspected to be transmissible, an appropriate deferral period must be considered, donors must be deferred appropriately, and testing may be considered. For example, in the United States, various precautionary approaches to such issues have recently been applied to the agent of SARS (donor deferrals) and Zika Virus (donor deferrals and donor testing requirements). Again, national regulatory authorities should be consulted for guidance as issues arise during a disaster.

## Potential consequences on operations

Blood component usage during disasters, particularly mass casualty events, may be altered to ensure rapid availability of blood products to those most likely to benefit. It remains essential that all patients admitted who may require transfusion have a baseline sample obtained prior to transfusion. Extreme care for sample-patient identification should be taken given that patient identification is often incomplete and pseudoidentifiers may be used in emergencies. Still, there are acceptable circumstances for interventions like the initial use of Group O red blood cells before blood typing results are available and reservation of Rh-negative blood for females of childbearing age.<sup>15</sup> These are ideally enumerated prospectively in an acceptable disaster plan and not left to on-the-fly decisions.

Adequate staffing can be an issue during any disaster. Key to any and all decisions made during disasters should be the safety and well-being of facility staff. In the days and hours before an anticipated weather event, during and after an emergency, staff members must be able to tend to their families and personal needs. Still, only trained staff should be used for regulated functions. Volunteers can be used to perform tasks for which they have been trained, especially nonregulated functions such as predonation education and maintenance of the canteen. Likewise, appropriate licensure is required to safely operate fleet vehicles. Emergency plans should include maintaining a list of staff trained in multiple functions. For example, staff members who have transferred from one area to another (and have maintained competency in the prior area) can be used in the previous function with appropriate certification and licensing.<sup>21</sup>

Equipment and supplies should also be assessed for exposure to water, humidity, and temperature extremes. FDA has produced useful information guides about the effect of disasters on medical devices.<sup>22</sup>

## Records management

Vital records must be secured and maintained. These documents include records of donors, donations, manufacturing, testing, quality assurance, product disposition, as well as transfusion records. Proactive planning needs to locate storage sites in protected spaces adequate for the kinds of disasters being anticipated (e.g., not locating servers or records in the basements of flood-prone sites). If these records are damaged or lost during a disaster, blood in inventory at that time may require quarantine and recall. Efforts should be made to retrieve and preserve any damaged records.

## The COVID-19 pandemic and transfusion medicine

There is no better example of a catastrophe impacting blood collection facilities and transfusion services than the emergence of SARS-CoV-2 and the resultant pandemic. In the earliest stages of the worldwide spread of this virus, preventive lockdowns to mitigate

transmission were widely implemented. As this occurred, collection organizations expanded stocks where feasible and prepared for an adverse impact on donor availability. The lockdowns eliminated most nonurgent medical care with data from the National Healthcare Safety Network documenting a steep decline in transfusion of red blood cells in the United States during March and April of 2020, followed by a recovery when health care began to reopen in May and June (personal communication from Basavaraju S, CDC, Office of Blood Organs and Other Tissue Safety, March, 8, 2021). Varying degrees of lockdown have been recurrent across varying jurisdictions in subsequent waves. At the time of this writing, the United States is in its fourth wave.

Preliminary publications in the United States and Canada have confirmed these trends and reinforced the utility of collaboration among collectors and providers to prevent and control severe shortages.<sup>23,24</sup>

Generally speaking, transfusion services made no or few changes in their procedures for receipt, testing or storage of pretransfusion samples for infection control purposes, while there was augmentation of personal protective measures for staff in some. On-the-fly staff training regarding proper employment of infection control measures was nearly universal and generally developed in the context of the institutional response to COVID-19. Shortage mitigation strategies, beyond those inherent in the cancellation and delay of nonurgent care, included clinician reminders about appropriate blood use and encouraging alternatives to the use of labile products.<sup>25</sup>

Collection facilities were heavily focused on maintaining adequate collections in an environment that remained safe enough both to attract donors and protect staff, and the blood community developed extensive materials in support of that goal.<sup>26</sup> The effort received major support with the designation of staff in blood collection facilities as essential health care workers.<sup>27</sup> This allowed their priority for receipt of personal protective equipment and vaccines, some increased flexibility in isolation and quarantine and supported business continuity during the implementation and deployment of appropriate nonpharmaceutical interventions to mitigate the risk of introduction and transmission of the virus at collection sites. When lockdowns eliminated the large bulk of mobile blood drives in the United States, collections were pushed into fixed sites and community events were scheduled in areas where fixed sites were not accessible, requiring the rapid implementation of recruitment and access policies to prevent symptomatic or exposed donors (and staff) from presenting. Amendments were made to human resources policies regarding contact, quarantine and isolation, and staff wellness screening. Requirements for physical distancing, masks and shields, and barriers between donors and staff in donor rooms, labs, and processing and distribution areas were imposed. Environmental cleaning procedures were reviewed and revised in compliance with public health recommendations. These policies were rapidly developed, often adapting materials developed more than a decade earlier in anticipation of pandemic flu.<sup>8</sup> The changes all occurred on the background of a move from in-person to remote working for many administrative personnel that both minimized their risks of exposure and the risk that they would introduce the virus into the working environment.

As a result of a very decentralized, some would say dysfunctional, public health response in the United States, collection facilities with operations in multiple states were faced with the additional complication of compliance with variable recommendations in diverse public health jurisdictions.

A frequent early question was whether SARS-CoV-2 was a transfusion transmissible pathogen.<sup>27</sup> This concern was largely based on obvious theoretical concerns raised by the multiorgan clinical expression of COVID-19 and the identification of viral RNA in both patients and healthy blood donors, in the absence of any evidence of such transmission. Subsequently, no report or allegation implicating SARS-CoV-2 as transfusion-transmitted has been published. There is an emerging consensus that if it occurs, it is rare and not a material threat where reasonable care is applied to donor selection.<sup>28,29,30,31</sup>

In the absence of effective therapy for COVID-19, there was great fervor in the blood community and among clinicians and regulators to develop and implement programs to collect, distribute, and evaluate convalescent COVID-19 plasma (CCP) for use as passive immunotherapy providing therapeutic antibodies.<sup>32</sup> Collection organizations, generally in collaboration with their hospital and health system collaborators, and some hospital systems mobilized rapidly in March and April to do so.<sup>33,34</sup> In the United States, an observational protocol, under an expanded access Investigational New Drug exemption, was developed as a collaboration by collectors, the Mayo Clinic, treating clinicians and the FDA, aiming to facilitate access to a promising blood component while gathering information on its potential value and safety when infused into hospitalized high-risk COVID-19 patients with features of severe infection. By August, results were sufficient for the FDA to grant an emergency use authorization for the wide use of CCP, based on evidence of clinical benefit, most especially with use earlier in infection of CCP with higher levels of antibody.<sup>35,36</sup>

Subsequently, randomized controlled trials have not shown consistent benefit in hospitalized patients (early studies were reviewed in ref. [37]). The largest of these trials, RECOVERY in the United Kingdom, enrolled over 11,000 of a planned 20,000 patients from May 2020 until it was suspended for futility in January 2021.<sup>38</sup> By Spring of 2021, collection and use of CCP, an innovative product created in the midst of an unprecedented disaster, was declining rapidly.<sup>39</sup> An additional large, international, randomized controlled trial in hospitalized patients (CONCOR-1) has been published that was also suspended for futility.<sup>40</sup> If any broad benefit is to be realized from CCP, infusing well-characterized plasma with high titers of neutralizing antibody very early in infection, likely prior to hospitalization as was done in an Argentine trial,<sup>41,42</sup> might be required (as has been observed for the use of monoclonal antibodies also available under emergency use authorization in the United States).<sup>43</sup> Unfortunately, the "SIREN-C3PO" study of early treatment was suspended for futility in March 2021.<sup>44</sup> Determining whether there are "niche" indications for prophylactic or therapeutic CCP in patients who have not yet or are unable to mount an adaptive immune response or when monoclonal antibodies cannot be used will require further studies.<sup>45</sup>

Transfusion of convalescent plasma carries with it all the usual concerns about the use of labile blood products including the inherent variability of the product, transfusion reactions (especially TRALI and TACO), and the transmission of infections, e.g., HIV, HCV, and HBV. Human immunoglobulins (intravenous and subcutaneous) and especially hyperimmune globulin from recovered patients have been proposed as a solution that would standardize the product, essentially eliminate the risk of transfusion-transmitted infection, and simplify treatment allowing the infusion of a relatively low volume of an immunoglobulin preparation with high titers of anti-SARS-CoV-2 activity.

High-quality data on COVID-19 clinical outcomes associated with the use of standard intravenous immunoglobulin are not yet available. A randomized trial in 59 patients with severe COVID-19 using “off-the-shelf” IVIg during the Spring of 2020 found a mortality benefit.<sup>46</sup> Given that the preparation used could not have contained significant levels of anti-SARS-CoV-2, the authors speculate that the effect is related to immunomodulation and anti-inflammatory effects. Subsequently, data have demonstrated that levels of SARS-CoV-2 antibodies in standard intravenous immunoglobulin (IVIg) preparations have risen progressively during the pandemic,<sup>47</sup> but clinical data on the effect of these levels are not available.

Multiple fractionators (the CoVIg Plasma Alliance) responded to the pandemic and the lack of highly effective treatment options for COVID-19 by establishing an urgent collaboration with the National Institutes of Health during the Summer and Fall of 2020 to collect plasma from convalescent donors, test their units with standard assays for infectious diseases, titer the plasma for anti-SARS-CoV-2 antibodies using a consensus assay, and pool the collections. The pools were subjected to fractionation with its orthogonal viral inactivation and removal processes and to concentrate the relevant IgG fraction. This hyperimmune globulin preparation was used in a phase three randomized clinical trial versus placebo in seriously ill COVID-19 patients (Inpatient Treatment With Anti-Coronavirus Immunoglobulin (ITAC)). Detailed published or preprint data are not yet available. However, a media announcement on April 2, 2021, stated that the trial had failed to “meet its endpoints.” These were clinical improvement compared to the standard of care in an ordinal outcome based on the patient’s clinical status on Day 7 plus a number of secondary outcomes.<sup>48</sup> Whether trials will be conducted using this preparation for postexposure prophylaxis of high-risk exposed individuals or infected patients very early in clinical illness has not been determined.

Even if effective in clinical trials, passive immunotherapy faces the potential operational barriers raised by the selection and increasingly wide geographical distribution of SARS-CoV-2 mutational variants.<sup>49</sup> Early evidence demonstrates that antibodies and vaccines designed against early progenitor strains of SARS-CoV-2 may lose activity against variant strains evolving locally.<sup>50,51</sup> For CCP, this raises the question of whether a unit collected several months previous to anticipated use or in another locale can be as effective as cotemporary plasma and/or plasma from convalescent donors near to the intended recipient. A post hoc analysis of observational data from the United States expanded access IND suggests that “near sourced” CCP (collected within 150 miles of the recipient) may be clinically superior to distantly sourced plasma.<sup>52</sup> Further, the cycle

time for lots of intravenous immune globulin preparations exceeds six months. If the same holds for hyperimmune globulin preparations, they may be “outrun” by the emergence of variants in diverse locales. Substantial effort will be required to understand the impacts of variant emergence on all these preventive and therapeutic interventions in enough detail to inform our need and ability to continually “redesign” them in response.

It is a truism that “when you have seen one disaster, you have seen one disaster.”<sup>53</sup> The breadth of scope of catastrophes makes it a fool’s task to try to touch every aspect of disaster planning and response in a short chapter. Herein, we try to enumerate the critical elements organizational leaders must consider during these activities and provide references to materials we have found to be of use in our own blood banking careers. It is “US-centric” but should be applicable to the iterative process of developing, exercising, and implementing disaster response capacity independent of where the reader is located. Perhaps the most important take home message is the need to be proactive in planning, aggressive in training and simulation, and blunt during after-action critiques when disasters occur. These must be active processes and the plans that evolve from them must not gather dust between occurrences.

The need and ability to develop entirely new “product lines” during an unprecedented disaster suggest our historical planning processes were adequate to do so while maintaining a sufficient blood supply to meet clinical need. That said, the many lessons learned and being learned pending the subsidence of COVID-19 will need to be incorporated into the plans of individual organizations and up the food chain to the national and international agencies responsible for imagining the future before they can be returned to the bookshelf awaiting the next catastrophe.

## CHAPTER 3

# Responding to regulatory challenges during public health emergencies

Peter W. Marks

Center for Biologics Evaluation and Research, U.S. Food and Drug Administration, Silver Spring, MD, USA

### Connection between public health emergencies and blood transfusion

The outbreak of Severe Acute Respiratory Distress Syndrome Coronavirus-2 (SARS-CoV-2), which is responsible for the COVID-19 pandemic that started in 2020, has served as a reminder of the importance of emergency response preparedness.<sup>1,2</sup> Particularly, blood and blood components are critical medical products needed for use during natural and man-made disasters as well as during epidemics and pandemics caused by various pathogens. The transfusion of blood and blood components in turn occupies a unique position among medical products, in that in addition to being potentially life-saving medical interventions, for certain infectious diseases, blood transfusion may become a method of infectious disease transmission.<sup>3</sup> This has most notably been the case for the viral pathogens hepatitis B, hepatitis C, and human immunodeficiency virus (HIV), among others (Table 3.1).

As blood transfusion became a more routine practice during the twentieth century, adverse effects outside of immediate and delayed transfusion reactions became more apparent. In particular, the development of hepatitis following the transfusion of blood products was noted in the 1940s to 1950s.<sup>4</sup> During the 1960s and 1970s, it was ultimately realized that about 30% of chronically transfused individuals developed hepatitis not attributable to hepatitis A or B, now known mostly to be attributable to hepatitis C.<sup>5</sup> The rapid development of acquired immunodeficiency syndrome (AIDS) associated with the spread of HIV among the hemophilia community in the early 1980s drove home the critical need for better screening of the blood supply and better manufacturing methods for blood derivatives.<sup>6</sup> Initial measures relying on questionnaire-based donor deferrals gave way to iterative generations of testing for hepatitis viruses and HIV. In addition, pathogen reduction technologies, such as heat inactivation, solvent-detergent treatment, and nanofiltration, were introduced into processes for the manufacture of blood derivatives.<sup>7</sup>

The relatively robust nature of pathogen inactivation technologies, reducing the infectious titers of most pathogens by many logs, with the notable exception of parvoviruses, has transformed the overall safety of blood derivatives prepared from plasma. However, transfusible blood components remain susceptible to emerging pathogens that are not addressed by current deferrals or screening

technologies. During the past few decades, West Nile virus, Zika virus, and babesia are just a few of the pathogens that have had to be addressed in the United States.<sup>8</sup> Although pathogen reduction technologies have now been developed for all blood components and are approved in the United States for use in platelet and plasma preparation, the time and expense associated with their implementation have limited their application to date.<sup>9</sup> Pending the development and introduction of a more streamlined safe and effective pathogen reduction technology, the blood supply will remain particularly vulnerable to the emergence of novel pathogens until a method for their detection can be developed.

Pending introduction of highly efficient and effective pathogen reduction technologies, the ability of the blood supply to become a vector for disease transmission will remain a weak point in our ability to address emerging pathogens. When novel pathogens emerge, a rapid response will continue to be necessary for the identification of the responsible pathogen and implementation of appropriate deferral or screening technologies to maintain a safe blood supply. In the end, therefore, our ability to keep the blood supply safe will ultimately rely on the basic pandemic response strategies described below.

### Approach to pandemic management

At any given time, there are hundreds of pathogens that could potentially be associated with epidemics or pandemics, and a number of these are known to be transmitted by blood transfusion or could potentially be transmitted by blood transfusion.<sup>8</sup> Four key aspects of addressing emerging infectious diseases (Table 3.2) include: (1) identifying the infectious agent and maintaining accurate epidemiologic surveillance, (2) developing and deploying accurate diagnostic tests, (3) instituting appropriate containment or mitigation measures, and (4) developing and deploying effective therapeutics and vaccines. Although SARS-CoV-2 has not been a pathogen of particular concern for blood-borne transmission, vigilance must always be maintained for this possibility in the setting of emerging infectious diseases. This is particularly true given the importance of blood product transfusion to routine medical care, to the management of individuals with immunocompromise and cancer, and due to its importance during natural and man-made disasters.<sup>10</sup>

**Table 3.1** Some Established and Potential Transfusion Transmitted Infections

<b>Established Transfusion Transmissible Pathogens</b>
Human immunodeficiency virus (HIV)
Hepatitis B virus (HBV)
Hepatitis C virus (HCV)
Human lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2)
Cytomegalovirus (CMV)
West Nile Virus (WNV)
Zika virus (ZIKV)

<b>Emerging Pathogens with Potential for Transfusion Transmission</b>
Ebola virus
Marburg virus
Dengue virus
Chikungunya virus
Lassa virus
Nipah virus
Powassan virus

**Table 3.2** Four Key Aspects of Epidemic and Pandemic Response

<b>Epidemiologic Surveillance</b>	<b>Containment and Mitigation</b>
Identify the infectious agent and maintain accurate epidemiologic surveillance	Institute appropriate containment or mitigation measures
<b>Diagnostic Testing</b>	<b>Therapeutics and Vaccines</b>
Develop and deploy accurate diagnostic tests	Develop and deploy effective therapeutics and vaccines

## Epidemiologic surveillance

Early recognition of infectious disease outbreaks is critical since the implementation of a containment strategy is most effective when the disease is localized. For known pathogens, the clinical identification of an outbreak should lead to the rapid implementation of appropriate diagnostic and treatment modalities. For novel emerging pathogens, the identification of a common symptom complex in a population may initially point to a potential infectious source and lead to isolation of the pathogen. The emergence of nucleic acid testing by polymerase chain reaction (PCR) has been transformational as it allows the rapid development of a diagnostic test.<sup>11</sup> Since such infectious diseases frequently originate in remote locations, and given the importance of PCR to early diagnosis, this technology has been adapted for use in remote settings.

## Diagnostic testing

As noted above, once epidemiologic intelligence suggests a novel outbreak, the rapid development of easily implemented diagnostic tests is needed. Although PCR performed in a laboratory initially may be useful, as an epidemic or pandemic progresses, the deployment of a more convenient testing methodology is desirable. The COVID-19 pandemic was quite instructive regarding the importance of the necessary characteristics of such tests.<sup>12</sup> Diagnostic accuracy coupled with ease of deployment and implementation are critical elements that should be addressed. Such accurate diagnosis is needed to determine disease epidemiology, which is critical for the implementation of a containment strategy, if one is possible. In addition to qualitative testing for nucleic acids, antigens, or antibodies for the determination of the presence or absence of disease, the availability of quantitative testing to determine the extent of the

antibody response to a passive or actively elicited immune response may also be relevant. For example, accurate determination of neutralizing antibody titers, either directly or through a surrogate marker, can be critical both for diagnostic and therapeutic applications. For example, determining the extent of the immune response may be critical for the identification of high titer units of convalescent plasma, which could possibly be used early on in an epidemic or pandemic, prior to the availability of more specific therapies,<sup>13</sup> and it is also very important for assessing the response to prophylactic immunization.

Another recent outbreak that illustrated the importance of the rapid development of testing strategies was the 2016–2017 Zika virus outbreak.<sup>14</sup> In the absence of a diagnostic test, blood donors had to be deferred based on location and travel history due to the possibility of exposure to the virus, which could be transmitted by blood transfusion. The development by manufacturers of screening assays for the blood supply allowed the implementation of a national testing program ensuring the safety of the blood supply.<sup>15</sup> As an aside, the complexity and cost of that implementation were not without controversy; however, early on in the outbreak, there was significant concern that significant morbidity could be associated with extensive spread of the Zika virus as the potential for its spread via multiple modes of transmission, including intimate sexual contact, was not yet fully understood.

## Containment and mitigation

With the identification of an infectious disease outbreak and the development of clinical or laboratory criteria to document infection, the next step is implementing a strategy to minimize morbidity and mortality. Initially, containment may be used to try to halt the spread of illness to new locations; if it is not successful, a transition to mitigation is necessary.<sup>16</sup>

Implementation of a containment strategy within a given location may involve the quarantine of individuals known to be infected with a pathogen as well as those who have had a high risk of having been exposed. On a broader level, containment may involve limiting travel either within a country or across international borders. Such limitations may involve screening of individuals to identify and defer travel by those with signs of illness to blanket deferrals of travel across borders for entire populations. The success of a containment strategy largely depends on how fast an outbreak is detected. Though it may seem paradoxical, infectious diseases that rapidly cause severe morbidity in most or all of individuals infected are generally easier to contain than those that are associated with variable symptoms, including a relatively high number of asymptomatic carriers. The situation with more asymptomatic carriers allows more disease spread prior to the implementation of containment measures. Ebola virus is good example of the former, and SARS-CoV-2 the latter, situation.<sup>17</sup>

A mitigation strategy generally involves the implementation of measures to reduce the effect of widespread disease transmission within a community. Such measures could include everything from cancellation of large-scale gatherings and attendance at schools or offices to wearing masks to prevent the spread of respiratory viruses. The mitigation phase of an epidemic or pandemic also includes the time during which nonspecific supportive care measures may be implemented prior to the development of disease-specific therapeutics and preventative vaccines. The introduction of specific therapeutics and vaccines generally takes place during the mitigation phase of the response to an infectious outbreak.

## Therapeutics and vaccines

Epidemics and pandemics associated with newly emerging pathogens present special challenges as first the pathogen must be identified and characterized in detail and then work must proceed rapidly to identify known or new drugs that can treat disease caused by the pathogen and vaccines that can prevent disease caused by the pathogen.<sup>18</sup> Those epidemics and pandemics associated with known pathogens may allow the deployment of existing antimicrobial agents and the adaptation of existing vaccines to the specific pathogen circulating. Known pathogens for which products have previously been developed, potentially using special pathways, such as the animal rule, can generally be relatively rapidly deployed, if they can be manufactured in sufficient quantity.<sup>19,20</sup>

For newly emerging pathogens, large-scale randomized clinical trials of therapeutics and vaccines may be required to demonstrate safety and effectiveness. These can be quite challenging to conduct during a pandemic for both practical and ethical reasons, and innovative clinical trial designs, such as ring vaccination, cluster randomization, and stepped wedge designs, among others, may need to be deployed.<sup>19</sup> Although the conduct of clinical trials may seem to be a potentially rate-limiting step in this process, prior influenza outbreaks, as well as the COVID-19 pandemic, have illustrated that manufacturing represents a step that is potentially even more limiting in the deployment of effective therapeutics and vaccines. In part, this is simply because of the scale of production that may be required. For example, even in the simplest case of a vaccine that requires only a single dose to provoke protective immunity, several hundred million doses need to be produced in order to protect the population of the United States, let alone allow for global export. Once a therapeutic or vaccine is produced, the challenges of facilitating its effective distribution and administration during a situation with pandemic limitations must be overcome. Preventive vaccines can be given at mass vaccination clinics established for this purpose. However, the administration of prophylactic or therapeutic parenteral agents may prove more challenging than it might first seem. Because health-care facilities may not have sufficient space for the containment of infectious disease in the outpatient setting, the use of special centers or even mobile units may need to be considered.

Ultimately, careful coordination of all of the above individual pandemic response actions is absolutely critical to most effectively controlling a pandemic as quickly as possible.

## Case study of a therapeutic: COVID-19 convalescent plasma

Cases of COVID-19 started to emerge in late 2019. By January 2020, the potential severity of infection with SARS-CoV-2 became apparent, and in China a clear need for potentially effective therapeutic interventions arose. Convalescent plasma obtained from individuals infected with other respiratory viruses had shown some potential benefit in other outbreaks, and the evidence was strongest when

high titer plasma was administered early in the course of infections.<sup>21</sup> Because of the prior experience suggesting its potential benefit, convalescent plasma was employed in this setting. Initial reports from China regarding small numbers of individuals with COVID-19 treated with convalescent plasma were somewhat encouraging.<sup>22,23</sup> Efforts in the United States to implement randomized clinical trials were slowed by challenges developing a reliable assay to assess the neutralizing antibody titers of the convalescent plasma collected from donors as well as challenges in a medical care system that in many places was overwhelmed. Ultimately, an expanded access program was implemented that treated close to 100,000 individuals.<sup>24</sup> Simultaneously and subsequently, several randomized clinical trials reported conflicting results. Ultimately, when confounding factors were deconvoluted, it appears that the infusion of high neutralizing antibody titer COVID-19 convalescent plasma does indeed produce a very modest survival benefit in those individuals who are earlier in the disease course and not intubated, as well as in those individuals who cannot develop an antibody response such as those with hematologic malignancies.<sup>25</sup> In retrospect, had the appropriate assays and clinical trial infrastructure been in place, the answer to the clinical question of whether COVID-19 plasma could provide survival benefit could have been answered much more efficiently.

## Summary

Although the COVID-19 pandemic that has taken millions of lives across the world is not yet under control as of mid-2021, there is hope that global vaccination campaigns will achieve this in the next few years, at most. Even as we come out of this pandemic, we must be prepared for the next infectious disease outbreak, whether in an epidemic or pandemic form. Fundamental to any epidemic or pandemic response plan for those pathogens capable of being transmitted by blood is the development of appropriate measures to protect the blood supply. The application of lessons learned in the current pandemic will hopefully expedite the response to future outbreaks and reduce the loss of life.

# **Blood donation**

## CHAPTER 4

# Recruitment and screening of donors and the collection of blood

Susan N. Rossmann<sup>1</sup>, Mary Townsend<sup>2</sup>, & Toby L. Simon<sup>3</sup>

<sup>1</sup>Gulf Coast Regional Blood Center, Houston, TX USA

<sup>2</sup>Vitalant Inc., Scottsdale, AZ, USA

<sup>3</sup>CSL Plasma, Boca Raton, FL, USA; and Department of Pathology, University of New Mexico School of Medicine, Albuquerque, NM, USA

The blood transfusion system begins with the donors. The methods and details of blood donor recruitment, assessment, and collection have changed over time and with technology, but the principles remain the same. An adequate number of donors must be available, they must be drawn with consideration for the safety of the donor and the recipient, and the products collected must be tailored to the needs of the patients needing transfusion. In the United States and many countries, routine blood donors are not usually remunerated, but donors of plasma for further manufacture generally donate more frequently and are usually paid. Plasma collections for this purpose are dealt with at the end of this chapter.

### Donor demographics

In 2019, the most recent year for which large-scale US data are available, 9,777,000 allogeneic whole blood (WB) units were collected, based on analysis from the CDC in the National Blood Collection and Utilization Survey, representing a decrease of 6% from the 2017 survey. This includes blood centers and hospital-based blood collectors but excludes about 14,000 autologous and directed donations. Additionally, 1,800,000 red blood cell (RBC) units were collected by apheresis (automated) procedures, an increase of 0.7% from 2017 in apheresis units. After losses due to testing and other reasons, the WB and RBC supply was 10,879,000, a decline of 5.8% from 2017, more than the 3% decrease between 2015 and 2017. Also, 2,359,000 apheresis platelets were collected, an increase of 0.9% since 2017.<sup>1</sup>

In 2019, a total of 10,981,000 successful donations of all types of blood products were made, 1.1% fewer than in 2017. The total number of individual donors was 7,316,000, about 8.5% fewer than in 2017. About 70% were repeat donors, while 30% donated for the first time. Of the total donations, 16.1% were made by individuals 65 years of age or older, an increase of 10.5% from 2017.<sup>2</sup> The age of the US donation population has been a continued concern. The first large-scale blood donation efforts in the US occurred during World War II (WWII), when both red cells and plasma were sought in volume to support the combat soldiers. Perhaps it is not surprising then that, until today, the greatest number of donors have come from the donors who “learned to donate” during that time and their children, the baby boomers. Over time, the demographics of blood

donors have skewed older as the baby boomers have aged.<sup>3,4</sup> Although donation is safe for older donors,<sup>5</sup> this age group cannot support donation indefinitely as their numbers decline and medical conditions render them unable to donate. Concern is particularly strong about apheresis platelet donations,<sup>6</sup> and various strategies have been proposed to ensure supply.<sup>7</sup> High school collections remain an important part of the blood supply in the United States; in one national study, 39% of first-time donors were under 20 years of age.<sup>8</sup>

Young donors contribute very much to the diversity of the donor pool, but in general, donations from racial and ethnic minorities are disproportionately less than whites,<sup>8,9</sup> and this is of concern for several reasons. Diverse ethnicities are a growing part of the US population and so are needed as donors if the country is to have a robust blood supply. Also, since many red cell antigens are associated with particular geographic and/or ethnic groups, donors of particular groups are needed to meet the needs of certain patients. For example, patients with sickle cell disease may need blood with specific types available almost exclusively within the African American community. However, donations from minorities make up less than a quarter of all donations in most studies. Increasing this proportion is a priority for blood collectors throughout the country. Studies of demographic and attitudinal differences in donation from ethnic groups, as well as possible interventions, continue to make contributions to this effort.<sup>10–14</sup>

In 2019, the number of males and females presenting to donate was roughly equal (6,644,000 males and 6,378,000 females), but females had a much higher rate of deferral (particularly due to low hemoglobin), so the number of donations by males was higher.<sup>2</sup> Female deferrals for the presence or risk of HLA antibodies which may contribute to TRALI also contribute to their lower donation numbers and exacerbate the apheresis platelet shortage.

### Donor recruitment and retention

In almost all circumstances, blood donors must be actively recruited from the population. Even in the most trying times, as during WWII when a blood program was being established for combat soldiers, donors must be deliberately sought.<sup>15</sup>

## Theories of donation behavior

In recent years, several groups have worked to establish a theory or framework for blood donor behavior. Ideally, such a theory would explain the observed behavior of donors and would provide information leading to the development of more successful methods of recruiting appropriate donors. It is generally assumed that the motivation of donation is altruism, as it is widely known that blood transfusion can save lives. The *theory of planned behavior* (TPB), proposed by Ajzen,<sup>16</sup> has been most widely used and applied to many health behaviors. *Donation* (the behavior) is preceded by an *intention* to donate. This intention is formed by the interaction of attitudes, subjective norms, and perceived behavioral control. *Attitudes* are the positive or negative evaluation of donating blood, while *subjective norms* are the perceptions of social pressure about donation. *Perceived behavioral control* in this model is the potential donor's own assessment of his or her degree of control over the donation. Emotional aspects of the blood donation process, beyond simple motivation, have recently been emphasized by several workers.<sup>17–19</sup> Adding emphasis to this component, including but extending beyond simple motivation, may improve the utility of the models to suggest areas for study and change. These changes may lead to improvements in the blood donor recruitment and retention process. We need not only more donors in general, but also more specific types of donors.

Ideally, the validation of any theory would occur by measuring actual blood donations. Unfortunately, this is difficult in the short run as for most donation types blood donation cannot occur very often, and it is difficult to follow a large panel of potential donors across a long period. Most blood donor recruitment studies and metrics are cross-sectional or run over only a short interval. Evaluation of the TPB mostly relies upon measurement of *intent* to donate as measured through other values that have been validated to correlate with actual donation. Other metrics have also been suggested and used in studies of TPB.<sup>20</sup>

The initial motivation for donation has long been assumed to be *altruism*, that is, the donation will benefit society. Altruism need not be “pure,” that is, of no benefit to the donor, and other types of altruism have been suggested and measured.<sup>21–23</sup> Notable is “warm glow,” which is a sense of feeling good after a donation (“I would feel good about myself after donating”) which has been shown to be important in some contexts, particularly for repeat donors. A number of workers have shown that motivation can be strengthened by motivational interviewing among nondonors and less motivated donors, leading in some cases to increased intention and retention as donors.<sup>24–26</sup> The effect on the most experienced and committed donors may be less noticeable.<sup>27–29</sup>

Perceived behavioral control is an important part of forming the intention to donate, and in particular the donor's control is threatened by fear of fainting, the risk of which is overestimated by the inexperienced donor.<sup>30–32</sup> The fear itself can increase the risk of fainting. Education and specific steps to reduce this occurrence not only has a direct benefit to the safety of the donor but also can improve the donor's sense of coping, and may lead to improved return and retention rates.<sup>33–37</sup>

Perceived control of donation is also threatened by deferral for any reason, and donors who have been deferred are less likely to return.<sup>38</sup> This is especially true for those who present to donate for the first time and those who have not donated in a long time, with longer deferrals causing more damage to return rates.<sup>39,40</sup> This is an important consideration in the careful crafting of donor deferral policies.

## Donor retention and repeated donations

Donors who repeatedly donate provide most of the blood donations in this country, and are highly sought. The TPB provides clues to a path for developing a first-time donor into a repeat donor, but research has not been particularly successful in achieving behavioral change. Several studies indicate that first-time donors who make a second donation or even several donations within the first year are much more likely to become regular donors,<sup>41</sup> but we do not have a clear idea of why or how that happens. Anxiety may be a part for many who do not return,<sup>42</sup> and even experienced donors may feel anxiety that is a barrier to more donation.<sup>43</sup> Traditional reminders and incentives may not be helpful in this situation. In the absence of a clear and effective intervention, individualized psychological support may be most useful.<sup>44</sup>

The issue of incentives for regular blood donation is not well-settled. Small incentives, such as T-shirts, are entrenched in the US donor system, and the FDA has rules on the amounts and types of incentives that may be offered to the “volunteer” donor.<sup>45</sup> Some donors, especially experienced and committed ones, do not seem to need or even desire additional incentives, at least not monetary ones. However, most studies of monetary rewards have been limited to surveys rather than trials. Within the European Union, policies and attitudes vary, and even those with a positive attitude to incentives did not feel they would change willingness to donate.<sup>46</sup> A study in Germany suggested that monetary incentives could encourage return of first-time donors after the first donation, but would not improve the long-term commitment of donors.<sup>47</sup> In recent years, the subject of remuneration of donors in the United States has repeatedly come up as the system is challenged to collect specific products (such as group O red cells, AB plasma, and apheresis platelets) in sufficient volumes to meet clinical needs. Several authors and authorities have suggested considering a model of remuneration, and trials are ongoing.<sup>7,48</sup>

## Extraordinary donations following disasters

Extraordinary circumstances may bring a sudden influx of donors, particularly when the event involves traumatic injury to a large number of people and thus might require a large number of units of blood for treatment. In fact, the blood needed most immediately must already be available to the hospitals, and so has been collected at least a day before the event. Donors donating shortly after the event do serve to replenish the supplies that have been used and provide robust supplies for coming days, but much of the donated blood may be wasted. In the mass shooting in Las Vegas on October 1, 2017, 58 persons were killed and 600 injured, with 220 hospital admissions. Five hundred blood components were transfused during the first 24 hours, and the public donated almost 800 units. More than 17% of the donated blood went unused.<sup>49</sup> Collections nationally were also increased over the next few days.<sup>49</sup> Following 9/11, about 572,000 units over the normal number were collected in September, October, and November,<sup>50</sup> and collections were increased more than 200% in the days following the San Francisco Bay Area earthquake of October 17, 1989.<sup>51</sup> In a study of some large blood centers following 9/11, there was a fivefold increase in first-time donors, while repeat donors increased 1.5 times.<sup>50</sup> In San Francisco, first-time donors increased from 26 to 45% following the earthquake.<sup>51</sup> Females showed a larger increase than males in both these events. The first-time donors had a return rate over the next months that was similar to their baseline, not increased.<sup>50–52</sup> No exceptional increase in positive test results was seen in either of the sites, considering the usual higher rates in first-time donors.

The SARS-CoV-2 pandemic led to some particular challenges in blood requirements and donor response. The large-scale social isolation that was enforced to stop the spread of the virus slowed blood collections tremendously. Normal medical procedures, notably elective surgeries, were cancelled for fear of infection or lack of hospital capacity. Gradually, severe blood shortages developed, and a public campaign by national leaders such as the Surgeon General led to a tremendous public response. Throughout, the donors and staff had to deal with personal protective issues and fears. The analysis of this disaster-type response in the face of a respiratory pathogen has led to new insights about donor motivation and acceptance of risks, and exemplified aspects that were shown in studies of “intention” to donate during previous avian flu outbreaks.<sup>53–55</sup>

### **Recipient-specific blood donation**

Following the recognition that HIV could be transmitted by transfusion, the notion of giving your own blood for elective surgery (autologous) or asking a friend or relative to donate blood for you (directed) gained attention from physicians and patients alike. A third type of recipient-specific donation (designated) is based less on fear of blood than from an exceptional medical need.

### **Autologous donations**

As might be expected, the collection of autologous RBCs peaked in the mid-1980s and early-1990s when the risk of transfusion-transmitted HIV was high, making autologous blood a safer option. Beginning in the early mid- to late-1990s, as testing technology advanced, autologous donation plummeted. The 2011 NBCUS showed a 59% drop in collections over 2008, with 58% of units ending in discard. 2013 NBCUS<sup>56</sup> showed a decline in autologous collection of 47% from the 2011 survey; by the 2015 NBCUS, autologous collections had dropped an additional 54.2%.<sup>57</sup> 2017 saw an additional drop in the collection of autologous red cells by 61.9%, followed by an additional reduction of 51% by 2019. Factors contributing to this steep decline in collections over time include the recognition of the higher cost of production due to special procuring and labeling requirements, increased waste due to discard, problematic hospital reimbursement, the widespread advent of blood management programs, and dramatic enhancements in the detection of relevant transfusion-transmitted infectious diseases (RTTIs). Etchason *et al.* reported that the additional cost of autologous blood ranged from \$68 to \$4873 per unit of blood and resulted in little benefit based on quality-adjusted years of life (QALY),<sup>58</sup> reaching many millions of dollars cumulatively.<sup>59</sup> Currently reasonable indications include surgeries for which there exists a high likelihood of transfusion such as select orthopedic, vascular, and cardiothoracic surgeries. Autologous blood may also be a rational approach for patients for which finding compatible blood may be challenging or even impossible, such as those with extremely rare blood types, multiple alloantibodies, or antibodies to high-frequency red cell antigens.<sup>60</sup>

While many of the processes used for the collection of whole blood are the same as those used to collect autologous RBCs, there are number of key differences. To collect autologous blood, the donor/patient's physician must write an order or prescription noting the anticipated date of use (surgery date), and the type and number of products needed. Eligibility criteria are less stringent and are targeted at protection of the donor/patient. Finally, the lower acceptable hemoglobin level is 11.0 g/dL for both males and females. Since autologous donors do not generally meet the strict criteria to which allogeneic, voluntary donors are held, if the

donated unit(s) are not transfused, they may not be used for other patients and must be discarded.

### **Directed donations**

The rise of directed donations coincided, as did autologous, with the recognition of HIV as an RTTI. Out of fear, patients anticipating transfusion began asking friends and family to donate blood on their behalf. Unlike autologous donations, directed donors must meet all criteria for volunteer nonremunerated donors. If the directed unit(s) are not transfused into the intended recipient, the units can be placed in general inventory for other patients. Contrary to popular belief, directed donations are not safer than those donated by volunteer donors. Often such donors are first-time donors, known to be less safe than regular, repeat donors. Further, because the donor is known to the recipient, the donor may be reluctant to divulge high-risk behaviors, and there is a risk of loss of confidentiality for the donor. In common with autologous units, directed units are more expensive due to costs associated with procuring, labeling, and ensuring they are reserved for a specific recipient. Since 2013, both the collection and transfusion of directed donations have declined; the decline from 2015 to 2017 was 25.7% with an additional 46.6% from 2017 to 2019. The rate of transfusion dropped 14.7% from 2015 to 2017 and another 83.9% from 2017 to 2019.

### **Exceptional medical need**

Collection of components for an exceptional medical need is infrequent and limited to very few indications. Donors must meet the same criteria as volunteer donors, with some exceptions. Such collections may occur once or regularly depending on the need. Examples include HLA-matched platelets collected from family members or volunteers, or donors with unusual blood types or red cell antigen types that may be used for patients with rare blood types, multiple alloantibodies, or alloantibodies to high-frequency red cell antigens. Such donors may give at regular intervals, with their components used fresh or frozen in rare donor registries. Ill neonates with neonatal alloimmune thrombocytopenia (NAIT) may require urgent transfusion of antigen-negative platelet products. Large BCEs and rare blood registries may keep a list of suitable donors who can be called on in an emergency to donate platelets. In areas where such services do not exist, platelets (washed) may be collected from the antigen-negative mother; this is considered an exceptional need due to waiver of the postpartum restriction (Chapter 34). Finally, granulocytes for patients with select infections or neutrophil function defects comprise a special product that must be collected and infused quickly. Donors are usually treated with steroids or filgrastim, and they may donate several times over a brief period of time as needed. Such donors are often called “designated” donors. Since granulocytes may need to be infused prior to completion of infectious disease testing, predonation testing is common (Chapter 19).

## **The collection process for blood components for transfusion: screening, informed consent, phlebotomy, collection, and postdonation**

### **Donor screening**

The basis of donor screening is twofold: to minimize risks both to the recipient and to the donor. The Food and Drug Administration (FDA) has long considered donor screening as the first layer of defense in a long line of mitigation steps to protect the blood supply.

Although all blood donations undergo testing for RTTIs, among many other tests, not all RTTIs can be detected readily by testing, and for some, approved tests may not exist. Even for RTTIs for which reliable tests exist, such as HIV and hepatitis B and C, there is a period between the time of infection and the time of detection, known as the infectious window period. If a donor donates during this infectious window, the test result may be (falsely) negative. In order to interdict RTTIs for which no test exists or for donors in the infectious window, donors are screened to identify risk factors that could indicate a potentially infected donor. For RTTIs for which there is no test, donor screening may be the sole method to eliminate infected donors. Questioning may include direct questions ("Have you ever had HIV?" or "Have you ever had malaria?"), indirect questions to identify risk factors ("Have you used intravenous injectable?"), or a combination of both types of queries.

Beyond RTTIs, donors must be assessed for underlying conditions or for medications that could negatively impact the recipient, the collected component, or the donor himself or herself. Donors with medical conditions such as cardiac or pulmonary issues, cancers, and a multitude of other medical conditions are identified to determine if it is safe for them to donate. Unfortunately, there is little consensus regarding which conditions warrant deferral or the length of such deferral. Many deferrals are based on the medical judgement of the day, opinion, or conventional wisdom rather than factual data.<sup>61,62</sup> Furthermore, a wide variety of deferral policies exist globally.<sup>63</sup>

Like deferrals for medical conditions, medication deferrals may be based on several factors: potential teratogenic impact on a developing fetus, an indication of an underlying condition, or potential deleterious effect on a specific component. An example of the latter is the prohibition of collection of platelets from a donor taking medications that inactivate platelets such as aspirin or of plasma from a donor taking an anticoagulant. Medication deferrals also vary widely, as determined by oversight by the local medical director, by national or even international standards.<sup>63</sup>

Acceptable donor age ranges from state to state in the United States. In the United States, most states allow donation by donors aged 17 or older, though some states allow 16 years old to donate with parental consent. In the United States, there is no standard upper age limit. As expected, both lower and upper age limits exist in different countries. The WHO recommends a lower limit of 18 years old with exceptions where permitted by national legislation. An upper limit is recommended at 65 years of age, with the acknowledgment that donors above that age usually donate successfully and have lower adverse reactions.<sup>63</sup>

In the United States, the Donor History Questionnaire (DHQ) developed by the AABB and approved by FDA is used by the large majority of blood collection establishments (BCEs) either in published or modified form. A precursor to the current DHQ, the "donor record card" published by AABB in 1953 consisted of a list of 21 diseases and conditions, and its compulsory use was never intended. Over the years, additional questions were added incrementally and haphazardly. With the recognition of the transmissibility of HIV in the mid-1980s, the number of questions rose dramatically in an effort to identify donors potentially at risk for transmitting HIV; by the 1990s, the questionnaire was both lengthy and complex. By the early 2000s, donors were asked about no fewer than 75 health, travel, medication, and infectious disease risk factors in 29 single-item, 14 compound, and 13 multi-item questions. In recognition that the questionnaire was becoming unwieldy, in 2000 the AABB convened a multiorganization group of experts

from the United States and Canada, including representative from FDA, survey design experts from CDC, and an ethicist, to comprise the AABB Donor History Task Force (DHTF). The assigned task was to revise and validate a new questionnaire, the DHQ.

The resulting DHQ was based on established survey design, including the use of "capture questions," for which a "NO" answer eliminates the need for further inquiry: elimination of "compound and multi-item questions" that require the donor to answer two or more questions, creating confusion; and the use of reverse-chronological formatting that enables the donor to move from recent to remote. The latter approach is based on studies that show people remember recent risks more accurately than remote risks; in addition, going back in time stepwise avoids "mental time-travel" that confounds memory. In addition, medical jargon was removed, and "sexual practices" were clearly defined. Most medications were removed to a separate list, the Medication Deferral List (MDL), so medications and their deferral periods can be added or removed without disturbing the flow of the DHQ.<sup>62</sup> Finally, the document was validated by CDC survey design experts using focus group and cognitive interview techniques. Companion documents developed for use with the DHQ include the MDL, Pre-donation Educational Material (DEM), optional flowcharts, and a User Brochure.

### **The current DHQ**

A comprehensive discussion of donor screening has been published.<sup>61</sup> However, since the DHQ is a dynamic document that is updated as new risks are identified and added, and as sophisticated testing technology shortens the window period, any detailed analysis is by nature short lived. In general, questions address the following factors:

- Current health of the donor
- Pregnancy
- Medication use including aspirin and antibiotics
- History of diseases such as malaria, babesiosis, cancer, and cardiac disease
- Travel history
- Activities that could result in potential exposure to HIV and hepatitis
  - Body piercing and tattoos
  - Receipt of transfused blood components
  - Receipt of allogenic tissues or a transplant
  - Injection drug use
  - Risky sexual practices
  - Accidental needle sticks and other blood exposures
  - History of incarceration
- Activities associated with potential risk of CJD or vCJD
  - Receipt of transfused blood components from the United Kingdom, France, or Northern Ireland
  - Travel or residence in some areas of risk
- History of vaccinations and/or shots
- History of recent donation of blood and components

Subsequent to the approval of the DHQ by FDA, the DHTF developed an abbreviated questionnaire (aDHQ) for frequent donors who donate within a specified period and for whom there have been no changes in their eligibility. The aDHQ resulted from longstanding requests from frequent donors for whom repetitiveness and length of the questionnaire were disincentives to donation, and from studies of behavioral scientists that demonstrated that recall was improved for recent compared with remote events. Companion documents (User Brochure, MDL, Flowcharts, and DEM) similar to those of the DHQ were also developed for the

aDHQ. All AABB-approved donor screening tools for both the full-length and abbreviated versions are available on the AABB website.<sup>64</sup> AABB nonmembers have full access to the documents.

### **Changes to the current DHQ based on history of MSM**

Deferrals for activities considered high risk, specifically men who have sex with other men (MSM), have been in place since the recognition that HIV could be transmitted through blood transfusion. From September 1985 to December 2015, FDA recommended indefinite deferral for MSM behavior. Over time, with the closing of the window period for HIV, the implementation of medications that could mitigate the transmission of HIV through sex, and the recognition that not all MSM activity was equally risky, countries including Australia and Canada have reduced the permanent deferral to shorter periods of time. Following the universal screening of blood with nucleic acid tests (NAT), the risk of HIV transmission was reduced to about 1 in 1.47 million transfusions.<sup>65</sup> Epidemiologic data from countries that changed their deferral policy for MSM indicated no safety concerns,<sup>66</sup> though studies of MSM in the United States indicated that risk would need to be monitored.<sup>67</sup> In December 2015, the US FDA issued Guidance reducing the deferral period for MSM to 12 months.<sup>68</sup> Data from the two years following implementation of the 12-month deferral along with data from countries that further reduced the deferral period to three months (Canada and United Kingdom) showed no safety concerns. Thus, the FDA Guidance was again revised in August 2020 to further reduce the deferral for MSM and other HIV risk behaviors (tattoos, piercing, commercial sex work, and injectable drug use) to three months.<sup>69</sup>

### **Changes to the FDA required deferrals for risk of CJD and vCJD**

Both CJD and vCJD are rare but invariably fatal degenerative diseases of the central nervous system belonging to a group of prion diseases or transmissible spongiform encephalopathies (TSEs). The FDA has required deferral of certain individuals thought to be at increased risk of TSEs including those who had exposures to cadaveric human pituitary growth hormone (hGH) or allogeneic dura mater, a blood relative of a person with genetic CJD, and individuals at risk of exposure to meat or insulin contaminated by vCJD. To date no transfusion-transmitted cases of CJD have been described and the risk remains theoretical. Four potential transfusion-transmitted cases of vCJD have been reported, isolated to the United Kingdom. Based on the theoretical risk of transfusion transmission and the absence of evidence of such transmissions, the FDA issued Guidance in 2020 revising many of the long-standing deferrals including:<sup>70</sup>

- Removal of hGH and bovine insulin manufactured from BSE-affected countries from the MDL
- Discontinuation of questioning about having a blood relative with CJD
- Discontinuation of deferral for residence on a US military base in Europe, with requalification and reentry options
- No changes in deferral policy for exposure to allogenic human dura mater

### **Educational materials and informed consent**

Before each donation, the donor is provided with predonation Donor Educational Materials (DEM) that must be read in entirety. He or she is also asked to sign an acknowledgment that they read

and understood the DEM and consent to donation. Under federal regulation § 21CFR630.10(g)(2), establishments must obtain the donor's acknowledgment that the donor

- has reviewed DEM
- agrees not to donate if a potential risk to recipient exists
- recognizes that a sample of blood will be tested for RTTI
- will be notified of an unsuitable donation
- has been notified of risks and hazards of the donation procedure, as may be provided in the DEM
- has an opportunity to ask questions and withdraw from donation
- must not be required to agree to exculpatory language through which the donor is made to waive legal rights

While both AABB and FDA require donor informed consent (IC), there is no standardized process for obtaining consent. The development and role of the DEM in conjunction with the new DHQ deserves special consideration. Over the years, both AABB and FDA placed requirements on donor screening that inevitably resulted in adding more and more questions. A key goal of the DHTF was to reduce the length and complexity of the questionnaire and to provide standardized donor educational information. In order to remove a number of specific questions about signs and symptoms of HIV from the DHQ, FDA agreed to allow those signs and symptoms to be moved from the questionnaire to the DEM. In addition, since as many as one-third of the questions referenced the terms, "sex, sexual contact, or sexual partner," and since the specific meaning of those terms was often misinterpreted, the DHTF decided to add detailed, graphic definitions of "sex" as it relates to risk factors for HIV, including vaginal, oral, and anal sex. Other information added to the DEM included a brief description of the donation process, lists of HIV risk behaviors, a brief description of testing, and an admonishment to provide accurate and complete answers. Unfortunately, over time as local BCEs added their local information (e.g., risks of donation, information on iron depletion and miscellaneous statements) to that of the AABB in order to house all information on a single document, these documents became anything but "standardized." Of note, many of these elements are considered required elements for donor IC, specifically a description of the process, the risks, benefits, and alternatives, use of the donated product/samples in research, ownership of donated samples/components, notification and possible disclosure of test results, and placement on a deferral registry. Since the essence of IC is the clear and understandable communication of outcomes and risk associated with blood donation, it is imperative that the DEM and IC documents meet this standard. Townsend *et al.* carried out a comprehensive survey of content and reading level of informed consent and related educational materials in US and Canadian centers, and demonstrated wide variation between centers in the length, completeness, and complexity of the documents. Further, documents were written at high reading levels (IC: 7.8–16.0 grade; DEM: 6.7–10.9 grade) using jargon most people would not understand, and were lengthy (DEM 649–2743 words; IC 131–996) resulting in a reading burden that deters donors from reading the critical information contained within, a finding confirmed by Wehrli and others.<sup>35,71</sup>

### **Method of administration**

In response to the HIV epidemic, FDA not only added a large number of screening questions but further required that specific questions had to be asked and answered verbally in a face-to-face setting with the donor. This type of questioning was thought to assure

honesty on the part of the donor, allowing the historian to directly observe the donor to identify any hesitancy or other indications the donor might be confused or less than honest. In contrast, studies by survey experts show that the opposite is true. Donors are more likely to honestly answer questions of a sensitive nature when presented anonymously.<sup>72</sup> It was for this reason that the DHTF designed the new DHQ to be self-administered. This approach was endorsed by a unanimous vote of the FDA Blood Products Advisory Committee. As a next step, the DHTF envisioned the application of computer-assisted self-interview (CASI) to expedite completion of the self-administered questionnaire and provide yet another layer of anonymity. Since the mid-2000s, most BCEs have implemented CASI screening of some sort. In recent years, donor prescreening has further expanded to allow donors to log on to a secure network from their home or work computer where they can self-complete an online questionnaire. The screening must be completed on the day of donation, and typically a bar code or other label may be generated for the donor to bring into the donation site. Using the bar code, the health screener is able to locate and review the completed questionnaire and to verbally follow-up on any questions that may require further clarification. As expected, self-assessment, whether written, by CASI, or online, enhances donor satisfaction with the screening process, reduces errors and omissions, and provides the confidentiality to ensure more accurate information.<sup>73,74</sup>

During the screening interview, if a donor becomes aware of disqualifying information or feels too embarrassed to answer, he may exit the donation site at any time. In addition, donors are provided a secure phone number and encouraged to contact the blood center immediately if they have an adverse reaction, if they become ill, or if they have second thoughts about the safety of their donated blood.

### Vital sign measurement

Although often referred to as a “mini physical exam,” the predonation health check is largely historic, not evidence-based and restricted to measurement of vital signs including temperature (*T*), pulse (*P*) rate and regularity, and blood pressure (BP). Hemoglobin or hematocrit is measured to prevent the collection of blood from an already anemic donor and, in some cases, to set collection parameters in automated collections. There is no uniform assessment of vital signs. In 2009, the 26th edition of AABB Standards for Blood Banks and Transfusion Services (BB/TS) eliminated the requirement for measurement of *P* and BP based on scientific evidence and recommendations from recognized experts in transfusion medicine and cardiology that these vital signs did not correlate with any risk of postdonation adverse events. However, the 2015 Final Rule issued by FDA set strict criteria for vital signs and for hemoglobin/hematocrit (at least 12.5 g/dL or 38% hematocrit for females and at least 13.0 g/dL or 39% hematocrit for males).<sup>75</sup> 21CFR630.10(f)(2) requires that the donor’s systolic blood pressure be between 90 and 180 mm of mercury, inclusive, and diastolic between 50 and 100 mm, inclusive. A donor with measurements outside these limits may be permitted to donate only when the responsible physician examines the donor and determines and documents that the health of the donor would not be adversely affected by donating. The CFR further requires (§630.5(b)(1)(i)(A) and (c)(1)(i)(A)(1)) that this determination may not be delegated and must be performed on site with the donor. Pertaining to pulse, §630.10(f)(4) states that “the donor’s pulse must be regular and between 50 and 100 bpm inclusive. A donor with an irregular pulse or measurement outside these limits may be permitted to donate only when the responsible physician determines and documents

that the health of the donor would not be adversely affected by donating.” A telephonic consultation by a physician is permissible for the evaluation of an unacceptable pulse.

In contrast, BCEs in other countries have widely varying rules ranging from no requirements for pulse and/or blood pressure to measurement only under specific conditions. In 2019, Canadian Blood Services (CBS) discontinued deferring whole blood (WB) donors for high or low BP, but continued measuring BP in first-time donors. In spring 2020, both CBS and Hema-Quebec stopped measuring BP in first-time and apheresis donors. The United Kingdom national health service blood program similarly dropped the requirement for obtaining vital signs other than temperature prior to collection. Other countries either do not require vital signs or make them voluntary, while they require measurement only in select populations.<sup>63</sup>

A final step of the donor assessment is the inspection of both arms for any evidence of previous intravenous drug use; at the same time, the antecubital areas can be assessed for any evidence of a skin condition that could compromise the sterility of the phlebotomy site, such as infections or skin lesions.

## Blood collection

### Whole blood

Whole blood (WB) collection represents the most common type of blood donation. A unit of WB can be easily processed into a number of components including packed red cells (PRBCs), whole blood derived platelets (WBDPs), plasma, and cryoprecipitate. For this reason, it may be the only blood product collected, especially in developing countries where access to automated collection devices is limited. The WB process is fairly quick, taking only around 45–60 minutes from registration, through medical screening, physical assessment, aseptic scrub, venipuncture, and recovery. Following the establishment of donor eligibility by medical and physical screening, the donor is placed in a comfortable position on a donor chair, cot, or bed. The phlebotomist examines both arms to determine which vein(s) appear best suited for a successful needle insertion. The application of slight pressure using a tourniquet or blood pressure cuff inflated to 40–60 mm mercury may assist in enhancing the prominence of the veins to identify the best candidate veins. Once a suitable vein is selected, the antecubital area at and around the needle insertion site is thoroughly scrubbed using an antiseptic solution and allowed to dry. After clamping the collect line, the needle is inserted using a swift, clean motion and secured in place using medical grade tape. The line is unclamped allowing blood to flow by gravity into a diversion pouch. The diversion pouch serves at least two functions: the skin plug, with any resident bacteria, is diverted away from the collection pouch reducing potential bacterial contamination of the product; after being sealed off, the diversion pouch then serves as a reservoir for blood to be collected into tubes for testing. Donor blood is then directed into a closed collection set with very frequent or continuous agitation to mix the blood with anticoagulant. WB collection sets are composed of multiple bags steriley connected. The primary bag contains an anticoagulant; satellite bags contain red cell storage solution and/or are used in the separation of blood into components.

### Postdonation care

Following collection of the designated volume of blood, the tubing is sealed from the donor, and the needle is removed from the arm and discarded without recapping. Gauze is placed over the needle

insertion site and direct pressure is applied. The donor is instructed to keep the pressure bandage on and avoid strenuous activity for a prescribed amount of time and to increase fluid intake. Donors are asked to remain in the refreshment area where they are provided snacks and beverages to begin the rehydration process. Donor adverse events such as vasovagal reactions are most likely to occur in the few minutes immediately postdonation, so donors are typically asked to stay in the area for at least 15 minutes, where they can be observed. Postdonation care instructions are provided describing actions to take if the donor feels unwell after donation, becomes ill in the week or two after donation, or has second thoughts about the safety of his or her donation.

### **Component separation**

WB may generally be stored without separation for up to 21 days. WB may be separated by centrifugation into PRBC, WBDP, and plasma components according to density. This allows longer shelf life, better inventory management, and more choices and resources for patient care. The capacity to provide patients with the different blood components they require is still limited in low-income countries: 37% of the blood collected in low-income countries is separated into components, 69% in lower-middle-income countries, 95% in upper-middle-income countries, and 97% in high-income countries.<sup>63</sup>

Using a “closed” separation system that is never open to outside air is important to prevent contamination with microorganisms during collection and component separation. Centrifuge-separated components are transferred from the original whole blood draw container to satellite bags through integrally connected plastic tubing. Adding nutrients and saline to the RBCs permits storage at 1–6 °C for up to 42 days (see Chapter 12). The preservative solution may be held steriley in one of the integral transfer bags until the plasma is separated off into a satellite bag after centrifugation, after which the solution may be added to the PRBC remaining in the original bag. Beginning in 2008 and moving through 2019, the production and transfusion of RBCs has been on a steady decline, with a 6% decline from 2017 to 2019. On a positive note, the discard of both WB and PRBC declined by almost 22% over that same time period.

Leukocyte reduction (LR) is accomplished by passing whole blood or PRBC through filters that reduce the number of white blood cells (WBCs). Ideally, this should be done as soon after collection as possible, but no longer than 72 hours. Leukoreduction has been shown to be more effective when done before storage because some of the adverse effects of transfusion are caused by factors produced or released by leukocytes during storage. Although LR can reduce untoward events, significant amounts of WBCs remain in LR products (up to  $5 \times 10^6$  WBCs/unit in the United States and  $1 \times 10^6$  in Europe). Automated apheresis collections often have technology that produces LR products during the collection process.

WBDP may be made by several methods. In the United States, an initial “soft” spin (slower speed) separates platelet-rich plasma (PRP) from the RBCs, and then a “hard” (faster speed) spin separates the platelets from the plasma. In Europe and many areas of the world outside the United States, “buffy-coat” platelets are produced by using first a “hard” spin to separate all cellular elements from the plasma. Then, the buffy coat containing the platelets, white blood cells, and a significant contaminant of RBC is further processed to isolate the platelets. In the United States, in 2019 WBDP represented only about 10% of platelets transfused; however, there was an almost 200% increase in the transfusion of WBDP over 2017. Additional information about platelet preparation and storage may

be found in Chapter 17. Traditionally, platelets were stored for 5–7 days at controlled room temperature, with gentle agitation, with the expiration dependent on the bacterial detection and/or removal processes used. In 2019, FDA issued guidance specifying conditions under which processes for mitigation of bacterial contamination of platelets could be considered for extended storage up to seven days.<sup>76</sup> Although currently not generally licensed, other options for platelet storage include the storage of platelets at refrigerator temperature for use in situations such as trauma and active bleeding, and other uses are being actively explored.<sup>77,78</sup>

Plasma separated and frozen within eight hours is called fresh frozen plasma (FFP), whereas plasma frozen up to 24 hours is known as PF24 or FP24. Each contains coagulation factors in quantities adequate for most patient indications. FP24 represented only 15% of the 4.1 million units of plasma transfused in the United States in 2004 but 47% of the 5.9 million units of plasma produced in 2011.<sup>56</sup> Data collected from hospitals no longer distinguish between FFP and FP24 as they are considered equivalent. This increase may be in part due to the concern about transfusion-related acute lung injury (TRALI) and the exclusion of women who have been pregnant from plasma donation. Blood centers are attempting to make plasma from all eligible donors of the needed types, even though the plasma logically cannot always be frozen within eight hours. More volunteer plasma is typically drawn than needed for transfusion. Plasma stored for as long as 72 hours before freezing may be sold for fractionation (discussed further in this chapter).

After separation from the RBCs, plasma may be pooled and treated with solvent and detergent (S/D) to decrease the risk of transfusion-transmitted disease. In addition, the pooling enables quality control of coagulation factors per lot, and the dilution dramatically decreases the risk of TRALI.<sup>79,80</sup> Other pathogen reduction techniques may be applied (see Chapter 42). Only a small amount of S/D-treated plasma is used in the United States due to economic factors and possible safety concerns regarding pooled products.<sup>81</sup> However, some countries in Europe rely on this process for the majority of plasma transfused.<sup>79</sup>

Preparation of cryoprecipitate involves thawing FFP at 4 °C in a circulating water bath, followed by centrifugation so that the supernatant plasma can be drained into an integrally attached storage bag (see Chapter 21). The remaining cold-precipitated material is then refrozen at 18 °C or less and stored for up to 1 year. Approximately 1.7 million units of cryoprecipitate were prepared in the United States in 2011, an increase of 16% since 2008.<sup>56</sup> Cryoprecipitate production in the United States has steadily increased since 2008, increasing to 1.86 million in 2015, 2.16 million in 2017, and 2.18 million in 2019. Cryoprecipitate infusion declined in the recent past, but increased from 2017 to 2019, probably related to use in trauma and massive transfusion situations.<sup>1</sup> In some regions in Europe, cryoprecipitate is not produced, as the use of factor concentrates for inherited bleeding disorders and plasma or fibrinogen concentrate for hypofibrinogenemia has proven satisfactory.

### **Apheresis Collection**

Another common type of blood collection, especially in industrialized countries, is apheresis. In the United States in 2019, 16.5% of red cells and 94% of platelets in the supply were collected using apheresis technology.<sup>1</sup> Apheresis collections provide a number of advantages. Many, though not all components are leukoreduced automatically during collection, alleviating the manpower and cost to filter components after the fact. Apheresis technology provides a

way to collect multiple components in a single setting—either a variety of different components or multiples of the same component. By using selection algorithms, BCEs are able to collect specific components based on inventory needs and donor attributes. Component selection criteria are based on a number of factors including:

- Donor factors—sex, height, weight, hematocrit, and platelet count—used to program the device to determine volume to be collected
- Risk of plasma containing antibodies (anti-HLA and anti- HNA) that can cause TRALI
- Donor blood type—Group O individuals may be selected for red cells and double red cells; Group A and AB individuals are sought after for platelet and plasma donations
- Time—the amount of time a donor has available to donate on any given day

So, for example, a large male with a high platelet count may be able to give three apheresis platelet units or a double RBC depending on blood type, while a female with TRALI risk may be restricted to an RBC or double RBC depending on weight, height, and hematocrit. In 2001, the FDA published a guidance on collecting RBC by automated apheresis methods, providing restrictions on the cumulative loss of red cells and plasma over a rolling 12-month period.<sup>81</sup> In addition, there is a 112-day deferral for donors giving double RBCs, which precludes donation of any component (red cell, platelet, or plasma). For donors giving a combination of a single RBC with any other component type, the usual 56-day deferral applies for another RBC donation, although donations of platelets and plasma may be allowed prior to 56 days (see Chapter 24).

### The collection process for source plasma: screening, phlebotomy, choice of product, collection, and testing of source plasma donors

The handling of source plasma donors differs in several respects from the handling of whole blood and apheresis donors providing blood products for hospital transfusion. Source plasma is collected by apheresis specifically for further manufacture into biological derivatives, in contrast to “recovered plasma,” which is the plasma remaining after RBC production from whole blood donation. About half of the recovered plasma collected for fractionation comes from Europe. Many European countries have maintained national programs that fractionate plasma from recovered plasma from volunteer donors. However, the demand for biological therapies worldwide requires the additional supply from remunerated or compensated (paid) donors. Source plasma is collected (in order of amount per population) in the United States, Austria, the Czech Republic, Germany, and Hungary from compensated donors. Smaller programs are found for collections from noncompensated donors (in order of number per population) in Australia, the Netherlands, Denmark, France, Sweden, and Belgium. In 2010, source plasma accounted for approximately 75% of plasma for further manufacturing worldwide, with recovered plasma accounting for the remainder. In 2012, approximately 26.2 million donations of source plasma were fractionated along with approximately 9 million liters of recovered plasma. Source plasma collections in the United States increased to greater than 53. 5 million donations in 2019; in the midst of the pandemic, it fell to 43.4 million collections in 840 centers in 2020. In 2019, in Europe 88 PPTA-certified centers collected 2.988 million units (website: PPTAglobal.org). The requirement for immune globulins has largely driven this increase

(data from [www.pptaglobal.org](http://www.pptaglobal.org)). The United States provides a large proportion of the world’s source plasma requirements (approximately 67%) for two reasons: first, under FDA regulations, source plasma donors can donate more plasma, more frequently, than is the case in most countries. Second, the United States has a well-developed source plasma industry that has invested in a network of centers that compensate donors for their time and inconvenience.

In both the United States and the European countries, source plasma is collected in fixed sites without mobile collections. Either the Autopheresis-C (Fresenius) or the PCS-2 (Haemonetics) is used for most collections. Recruitment is typically by word of mouth, newspapers, radio, and posters, although more recently social media has been employed. The donor groups are heterogeneous. Sites near campuses that can attract student donors are common, and payment varies. More money is paid for donations from immunized donors for hyperimmune plasma (rabies immune plasma, tetanus immune plasma, hepatitis B immune plasma, anti-D plasma, etc.) and by those from donors with disease-state antibodies needed for diagnostic manufacture.

In addition to specific national regulations and guidance, in the United States and Europe an International Quality Plasma Program (IQPP) of the PPTA is also followed. The program has been judged successful because the major manufacturers in Europe and the United States will only use plasma from these programs. This self-regulation includes the following:

- *Community-based donors:* Donors must have a permanent address in the vicinity of the center.
- *Qualified donor standard:* Each donor’s plasma is used only after two medical screenings, and required viral testings are successful and less than six months has elapsed between the two donations.
- *National Donor Deferral Registry (NDDR):* All donors deferred for viral marker testing are entered into an NDDR that must be checked before each *applicant* (i.e., not qualified) donor is accepted.
- *Viral marker standard:* This requires centers to keep their viral marker rates below established levels.
- *60-day inventory hold:* This is required so that units from a donor with a subsequent positive test or disqualifying information can be removed before being pooled (part of the Q-SEAL Standards for fractionators). FDA had incorporated the hold into the regulations. During the COVID epidemic, it temporarily reduced the hold to 45 days.

The community-based donor standard discourages transient individuals from donating as this population has been associated with an increased incidence of infectious disease markers. In the United States, an electronic current donor registry run by PPTA prevents cross-donation in multiple centers that exceeds the limits. A minimum weight of 50 kg (110 lbs) must be met. At each donation, the hematocrit and total protein are determined from a finger-stick blood sample. The hematocrit must be 38% or greater (recently increased by FDA to 39% for males), and protein must be 6.0 g/dL or greater. The protein is measured using a refractometer (the only device currently available to meet the FDA requirement).

Initially, the donor is subjected to an extensive interview similar to that used for blood donors, followed by a brief physical examination by a physician. In the United States, a physician substitute may be used, such as a nurse, paramedic, or other health professional trained to do the physical exam and operating under the guidance of the center medical director. The physical examination consists of an external eye, ear, and nose exam, with an examination of the throat with a tongue blade and light. Lymph nodes in the neck area

are palpated. Auscultation of the back and front of the chest for lung abnormalities is followed by auscultation of the heart. The abdomen is examined for liver and spleen enlargement. A short neurological and extremity review completes the examination. In some centers, a urine dipstick for protein and glucose is also performed. After passing these initial tests, the donor can donate as an *applicant* donor. Collected units are held until the donor has two successful donations without any positive infectious disease markers. If the donor does not return for the second donation within six months, the plasma is considered an "orphan" unit and cannot be used for injectable product. In Europe, the first donation is for sample only. In the United States, the donor must pass initially, and every four months, tests that include serum protein electrophoresis, total protein, and syphilis. The physical examination with full interview is repeated annually or if the donor has not presented in the past six months. An informed consent must be executed on the first donation and again whenever the consent is changed.

The donor donates according to a nomogram: body weights of 50–67.5, 68–79, and greater than 79 kg can donate 625, 750, and 800 mL plasma, respectively, not counting anticoagulant. This nomogram was promulgated by the FDA in 1992; recently, it has been subject to reconsideration. It has two basic drawbacks: (1) it does not take into consideration the donor's height or hematocrit which influences the total plasma volume; (2) being discontinuous, donors will donate much more plasma at some weights with a very minimal change in weight. A retrospective analysis showed that the ratio of the plasma volume collected compared to the total plasma volume ranged from 15 to 42% in a study of over 100,000 donations. The ratio was inversely proportional to weight which meant that lower weight donors donated a higher percentage of their plasma volume. The authors made two key points: (1) despite the good safety records of the 1992 nomogram, there were significant differences in risk of a hypotensive reaction based on proportion of plasma volume drawn; (2) the efficiency of plasma collection was suboptimal with many large donors donating a small percentage of their plasma volume.<sup>82</sup> Accordingly, the Haemonetics Corporation developed a personalized nomogram that they showed optimized collection yields without increasing adverse events. This nomogram was continuous and used BMI (height and weight) and hematocrit to achieve a collection target of 28.5% of plasma volume with a maximum removal of 1000 mL.<sup>83</sup> This is now becoming available in the United States. Some variation of this might be available in the future from other manufacturers.

Standards from the quality program of the Source Plasma industry group PPTA require infusion of saline at the end of the donation. After a brief rest in the donation chair, the donor is allowed to collect the compensation (usually electronically added to a debit card) and leave. Refreshment and recovery areas are not common in plasma donor centers. In the United States, donors are allowed to donate no more than twice in seven days, with at least two days between donations. A donor could theoretically donate 104 times per year (65–83 L, depending on donor weight).

The Council of Europe recommendations limits the amount of plasma collected per session to 600 mL, not counting anticoagulant.<sup>84,85</sup> There is also a 15 L annual limit. German national guidelines set in 1999 allowed donations of up to 650 mL plasma twice weekly with an annual limit of 25 L. Donors must weigh a minimum of 50 kg and have a hemoglobin level of 12.5 g/dL in females and 13.5 g/dL in males. Immunoglobulin G (IgG) along with total protein is measured at every 5th donation and must be at least 115 g/L and 6 g/dL. CBC is performed initially and at every

15th donation. Donors are also examined by the physician at every 15th donation as opposed to annually by a physician or physician substitute in the United States. Europe also has rules for permanently excluding donors who have a pattern of low protein and/or IgG.

To determine if less restrictive donation standards (closer to those in the United States) were safe, 21 German plasma donor centers participated in a study known as SIPLA. They found that donors weighing greater than 70 kg could donate 850 mL each session up to 60 times per year with appropriate monitoring (up to 51 L total per year). Currently, there is an effort to change European requirements to be consistent with these findings.<sup>86,87</sup>

Each donation by a source plasma donor is tested serologically for HIV antibody, HBSAg, and hepatitis C antibody. Nucleic acid testing is done on each donation for HBV, HCV, and HIV. A positive test results in deferral. This is usually regardless of results of confirmatory tests that are performed for donor counseling. In addition, tests for hepatitis A and parvovirus are also performed. If positive, the units are discarded. Donor and health department notification are required for hepatitis A positivity along with look-back and look forward.

Due to the investment in the applicant's first donation, donor centers cultivate long-term donors who donate often. Some very dedicated donors are given vaccines to provide rabies immune plasma, tetanus immune plasma, hepatitis B, or other immune plasma in order to make specialty immunoglobulins. Rh-negative donors who are not of childbearing potential can become donors of Rh-immune plasma for manufacture into Rh immune globulin. This is done by immunization with carefully "qualified" and characterized D-positive red cells. Long-term consistent donation is particularly important for these specialty donors.

There are additional requirements for donors receiving red cell immunizations, including physician performance of the initial physical examination and a separate informed consent, physician presence when immunizations are given, and a specific physician approval of the red cells to be injected. Meticulous preparation of the red cells for immunization occurs. Red cells from whole blood donors are frozen and collected over a year. Only when a year's viral marker testing remains negative, the cells can be deglycerolized and used to immunize a donor. When the red cells from a specific whole blood donor are first used, they are given to 1–3 recipients for a year. When viral marker testing is negative throughout the year for those recipients as well as the donor, the cells are then "qualified." Plasma from these donors is used to manufacture Rh immune globulin, and the pool must contain a sufficient concentration (titer) of antibody to allow acceptable product to be made.

Rates of viral marker test positivity in donors are monitored, and plasma centers are expected to take steps to reduce levels when they rise above predetermined alert levels. Source plasma donors tend to be more likely male, younger, and larger in size than volunteer donors, probably reflecting the more demanding donation program frequency. In addition, they are more ethnically diverse. Some of these factors act to increase prevalence and incidence of viral diseases. Socioeconomic status and compensation programs might play a role as well. With the push toward voluntary donations worldwide, the payment of plasma donors has been criticized. Nevertheless, monetary compensation of source plasma donors has had an enviable safety record for the last 20 years since many of the additional controls have been put in place. The viral reduction and inactivation treatment of the final product provides additional safety. Thus, the layers of protection operate differently in source plasma programs than in the volunteer programs, but are still

highly effective in preventing infectious units from entering plasma pools and in ensuring safety of the final product.<sup>88–90</sup>

### Blood collection changes with patient needs

The clinical use of blood transfusion has developed tremendously over the last century, and blood collection has changed correspondingly. Transfusion of components, for example, has been both encouraged and facilitated by the development of automated collections that allow precision in the selection of the proper component and the donor to give it. The ongoing improvement of safety has been facilitated by improved donor screening as well as testing. Consideration for the health of the donor as well as the recipient remains critical to the willingness of millions of volunteers to donate blood and plasma freely and repeatedly.

## CHAPTER 5

# Blood donor testing

Nancy L. Van Buren & Jed B. Gorlin

Innovative Blood Resources and Community Blood Center of Greater Kansas City, MO; and Divisions of New York Blood Center Enterprises, St. Paul, MN USA

### Background

Each and every donation is tested by an array of assays including ABO and Rh, antibody screen, and infectious disease testing. Other serological testing may include anti-A/B antibody titers of group O whole blood and apheresis platelets to reduce the risk for hemolytic transfusion reactions from passively transfused antibodies when significant amounts of incompatible plasma may be transfused. Routine testing of female platelet donors with history of pregnancy for the detection of human leukocyte antigen (HLA) antibodies helps mitigate transfusion-related acute lung injury (TRALI).

Transfusion-transmitted infection (TTI) has become an extreme rarity due to more effective donor selection, strict US Food and Drug Administration (FDA) regulations, and extensive laboratory testing for transmissible diseases, which has made significant progress over the past four decades. Required testing for transfusion-transmissible diseases includes syphilis, hepatitis B virus (HBV) (in three different assays), hepatitis C virus (HCV) and human immunodeficiency virus (HIV) with two different assays, human T-cell lymphotropic virus (HTLV), Chagas' disease, West Nile virus (WNV) and, until 2021, included Zika virus (ZIKV). The redundancy of assays for HIV, HBV, and HCV includes both serological assays and molecular screening with nucleic acid tests (NATs). As of May 2020, testing of all blood components for babesiosis is required for 14 states or districts considered to be endemic for this transfusion-transmissible infection.

Bacterial testing of all platelet products is routinely performed unless they are pathogen-reduced. Other laboratory testing that may also be performed includes serological testing for cytomegalovirus (CMV), platelet antigen typing, and extended red blood cell (RBC) antigen typing.

### Safety of the blood supply

Although the goal of a "zero risk" blood supply is, by definition, impossible to achieve, risks from transfusion-transmitted infection are quite rare. Each unit of whole blood or apheresis components undergoes an extensive battery of tests (Table 5.1).

### Blood component testing

Testing of voluntarily donated blood is carried out on blood samples obtained for this purpose at the time of donation. Blood is collected for testing in an integrally connected diversion pouch,

and the maximum volume of blood that can be retained for testing is about 50 mL. (Of note, the FDA allows plasma collection centers to perform the infectious disease screening on the collected plasma, thereby minimizing additional red cell loss from these paid donors.) Automated systems with high-throughput testing for RBC typing and antibody detection are typically used in blood centers (Table 5.2).

### ABO typing

The most common cause of a fatal hemolytic transfusion reaction is the administration of ABO-incompatible RBCs.<sup>1</sup> Therefore, the ABO and Rh typing of the donor units are of critical importance. Usually, ABO and Rh typing are carried out together, along with RBC antibody detection testing, because these tests involve RBC antibody–antigen interaction. While ABO and Rh typing maybe done in a variety of modalities, virtually all blood centers use automation (Table 5.2). The choice of the particular method and instrument will depend on throughput requirements at the donor center testing laboratory. Most systems incorporate room temperature testing and centrifuges or other manipulation to foster agglutination. Following a wash or dispersion step, the resulting mixture is observed either visually or by an instrument.

### Rh typing

The Rh type refers to the D antigen (also Rh or RhD). It is the second most immunogenic RBC antigen next to the ABO blood group type. Alloantibodies to the D antigen can cause severe or fatal hemolytic disease of the newborn or transfusion reactions. In particular, the transfusion of Rh-positive RBC-containing products should be avoided whenever possible to Rh-negative women of current or future childbearing age.<sup>2</sup>

Donor centers typically use automated platforms to perform D antigen testing using typing reagents, which must also be sensitive enough to detect a serological "weak D" individual to label their blood products as Rh positive. Additional testing is recommended in the patient setting, particularly for women of childbearing age. In the blood center setting, weak D testing is performed by including the antihuman globulin phase of serological testing, which can be done manually or by certain automated testing platforms. Antisera reagents that are polyclonal high protein, chemically modified low protein, or a combination of polyclonal-monoclonal

**Table 5.1** Donor Testing Performed in the United States

Blood Grouping Tests	Methodology
ABO Rh typing	Agglutination
Red cell antibody detection	Serologic
Transmissible disease screening tests	Microhemagglutination, EIA, or RPR
Syphilis (treponemal or nontreponemal antibody)	EIA or CMIA
Hepatitis B surface antigen (HBsAg)	EIA or CMIA
Hepatitis B core antibody (anti-HBc)	EIA or CMIA
Hepatitis C antibody (anti-HCV)	Pooled PCR or TMA
HBV/HCV/HIV NAT	EIA or CMIA
HIV-1/2 + group O antibody (anti-HIV-1/2 + O)	EIA or CMIA
HIV antigen/antibody combination test	
HTLV-I/II antibody (anti-HTLV-I/II)	EIA or CMIA
WNV NAT	Pooled or IND, PCR or TMA
ZIKV NAT <sup>a</sup>	Pooled or IND, PCR or TMA
<i>Trypanosoma cruzi</i> antibody (anti- <i>T. cruzi</i> ) <sup>b</sup>	EIA or CMIA
<i>Babesia</i> NAT <sup>c</sup>	Pooled or IND PCR or TMA
Bacteria (platelets) <sup>a</sup>	Culture +/- secondary bacterial testing

HCV, hepatitis C virus; HTLV-I, human T-cell lymphotropic virus type I; HTLV-II, human T-cell lymphotropic virus type II; WNV, West Nile virus; ZIKV, Zika virus; EIA, enzyme immunoassay (or similar ELISA, enzyme-linked immunosorbent assay method); CMIA, chemiluminescent microparticle immunoassay; PCR, polymerase chain reaction; NAT, nucleic acid test; TMA, transcription mediated amplification; IND, individual; RPR, rapid plasma reagent by particle agglutination.

<sup>a</sup> U.S. testing requirement for Zika withdrawn by FDA in 2021.

<sup>b</sup> Required on first donation only.

<sup>c</sup> Required in endemic states in accordance with FDA Babesia Guidance to Industry.

**Table 5.2** Automated Systems for Red Cell Typing and Antibody Testing of Donated Blood<sup>d</sup>

Company	Product	Type of Assay
Grifols	Erytra	Gel-phase test
Immucor	NEO Iris	Capture solid-phase test
Immucor	Echo	Capture solid-phase test
Bio-Rad	Tango	Solid-phase test
Ortho	Provue/ID-MTS Gel	Gel-phase test
Ortho	Autovue Innova	Column-agglutination test (glass beads)

<sup>d</sup> All of these systems can also be used for crossmatching.

low-protein reagents are available to detect weak D RBCs, so additional testing of donors who type as Rh negative is no longer necessary. Serological testing, however, can fail to identify rare donors with low antigen expression (weak D and Del) resulting in some weak D+ units being labeled as D-.<sup>3</sup> This may result in inconsistency with historical test results and consideration of *RHD* testing by DNA methods, as well as loss of donor products because of the inability to label donor RBCs that give variable results in serological D testing.

## Red blood cell antibody detection

Serum or plasma from donors is tested for unexpected antibodies to RBC antigens using methods that will detect clinically significant antibodies.<sup>4</sup> Approximately 0.5% of donated units will test positive in the antibody detection test.<sup>5</sup> While most antibodies are due to exposure from previous pregnancy or transfusion, RBC antibodies may rarely be naturally occurring or detected in a donor with autoantibodies. They may also rarely result from residual passive anti-D antibody detectable in a recently pregnant female who received prophylactic Rh immunoglobulin administration.

Transfusion of RBC alloantibodies in components containing donor plasma may result in shortened RBC survival or hemolysis of recipient RBCs, or rarely cause hemolysis of other transfused donor RBCs.<sup>6</sup> Although blood components that contain RBC antibodies can be used for transfusion, they must be labeled with antibody specificity, and the receiving hospital transfusion service would only transfuse to antigen-negative patients or wash the product. Practically, this is usually limited to blood centers offering anti-Rh(D) antibody positive Rh(D) negative units, intended for transfusion to Rh(D) negative recipients, but since the patient may now demonstrate the passive antibody, subsequently requiring full crossmatch, many hospitals will no longer accept such units. Therefore, donors with alloantibodies may be diverted to become reagent blood donors or donate for research.

To demonstrate clinically significant antibodies, the donor plasma is incubated at 37 °C with reagent RBCs in one of the following media: saline, albumin, low-ionic-strength solution, polyethylene glycol, or polybrene. Currently, gel, solid-phase systems, and affinity columns may also be used for RBC antibody detection.<sup>7,8</sup> Use of automated platforms facilitates ABO and D testing and antibody screening on a single instrument. In contrast with the patient setting, the use of either donor plasma or serum may be used to test against either pooled or individual reagent RBCs of known phenotypes.

## ABO antibody titers

Blood products may be tested for the presence of high-titer anti-A (most commonly) and/or anti-B to prevent hemolytic transfusion reactions secondary to ABO incompatibility of isoagglutinins in incompatible plasma. In the United States, this may be performed with a variety of methods and cutoff values as there is no universally agreed upon standard for “low titer.” The two settings where this is routinely applied include (a) the use of group O donors for whole blood and (b) apheresis platelet products.

Low titer group O whole blood is being used increasingly in trauma or acute blood loss.<sup>9</sup> Because group O whole blood has a full unit of plasma, which is incompatible with RBCs of nongroup O recipients, facilities must consider which patients will be eligible for this product, how many units can be received by eligible patients, and how to monitor for adverse events? In addition, transfusion services must have a policy concerning transfusion of significant volumes of plasma containing incompatible ABO antibodies.<sup>10</sup> In practice, however, clinically significant hemolysis following “low titer” WB infusion is rarely observed. Specifically, in a clinical trial using up to four such units in the civilian setting, no hemolysis or complications were observed.<sup>11</sup>

Clinically significant hemolysis is a rare but potentially severe complication of administering ABO-mismatched platelet transfusions. In particular, single-donor platelet products from group O donors (apheresis platelets) are most commonly implicated because of the presence of unusually high titers of anti-A in the plasma.<sup>12</sup>

Blood centers may perform titers on group O platelet components to mitigate risk of hemolysis when non-ABO-identical platelet transfusion is required.<sup>13</sup>

A variety of methods and cutoff values are currently used in the United States to determine which products are high titer and therefore at higher risk for causing a hemolytic reaction. Group O whole blood components may be tested for the presence of high-titer anti-A and/or anti-B using a specified dilution with either group A, group B, or pooled group A and B RBCs. Arbitrary selected titers

range from 1:50 to 1:256 with continued debate on the titer and which antibody class, IgM or IgG, to test to ensure optimal safety. Many centers test only for anti-A titer because there is considerable concordance of anti-A and anti-B titers for most donors. Testing may be performed either manually or on an automated platform. Components that are low titer are labeled appropriately.

Similarly, liquid or thawed group A plasma may be used for emergent transfusions. While some centers offer tiered plasma components, many simply use without tiering; a multicenter survey documented safety of untiered products (from male donors) in this setting.<sup>14</sup>

### **Direct antiglobulin testing**

The direct antiglobulin test (DAT) is not routinely performed on blood donors; however, a positive DAT on a unit of blood is occasionally identified during the course of Rh(D) type confirmation or compatibility testing in the hospital transfusion service. Although this is a rare event in blood donors, it reportedly occurs in about 1 per 7000–14,000 donors.<sup>15</sup> Occasionally the positive DAT result is caused by a viral infection or autoimmune disease, including systemic lupus erythematosus and other disorders associated with antiphospholipid antibodies.<sup>16</sup> Although there is often no explanation for this positive test result in an otherwise healthy donor, there is evidence that this finding is associated with an increased risk for malignancy.<sup>17</sup>

Several methods of testing are available, including tube testing, column agglutination (gel testing), and buffered gel cards.

## **Testing for transmissible diseases**

### **General concepts of infectious disease testing**

The World Health Organization requires screening of all blood donations for HIV-1 and HIV-2 by either a combination of antibody–antigen or HIV antibodies, HBV by screening of hepatitis B surface antigen (HBsAg), HCV by screening of a combination of HCV antigen–antibody or antibodies, and syphilis by screening of *Treponema pallidum* (TP) antibodies.<sup>18</sup> Screening of blood donations for infectious diseases has been in place since the 1950s when syphilis testing became routine. The decision to implement a test and the strategy used in dealing with the test results are complex issues.<sup>19</sup> The presence of an asymptomatic phase of infection, the prevalence of the disease in the donor population, the likelihood of transfusion transmission as well as the viability of the infectious disease agent during component storage are important factors to consider. Over the past several decades, major advances in the quality of laboratory testing and response to emerging infections have significantly improved safety as demonstrated by declining rates of post-transfusion infection and reductions in estimated residual risk for such infections.<sup>20–23</sup>

In the United States, screening tests of infectious disease (pre-release tests) used in blood component manufacturing are classified as “biologics” by the FDA. Test sensitivity and specificity are of great importance with the FDA historically encouraging very sensitive tests. This results in a significant rate of false-positive results because typically there is low prevalence in the blood donor population of the screened analyte, resulting in a low positive predictive value. False-positive screening tests may be addressed by well-defined confirmatory test algorithms and approaches to donor notification, counseling, and follow-up of reinstatement protocols, when allowable per FDA guidelines.

Donated units of blood products must remain in quarantine until testing is completed. If tests are nonreactive, they are considered negative for the infectious disease marker, and the blood products from the associated donation may be released from quarantine and issued.

Serological tests for infectious disease are developed to detect antibody, antigen, or combined antibody–antigen for a particular agent. A commonly used screening test method in this category is the enzyme immunoassay (EIA) or the similar enzyme-linked immunosorbent assay (ELISA). These tests typically use viral lysates to capture the antibody, and adherent donor antibodies are detected with antiglobulin conjugate. For serological testing, the FDA typically allows repeat testing to diminish the rate of false positives. Specifically, serological tests with initially reactive screening results are retested in duplicate. If both repeat test results are nonreactive, the donor sample is classified as negative. However, if one or both repeat tests are reactive (termed repeatedly reactive), the products cannot be released for allogeneic transfusion and must be destroyed, the donor deferred, and confirmatory testing, if available, must be performed.

Direct methods of testing of RNA- or DNA-specific sequences for various infectious agents by nucleic acid testing (NAT) using either a polymerase chain reaction (PCR) or transcription-mediated amplification (TMA) have considerably advanced blood safety.<sup>22</sup> Samples may be tested individually or in pooled aliquots (minipools of six or more samples) or with a multiplex approach (i.e., NAT HIV/HCV/HBV). Because NAT is an expensive, yet sensitive technology, a pooling strategy decreases average cost but requires well-defined algorithms for individual testing, when a positive pool is detected. A combination of NAT and serological testing is required in the United States for HIV, HBV, and HCV as some pathogens may have insufficient concentrations of detectable nucleic acid either due to treatment or in very early or late stages of the infection.<sup>23</sup>

Additional supplemental or confirmatory testing is often required after a positive screening test result to determine the clinical significance of a positive screening result and subsequent donor management. This testing is typically performed using assays with different sensitivity and specificity characteristics compared with the initial screening tests. Not all screening tests have a confirmatory test, such as the test for antibodies to hepatitis B core antigen (anti-HBc), which is problematic for donor counseling and deferral. The results of confirmatory testing improve accuracy and predictive value of the screening test results, whereas supplemental tests may aid with product management and donor notification and eligibility for re-entry or reinstatement, if deferred from donation.

In the United States, most tests are mandated in the FDA Code of Federal Regulations (CFR) or under specific FDA Guidance documents and American Association of Blood Banks (AABB) standards. Blood product testing in general is highly regulated and typically performed by any number of automated testing systems available for infectious disease testing (Table 5.3).

Consideration when implementing new blood donor screening includes sensitivity and specificity of the assay, the disease prevalence in the donor population (which determines positive-predictive value), and the likelihood of transmission of the disease to blood recipients.<sup>19</sup> Tests that perform very well in a patient population have different ramifications in a normal donor population. For instance, a test with a specificity of 99.9% performed on 12 million blood donors will yield 12,000 false-positive test results. However, if the disease preva-

HIV, human immunodeficiency virus; HBc, hepatitis B core antibody; HBV, hepatitis B virus; HCV, hepatitis C virus; HTLV, human T-cell lymphotropic virus; TP, *Treponema pallidum*; T. cruzi, *Trypanosoma cruzi*; NAT, nucleic acid amplification test; EIA, enzyme immunoassay; ChLIA, chemiluminescent immunoassay; CMIA, chemiluminescent immunoassay; ID, individual (not pooled) testing; ESA, enzyme strip assay.

<sup>a</sup> Testing required in endemic states in accordance with FDA Babesia Guidance to Industry.

<sup>b</sup> Required on first donation only.

<sup>c</sup> Confirmatory testing not applicable for NAT; supplemental testing may be performed for purposes of donor notification and counseling.

<sup>d</sup> U.S. testing requirement for ZIKV withdrawn by FDA in 2021.

lence is 1 per 500,000 in a blood donor population, for example, only 24 people would truly have the disease in the 12 million tested. This means the positive predictive value (24/12,000) is 0.2% or a 99.8% false-positive rate. When the prevalence of the disease being screened for is low in the donor population, the implementation of tests with less than perfect specificity is fraught with challenges. Confirmatory testing should be available to distinguish those who are truly positive from those who are not, and effective systems must be in place to carry out the supplemental or confirmatory testing necessary to provide this information (Table 5.4). For donors who have a true positive test, complete and accurate information must be available describing the significance of the test result.

### Testing in resource-limited settings

In resource-limited countries or areas of the world highly endemic for an infectious disease agent, it may be more cost-effective to prescreen donors with rapid tests before collecting

their blood.<sup>24</sup> Serial testing strategies such as starting with the most prevalent disease like hepatitis B may then be followed by testing nonreactive donors for HIV, and then further testing for syphilis and HCV.<sup>25</sup> Rapid tests are often used.<sup>26–29</sup> An excellent comparison of rapid tests for hepatitis C has been reported.<sup>29</sup>

### Plasma for further manufacture: source plasma

Source plasma donors are collected by apheresis and must meet the requirements for allogeneic plasmapheresis donors, including infectious disease testing. There are a few notable exceptions from allogeneic blood donors in the United States. Because plasma for manufacture is subjected to pathogen reduction, regulators have not required tests for WNV and ZIKV to be done on source plasma (SP). Hepatitis B core antibody testing has never been required because of the desirability of having that antibody in final

immunoglobulin (IG) product. The current test menu is serology for HIV antibody (now a combination of antigen/antibody on the Alinity), HCV antibody, and hepatitis B antigen. Molecular testing (NAT) includes HIV, HCV, and HBV. The pool sizes may be significantly larger. Source plasma screening also includes in-process testing for hepatitis A virus (HAV) and Parvovirus B19. Although these viruses are usually inactivated by current methods, testing is required for historical reasons because of the nonenveloped nature of the viruses. All units with positive results are removed. While donor notification is not strictly required for in-process testing, the FDA has recently indicated that hepatitis A positive donors should be notified as it is a reportable disease infection to state health departments. There is also lookback of 183 days and look forward or deferral of donors of 120 days for hepatitis A. This is based on European regulations; there are no US regulations related to this. Typically, new infection in repeat donors is detected by NAT. Testing may be performed in a staged series, starting with serology and only advancing to NAT testing when all serological tests are negative. Rules for donor notification and re-entry are the same. All positive tests in the United States must be reported to the National Donor Deferral Registry so that individuals cannot donate in another company's center. Syphilis testing is performed only on initial donation and once every four months thereafter. Historically, it was instituted as a public health measure. SP donors

are typically tested only initially for irregular red cell alloantibody and excluded from further donation if it is positive, unless they have anti-D and are recruited into a program for RH-immune plasma. Blood typing is only occasionally done for products for Von Willebrand disease (VWD).

## Donor management

FDA regulations address donors with reactive infectious disease test results in 21 CFR 610.41. In addition, FDA guidance documents and AABB Association Bulletins provide detailed information regarding requirements for donor testing, notification, and deferral, as well as guidelines for reinstatement following FDA-defined requalification algorithms. Donor management and eligibility for re-entry is dependent on the combined results of the donor screening test and resultant supplemental or confirmatory tests for each specific pathogen targeted for disease marker testing (Table 5.5).

The introduction of HIV testing brought about a major shift in donor notification. The process of notifying donors of abnormal infectious disease testing results is sensitive and may lead to confusion or distress. Care must be taken in any written communication of abnormal results to donors, as well as provision of donor counseling to address questions or concerns<sup>30</sup>

**Table 5.5** Donor Management of Reactive Infectious Disease Results

Reactive Screening Test	Supplemental/Confirmatory Test Results	Deferral Type	Re-entry Eligible
HIV-1/2 Ab RR or HIV Agn/Ab RR HIV NAT positive	Confirmed positive Negative or indeterminate NA	Permanent Indefinite Permanent, if HIV-1,2 Ab RR Indefinite if HIV NAT only None after 1x* Indefinite after 2x	No Yes No Yes NA Yes

<i>T. cruzi</i> Ab RR	Negative Indeterminate or positive	Indefinite Permanent	Yes No

Ab, antibody; Ag, antigen; RR, repeat reactive; NR, nonreactive; NAT, nucleic acid test; BABS, Babesia; HBc, hepatitis B core; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; *T. cruzi*, *Trypanasoma cruzi*; WNV, West Nile virus; ZIKV, Zika virus.

\* Temporary deferral for 56 days.

\*\*U.S. testing requirement for ZIKV withdrawn by FDA in 2021.

Note: Performing a discriminatory NAT assay on a reactive sample is a required step for those establishments using pooled or certain multiplex tests that do not simultaneously detect and discriminate HIV RNA, HCV RNA, and HBV DNA in the same reaction. Donor re-entry policies must conform with current FDA guidance.

Sources: FDA guidance documents: [www.fda.gov/vaccines-blood-biologics/biologics-guidances/blood-guidances](http://www.fda.gov/vaccines-blood-biologics/biologics-guidances/blood-guidances)  
CFR documents: [www.Ecfr.gov](http://www.Ecfr.gov)

It is imperative to have a robust donor notification system that embraces the following ethical concepts:

- 1 Confidentiality:** Even notification of a false-positive result may be misconstrued by the donor or a close family member. It is vital to have a secure strategy to notify donors in private. This is particularly challenging in the setting of prescreening donors with point of care rapid screening tests in countries with high disease prevalence.
- 2 Informed consent:** Donors should be aware of the potential for and implications of donor testing, including potential for deferral and mandatory reporting of certain positive results to local departments of health.
- 3 Truth telling and deferrals:** Collection and testing centers are obligated to share any information of potential medical significance, including sickle trait testing as well as infectious markers with health implications such as positive tests for HIV, HBV, and HCV.
- 4 Treating donors fairly:** There are ethical obligations to both donor and recipient and there is no specific right to donate. Where directed donation or autologous donation are allowed, they should be used in a medically appropriate and consistent fashion.

## Product management

Blood products are kept in quarantine until all testing is completed. Results of infectious disease testing are necessary prior to labeling and releasing products for transfusion. The screening test results determine product disposition (Table 5.6). In addition, final test results are used to direct retrieval of previously released products and trigger transfusion recipient notification (i.e., lookback).

## Retrieval of in-date products and recipient notification

Results of infectious disease testing not only impact currently collected components, but are also used to retrieve previously released products and trigger notification of prior recipients, when indicated, by a process known as lookback. FDA and AABB recommendations are very specific for each infectious agent depending on the test method to address the concern that a previous donation with a

negative test result could have been in the “window” phase of early infection, even though the screening test results were negative.

Specific requirements and algorithms for managing components from prior blood donations, including recipient notification of prior donations for HIV and HCV test results, are available (21 CFR 610.46 and 610.47). Lookback is required by law for both of these infectious agents. FDA guidance documents and AABB Association Bulletins govern the management of other licensed screening tests. Investigational protocols for unlicensed screening assays outline requirements for product retrieval and recipient notification (Table 5.6).

The lookback process requires notification of consignees who have received components from previous collections from a donor who is now reactive for a particular infectious disease marker. They must be notified in order to begin recipient tracing for the purpose of notification of recipients of previously transfused products for testing and counseling. The transfusion service consignees are responsible for notifying the physician(s) of the recipient(s) to begin notification of the recipient(s). The transfusion service may also notify the recipient(s) directly. The notification process shall include a minimum of three attempts to notify the recipient (or a relative or legal representative of the recipient in the case of HIV) and must be completed within a maximum of 12 weeks for HCV or HIV.

## Donor Re-entry

Blood centers were reluctant in the past to perform donor re-entry after indefinite deferral due to donations associated with positive infectious disease marker test results on a serologic test that is not confirmed by additional testing. In 2010, the FDA eased the pathway for re-entry of previously deferred donors with introduction of specific guidelines.<sup>31</sup> Detailed eligibility is defined in FDA guidance documents.<sup>32</sup> These describe additional testing requirements following a minimum time period of deferral, at which point the donor may be notified to return for follow-up testing. Guidelines for re-entry eligibility are currently available for donors with possible false-positive test results for HIV, HBV, HCV, HTLV, syphilis, and *T. cruzi* (Table 5.5). Prior to allowing the donor to be re-entered into the donor pool, both the original screening test and a licensed

**Table 5.6** In-Date Product Retrieval and Recipient Notification

Reactive Screening Test Result*	In-Date Product Retrieval		Recipient Notification (Lookback)
	Blood Components	Recovered Plasma	
HIV-1/2 Ab or HIV Ab/Ag combo test	All products	Unpooled only	Indefinite or 12 months from most recent licensed negative
HIV NAT	All products	Unpooled only	1 year
HBsAg	All products	Unpooled only	5 years or 12 months from most recent negative
HBc Ab	All products	None	None
HCV Ab	All products	Unpooled only	10 years or 1 year before last known reactive
HCV NAT	All products	Unpooled only	1 year
HTLV Ab	All products (unless frozen)	None	5 years or 12 months from most recent negative (none for frozen components)
<i>T. cruzi</i> Ab	All products	None	All products
WNV NAT	Products in prior 120 days	Products in prior 120 days	120 Days
ZIKV NAT	Products in prior 120 days	Products in prior 120 days	120 Days
BABS NAT	All products	None	12 months from positive draw date

Ab, antibody; Ag, antigen; RR, repeat reactive; NR, nonreactive; NAT, nucleic acid test; BABS, Babesia; HBc, hepatitis B core; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; *T. cruzi*, *Trypanasoma cruzi*; WNV, West Nile virus; ZIKV, Zika virus.

\* Refers to repeat reactive screening tests by serology or positive tests by NAT based on individual or discriminatory testing, if a pooled or multiplex test was performed.

supplemental or confirmatory test must be negative. Specific re-entry algorithms should be developed in conformance with FDA guidance. For example, FDA allows re-entry as early as eight weeks after an initial RR test for HIV if the confirmatory testing was negative on the index donation. In contrast, donors are not eligible for re-entry until six months have elapsed following HCV repeat reactive screening tests.

### HIV testing

HIV is an RNA lentivirus in the subgroup of the retrovirus family. HIV infection may progress to acquired immunodeficiency syndrome (AIDS). With current donor screening and testing, the risk for TTI is less than one in two million blood products in the United States.

### HIV antibody testing

HIV antibody testing generally uses recombinant antigens, but historically viral extracts have also been used. Multiple antigens are typically incorporated to maximize the sensitivity as well as capturing multiple virus strains. The first blood donor screening test for anti-HIV-1 was licensed in 1985. Subsequent HIV assays included antigens from both HIV-1 and HIV-2. Because there is greater than 50% homology between HIV-1 and HIV-2 DNA, the HIV-1 test detects about 90% of HIV-2 strains.<sup>33</sup> However, as cases of transfusion-transmitted HIV infections from HIV-2 began to appear in the United States,<sup>34,35</sup> the FDA requested that HIV test kits include antigens specific for HIV-2. Efforts to improve donor screening also focused on narrowing the preconversion window phase of infection.<sup>36–38</sup> HIV-1 group O infection was later identified in certain African countries, where it was found to be endemic. Currently, licensed HIV-1/HIV-2 plus O EIA antibody tests are routinely used for HIV antibody screening of donors. Traditionally, HIV antibody screening tests have utilized chemiluminescent immunoassays (ChLIA) or enzyme immunoassay (EIAs). More recently, the so-called fourth generation of HIV screening tests for blood donation have introduced a combined antigen/antibody test.<sup>39</sup> Newer chemiluminescent microparticle immunoassays (CMIAs) have been approved for blood donor testing, which use a method for the simultaneous qualitative detection of human immunodeficiency virus (HIV) p24 antigen and antibodies to HIV type 1 (HIV-1 group M and group O) and/or type 2 (HIV-2) in human serum and plasma specimens. It is anticipated that these fourth-generation assays will increase accuracy and reduce the number of donations requiring confirmation, save time and money, and reduce the number of discarded blood donations and allow re-entry processes.<sup>40</sup>

### HIV NAT

NAT for blood donor screening introduced a new era in the field of blood safety.<sup>41–45</sup> HIV NAT testing is performed by either PCR or TMA. Testing may be performed on pools of 6–16 donor samples (minipools), to reduce the expense without significantly decreasing sensitivity, or individually (ID NAT). Currently, donor testing is typically performed in a multiplex assay for HIV/HCV/HBV. If a tested pool is positive, discriminate testing with individual donor (IND) NAT is required. In areas of high endemic disease prevalence, such as South Africa, it is more practical to simply screen all donors individually as the

frequency of required pool resolution would obviate any benefit of starting with pools.<sup>46</sup>

There is recent evidence that the results of diagnostic and screening assays for HIV may be altered in individuals who are taking antiretroviral therapy because of the suppression of circulating HIV RNA below levels of detectability by NAT.<sup>47</sup> Similarly, there is concern that rare individuals may be able to transmit HIV after receipt of prescription preexposure prophylaxis, even though they believe they are protected from infection. In a recent study of HIV antibody-positive, NAT-negative donors in South Africa, approximately 66% had been receiving antiretroviral therapy.<sup>48</sup> Test results in these donors may not reflect likelihood of infection transmission.

### HIV confirmatory testing

For blood samples that test repeat reactive (RR), additional testing must be performed if serology is not confirmed by positive HIV NAT (Table 5.4). Until recent years, confirmatory testing for HIV was routinely performed by HIV-1 Western blot (WB) or immunofluorescence assay (IFA) followed by anti-HIV-2 if HIV-1 is not confirmed. The criteria for HIV-1 positivity on WB are the presence of antibody against any two of the associated proteins. Sera that react with only one protein are considered indeterminate, which can occur for a variety of reasons and typically have no relationship to HIV infection. An immunochromatographic assay (Geenius<sup>TM</sup>) for HIV-1/2 has enabled an improved approach for HIV-1/2 testing.<sup>49</sup> Recently, FDA approved for blood donor testing a supplemental assay, which avoids the significant rate of indeterminates seen on WB and offers a single, simplified approach for HIV-1/HIV-2 antibody confirmation and differentiation, enabling the replacement of previously used FDA-licensed supplemental assays.<sup>50,51</sup> The supplemental results of testing help determine the infectious state of the donor for purposes of counseling and consideration of re-entry, as allowable by the 21 CFR and FDA Guidance for Industry. Components of blood collected from donors with either reactive anti-HIV serology or positive NAT tests must be discarded and the donor indefinitely deferred, except for autologous blood collections.<sup>52</sup>

### Hepatitis B testing

HBV is a DNA virus in the *Hepadnaviridae* family, which is highly prevalent in Asia and Africa. Although most cases (~95%) acquired during adulthood are cleared, perinatally acquired cases may result in chronic infection. The first blood donor screening test for this virus was required in 1972.

### Hepatitis B surface antigen

Testing for HBsAg was first introduced in 1971 shortly after the discovery of the hepatitis-associated antigen. Although test methodology has evolved over the years, currently an EIA system is used. Antibody to HBsAg is coated onto particles, the donor's serum is added, and any HBsAg binds to the particle and is detected by a second anti-HBs (antibody to HBsAg) that is linked to an enzyme. Automated testing methodologies often use chemiluminescent labels, replacing the enzyme conjugates and chromogenic detection methods. Confirmation of a positive test is done by a neutralization step adding anti-HBs antibody and repeating the assay. A substantial reduction in activity signifies a true positive or confirmed positive test.

### **Anti-HBc antibody**

The test for anti-HBc was originally introduced in hopes of identifying cases of hepatitis B with below detectable HBsAg.<sup>53</sup> It was also used as a surrogate assay with ALT testing for non-A, non-B hepatitis in 1987 prior to the identification of HCV.<sup>53-55</sup> The implications of anti-HBc and lack of correlation with HBsAg and HBV DNA have been observed, including rare donors infectious for hepatitis B who have a negative HBsAg test.<sup>56</sup> Hence, donor screening tests are designed to detect both IgM and IgG antibodies. The anti-HBc test is different from the others in that it is an inhibition-type assay. HBc is bound to the solid phase, and the indicator (enzyme-linked) probe is anti-HBc. The anti-HBc in the probe competes with the donor's serum sample, and if anti-HBc is present in the donor's serum there is less binding of the labeled probe and a reduced assay activity, indicating a positive test. A direct antiglobulin assay for anti-HBc is also available. Unfortunately, the inhibition-type assay is subject to greater variability than the direct-type assay used for other tests, and this has resulted in a considerable false-positive rate for the anti-HBc test.<sup>57</sup> Notably, most non-US countries do not use this test.

Unfortunately, no confirmatory test method exists for the anti-HBc test, which has resulted in a unique approach when other tests for HBV are negative. Donors are indefinitely deferred after the second RR anti-HBc donation if the other HBV markers are negative. Due to the concern that such a donor could be at the tail end of an active HBV infection, recent FDA guidance has added the recommendation to perform IND HBV NAT testing to increase the sensitivity for the detection of HBV present at very low levels, which could be below detectable limits in pooled samples.<sup>58,59</sup> Donors who are RR for anti-HBc on more than one occasion, but remain negative for NAT and HBsAg, are eligible for re-entry for blood donation after a minimum of 8 weeks after the last RR anti-HBc donation.

### **HBV NAT**

HBV-NAT is a required screening test for HBV. The slow doubling time of that virus causes low levels of viremia during the window phase.<sup>41</sup> HBV DNA levels in HBsAg-positive and anti-HBc-positive blood donors can be extremely low. HBV may be detected later in infection when HBsAg has already cleared, but those donors would also be detected by the required anti-HBc test. Current minipool HBV-NAT methods would miss about 6% of these donations, and about 3% would not be detected even by single-donor NAT.<sup>58,60</sup> Therefore, the widespread adoption of NAT testing for HBV was very slow.<sup>56</sup> A recent study of the incremental cost utility of NAT after the implementation of serology screening prompts the need for further discussion of these testing strategies in the future.<sup>61</sup>

### **Hepatitis C testing**

HCV is a single-stranded RNA flavivirus, which is transmitted through blood exposure. It is typically asymptomatic during the acute phase, but may result in slowly progressive chronic infection yielding cirrhosis and liver failure.

### **HCV antibody screening**

The primary anti-HCV antibody test used for screening blood donations is a third-generation EIA. Peptides of the HCV are bound to the solid phase, and an enzyme-linked antiglobulin is the detection system. The mix of peptides in the assay system has been adapted to improve test performance and reduce false-positive reactions.<sup>62</sup> The currently available tests have recombinant HCV

antigens representing four viral sequences. A positive screening test is repeated in duplicate, blood from donors with RR results is destroyed, and donor notification and deferral are required. For many years, the confirmatory test performed for anti-HCV antibodies was the FDA-licensed recombinant immunoblot assay against HCV antigens, which became commercially unavailable in the United States in 2012.<sup>63</sup> Since then, supplemental testing has been accomplished using an alternate EIA test method.

### **HCV NAT donor screening**

In the United States, there are two commercially available, licensed NAT assays for volunteer blood donor screening: one is a PCR test and the other is based on TMA technology for the detection of HCV RNA in the donor sample. Both test methods can identify HCV RNA with an average of 11 days after infection and are available in a multiplex format (HIV/HCV/HBV). Multiplex testing occurs in minipools of 6–16. If a pool is positive, discriminate testing of individual samples is required and the donor is indefinitely deferred.

Blood donors with positive HCV NAT results in the absence of anti-HCV are likely to have been recently infected. The most common reason for this is injection drug use.<sup>64</sup> However, immunocompetent HCV-infected individuals may occasionally not have a persistent HCV antibody response.<sup>65</sup> If a donor with a negative HCV NAT has RR anti-HCV test results, they are indefinitely deferred. Results of supplemental testing in this situation assist with donor notification, counseling, and eligibility for donor re-entry following a period of at least 6 months. If all repeat HCV testing is negative, including IND HCV NAT, the donor can be reentered.<sup>66</sup>

### **Human T-cell lymphotropic virus testing**

Testing of US blood donors for antibodies to HTLV-I and HTLV-II using an FDA-approved EIA or ChLIA test began in 1997. Supplemental/confirmatory testing may be performed by repeating the test using an alternate manufacturer's assay or by WB. FDA-approved the MP Diagnostics HTLV Blot 2.4 in 2014, which uses a combination of envelope recombinant proteins and viral lysate (envelope rgp46-I, rgp46-II, and GD21, and gag p24 and p19 antigens) to confirm the presence of antibodies against HTLV-I/II and differentiate between HTLV-I and HTLV-II infection (gag p24 and p19 antigens). A donor who is negative or indeterminate with supplemental testing may continue to donate. However, donors positive with a supplemental test or who are RR on the screening test on two separate donations are permanently deferred.

HTLV-I is a virus that is endemic in certain areas, including Japan and the Caribbean region. It is associated with a slowly progressive myelopathy in a small percentage (<2–4%) of infected individuals. HTLV-II is most likely to occur in donors with either a history of intravenous drug use or sexual contact with an intravenous drug user. Most infections are asymptomatic, but there is a very low lifetime risk (<4%) of development of adult T-cell leukemia/lymphoma. Because these viruses predominantly infect T-lymphocytes, leukoreduction may theoretically prevent infection. The seroprevalence in blood donors in the United States is less than 0.01%.<sup>67</sup> The impact of testing on improved patient safety is questionable and donor counseling is challenging due to the low risk for the development of the disease. Blood collection establishments outside the United States rarely screen for HTLV.

## West Nile virus testing

WNV is a single-stranded RNA flavivirus, which is primarily spread in the United States by the *Culex* mosquito species.<sup>68</sup> After confirmation of transfusion transmission of WNV to 23 patients in 2002, the FDA mandated testing of all components of blood collection in 2003. WNV NAT was rapidly implemented, in part due to existing NAT platforms for HIV and HCV testing. Testing of blood donated from epidemic areas began in early summer 2003.<sup>69–72</sup> NAT testing has been quite effective in reducing the likelihood of transfusion-transmitted WNV infection.<sup>69–72</sup> Routine testing is done in pools similar to HIV and HCV, but due to low-level viremia, WNV is switched to individual testing during the epidemic season based on surveillance for infection in the region.<sup>73</sup> Blood donor WNV testing provides valuable information about community-wide disease prevalence.<sup>74</sup>

## Zika virus testing

ZIKV is a tropical arbovirus of the flavivirus group. Although first discovered in Uganda in 1947, human infections were first recognized in Africa and Asia in the 1960s, with epidemic spread to the Pacific Islands and beyond in the 2000s. An American outbreak was first identified in Brazil in 2015, where it was linked to the alarming observation of babies born with microcephaly presumably due to maternal–fetal transmission. With the recognition of the possibility of transfusion transmission, an FDA Guidance for Industry was issued in February 2016 with recommendations for donor screening, deferral, and product management to reduce the risk for transfusion transmission of ZIKV.<sup>75</sup> As the epidemic evolved and autochthonous (local acquisition) mosquito-borne infection was identified in pockets of southern Florida and Texas, the FDA published a revised ZIKV guidance that included a testing requirement in July 2018.<sup>76</sup>

Based on the FDA guidance recommending either NAT or pathogen reduction of blood products, ZIKV testing of the blood supply is performed by one of the two commercially available platforms, which uses either real-time PCR or TMA to detect ZIKV RNA. Both methods of detection are highly sensitive and specific. Donors with a positive test result are deferred for 120 days, similar to those with a positive WNV result. The first test introduced was ID NAT, with more recent testing allowed in pools with algorithms for conversion back to ID NAT under appropriate circumstances.

A study of ZIKV-infected US blood donors revealed that they were all acquired from travel to affected areas outside the country.<sup>77</sup> A cost-effective analysis estimated that \$137 million per year is spent on donor ZIKV testing at a cost of at least \$5.3 million per RNA-positive test.<sup>78</sup> Given an absence of evidence of autochthonous transmission since 2017<sup>79</sup> and the questionable impact on patient safety,<sup>80,81</sup> the continued need for Zika screening was debated. The FDA has specifically excluded the need for Zika screening in products treated with an approved strategy for pathogen reduction and discontinued the test requirement in 2021 following waning of the outbreak.<sup>82,88</sup>

## Testing for babesiosis

*Babesia*, an intraerythrocytic parasite, can be transmitted by transfusion of red cell containing components. Up to 1% of donors in some endemic areas test positive for prior exposure on a donor screening test.<sup>83</sup> Targeting tested units for only immunocompromised patients at greatest risk would have limited efficacy given

that many of the affected recipients in case series do not belong to obvious at-risk groups.<sup>84</sup> Initially, antibody-based screening assays were trialed but subsequently replaced by more specific NAT-based assays.<sup>85,86</sup>

The impact of *B. microti* blood donation screening has been reported.<sup>87</sup> The FDA Guidance for Industry document recommends the implementation of year-round *Babesia* testing of all donations collected in 14 states (Connecticut, Delaware, Maine, Maryland, Massachusetts, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Vermont, Virginia, Minnesota, and Wisconsin) and Washington, DC, unless the blood products are pathogen reduced using an FDA-approved technology.<sup>88</sup> (Of note, there are no well-documented transfusion-transmitted cases from plasma or platelets collected by apheresis only.)

Currently, two licensed tests are available for donor screening by NAT, the Grifols Procleix *Babesia* Assay and the PCR-based NAT assay by Roche, which are highly sensitive qualitative tests for the detection of *Babesia* ribosomal RNA or DNA. In the United States, testing may be performed individually or in minipools (up to 16 samples), which is allowed because of the high clinical sensitivity of the assay. These test systems detect four *Babesia* species: *B. microti* (most prevalent in the United States), *B. duncani*, *B. divergens* (most prevalent in Europe), and *B. venatorum*. These both require use of a special collection tube containing lysis buffer to disrupt red cells as most organisms are intraerythrocytic.

## Syphilis testing

Syphilis testing has been conducted on donated blood for more than 50 years.<sup>89</sup> However, no well-documented cases of transfusion transmission have occurred in the last three decades. Fortunately, the spirochete is not infectious after approximately 72 hours of refrigeration in stored blood.<sup>90</sup> A study<sup>91</sup> using nucleic acid amplification technology did not find TP DNA or RNA in any of 169 samples from blood donors with positive serological tests for syphilis. Thus, the current testing probably does not identify infectious units.<sup>89,91,92</sup> Consideration of discontinuing syphilis screening has been controversial.<sup>93</sup> However, as the AIDS epidemic began to unfold, the syphilis test was retained as a surrogate marker of risk for sexually transmitted diseases, including HIV. This has not proved to be an effective way to identify HIV-infected donors, and syphilis testing need not be retained for this purpose.<sup>92,93</sup> Room temperature storage of some blood components, particularly platelets, will not inactivate the spirochete. Syphilis is more common in many parts of the world, but many treponemal-specific screening methods are not positive early in infection. While reagin-based methods (RPRs) may have better early sensitivity, they are plagued by a high false-positive rate.<sup>94</sup>

## *Treponema pallidum*: *T. pallidum* and non-*T. pallidum* testing

Antibody screening tests for syphilis may be performed by using either TP or non-TP tests. TP tests identify both current and distant infection, whereas non-TP tests identify active or recent infections and become negative after the treatment of syphilis infection. TP tests target detect antibodies against specific TP antigens, such as the MHA-TP micro-hemagglutination test. In contrast, non-TP tests (such as the rapid plasma reagin test) detect antibodies that react against anticardiolipin phospholipid and may be present in a variety of disorders and inflammatory conditions. Confirmatory or supplemental testing should be performed following a reactive screening test result. Tests in this category

include fluorescent TP antibody absorption (FTA-ABS) or the Syphilis-G EIA.

Donors with a reactive screening test may return for donation if supplemental testing is negative; however, if supplemental testing is positive, the donor is indefinitely deferred but may be eligible for re-entry in accordance with FDA Guidance.<sup>95</sup>

### Chagas' disease testing

*Trypanosoma cruzi* is the causative agent of Chagas' disease, also known as American trypanosomiasis. It is a tropical parasitic disease, which can also be transmitted by transfusion, as well as solid organ transplantation and transplacental transmission. With increased immigration to the United States from Central and South America, seroprevalence of this organism has increased during recent decades. Many patients with chronic *T. cruzi* infection are asymptomatic, and a question only based approach is ineffective.<sup>96</sup> Cases of transfusion-transmitted Chagas' disease are extremely rare in the United States.<sup>97–99</sup> Multiple ELISA-based assays with high sensitivity and high specificity are FDA approved, but blood donors are only required to be screened once. Virtually, all US donors with confirmed positive tests were born in *T. cruzi*-endemic areas, and no seroconversion of test negative donors has been observed.<sup>100</sup>

### CMV testing

CMV testing is an optional test performed on donated blood products. The virus largely remains latent in the donor's leukocytes and hence transfusion transmission may be largely abrogated by effective leukoreduction.<sup>101,102</sup> Several types of CMV antibody detection methods are available, including enzyme-linked assays (EIA), latex agglutination, solid-phase immunofluorescence, complement fixation, and indirect hemagglutination. These methods can be used to detect IgG or IgM antibodies with a specificity of 85–98% and a sensitivity of 95–99%.<sup>102</sup> The two assay methods used most commonly are the EIA and the latex agglutination test.

CMV infection is rather common in the general population, with 30–80% of blood donors testing positive with the EIA or latex tests, but probably only about 1–3% of donors are actually infectious.<sup>102</sup> IgM antibodies may indicate more recent infection. Although PCR is a very sensitive assay to detect viral DNA, this has not been widely applied for CMV in blood donors. Thus, selective screening for susceptible patients has been advocated.<sup>103</sup>

More recently, prestorage leukoreduced (LR) blood components have been widely implemented to prevent transfusion-transmitted CMV infection (TT-CMV) as most clinicians consider them an acceptable and preferable method of providing CMV "safe" blood products.<sup>104,105</sup> A recent study of umbilical cord blood transplant patients receiving prestorage LR, CMV-unselected blood components between 2007 and 2017 in a Japanese pediatric center found no cases of TT-CMV.<sup>106</sup>

### Additional testing for blood derivatives

Plasma not needed for transfusion or directly collected for preparing derivatives is required to have additional screening for Parvovirus B19 and HAV due to the very large pool sizes used in

preparing these products. Plasma from 5 to 20,000 donors may be pooled in making large derivative lots.<sup>107</sup> Most plasma centers use a donor retested policy, i.e., not including a product into a pool until the donor has returned and been retested and found negative for all infectious disease markers a second time. In addition, the process sometimes includes solvent-detergent treatment that effectively inactivates lipid envelope viruses. Since both Parvovirus and HAV are nonlipid envelope viruses, this inactivation step is not effective against these two viruses and breakthrough infusion-related infectious for each have been reported.

### Bacterial testing of platelets

The primary components associated with transfusion-transmitted bacteria are whole blood-derived and apheresis platelets.<sup>108</sup> Platelet concentrates are stored at room temperature; however, *Yersinia enterocolitica* transmission from RBCs stored at refrigerator temperatures is also reported. For both, the source of potential contamination is usually blood or the skin at the venipuncture site, and almost never the blood collection pack. Steps taken to minimize the possibility of transfusion-associated sepsis include effective skin decontamination, diversion of the first 20–40 mL of blood proper storage and handling conditions, and the detection of bacteria before transfusion.<sup>108–110</sup>

The method most widely used currently in the blood center setting for bacterial testing of platelets is an automated culture system frequently used in hospitals for patient blood cultures.<sup>111</sup> Both the BacT/ALERT and BacTec systems can be used for the detection of bacteria in platelet products, with the ability to detect levels of 10 and 100 colony-forming units per milliliter.<sup>112</sup> Another system tests platelets at the time of release for transfusion when the level of organisms is higher and more easily detected.<sup>113</sup> However, current bacterial detection strategies do not detect all contaminated units and have not eliminated all transfusion-related septic fatalities.<sup>114–116</sup> In fact, sepsis attributed to bacterial contamination of platelets despite being treated with pathogen-inactivation technology has also been identified.<sup>117</sup>

Given the remarkable reduction in the viral risk from transfusion in recent decades to improve safety, the low but persistent risk for bacterial contamination has become the greatest residual threat of TTI resulting in fatality.<sup>1</sup> In September 2019, the FDA finalized the bacterial risk-control strategies for blood collection establishments and transfusion services to enhance the safety and availability of platelets for transfusion guidance for industry, which was updated to extend the deadline for implementation in December 2020.<sup>118</sup> The goal is to further mitigate the risk for septic reactions from platelets, which currently has a reported rate of approximately 1 per 100,000 platelet transfusions.<sup>118</sup> In contrast, sepsis from transfusion of bacterially contaminated RBC components is generally regarded as a rare event.<sup>119</sup>

The two main options are pathogen reduction or bacterial testing, which include single-step and two-step strategies. The single-step strategies require large-volume delayed sampling for culture using aerobic and anaerobic cultures of each platelet product, no sooner than 36 or 48 hours, resulting in expiration at 5 or 7 days, respectively. The two-step strategies involve an initial culture no sooner than 24 hours, followed by a secondary method of bacterial testing by either culture or a rapid test method after day 3 of the 5-day platelet shelf life.

## Other laboratory testing

### HLA antibody testing

With antibodies against HLA and human neutrophil antigen antibodies in blood products (usually platelets or plasma) implicated as an etiology of transfusion-transmitted lung injury (TRALI), efforts to mitigate this risk have been implemented.<sup>120</sup> Collection of plasma (largely limited to male donors) and platelets from males, never pregnant females, or HLA antibody-tested females became mandatory in the United States with the goal of further reducing the TRALI incidence.<sup>121</sup>

Two types of assays are commonly used in blood centers for HLA antibody screening of blood donors. Automated methods for testing may be based on either EIA methodology or a multianalyte assay system using an advanced flow cytometer with microbeads coated with purified class I or class II HLA antigens and preoptimized reagents for the detection of class I or class II HLA antibodies in human donor sera.

### Extended blood group antigen typing

Units of RBCs lacking specific antigens may be requested for patients with RBC antibodies or who require prophylactic antigen-matched units. Transfusion recommendations for RBC antigen matching to prevent alloimmunization in patients with sickle cell disease, thalassemia, and other transfusion-dependent anemias have been published.<sup>122-125</sup> Traditionally, antigen-negative units were identified through serological testing. With the advent of RBC genotyping, many blood centers supplement testing by performing extended RBC antigen typing using DNA-based technology, which provides a reliable and cost-effective prediction of the RBC phenotype.<sup>57</sup> The additional benefits of genotyping for further improving transfusion practice have been documented in recent years.<sup>126-129</sup>

Automated high-throughput platforms for mass-scale RBC genotyping will help identify desirable antigen-negative blood donors and improve availability of antigen-negative units.<sup>130</sup>

### Role of platelet antigen typing

Blood and platelet donors are not routinely tested for platelet-specific antibodies; however, some blood centers perform platelet antigen testing to identify those who are negative for the HPA1a (PlA1) or other platelet-specific antigens. HPA-1a is most commonly involved in neonatal alloimmune thrombocytopenia or post-transfusion purpura.

### Role of platelet serology

Blood centers may be requested to perform platelet antibody testing on patients who are refractory to transfusion to rule out an immune-mediated cause. Serological testing for the detection of HLA or non-HLA antibodies can be performed by a variety of serological methods. Solid-phase RBC adherence testing for the detection of platelet antibodies is commercially available. Other methods of platelet antibody detection include flow cytometry and EIA/ELISA techniques. If antibodies are present, platelet compatibility testing can be performed by crossmatching

patient plasma against apheresis platelets available in the inventory for transfusion. Alternatively, HLA-matched platelets can be provided, if the platelet donor has been HLA typed and the platelet refractory patient has known HLA antibody specificity.

### Parvovirus B19 and hepatitis A virus testing

These viruses can be transmitted by transfusion, but the main concern has historically been transfusion transmission via plasma derivatives. NAT for Parvovirus B19 and HAV is now done for SP (intended for the manufacture of derivatives), which has been described earlier in this chapter under plasma for further manufacture.

### Hemoglobin S testing

Many patients with sickle cell disease require blood transfusion therapy. The goal is to decrease the proportion of RBCs containing hemoglobin S to reduce sickling and prevent increased viscosity of their blood. Healthy donors who have the sickle cell trait may be unaware that they have hemoglobin S. In this era of universal leukoreduction, RBCs from donors with hemoglobin S trait often may adhere to the WBC reduction filter resulting in occlusion or failure to completely leukoreduce the unit, resulting in a "filter failure."<sup>131</sup> In addition, blood provided for patients with sickle cell disease requires some degree of prophylactic antigen matching (Rh and Kell) or additional antigen typing if RBC alloantibodies are present. Blood from donors of African ancestry may be preferentially tested for their phenotype characteristics, so testing for hemoglobin S must also be performed. RBC units must be labeled/tagged to indicate that they are hemoglobin S negative. Hemoglobin S-tested blood is also typically requested for intrauterine transfusion and neonatal exchange transfusion.

Most methods of screening for hemoglobin S are performed manually using a phosphate solubility method. RBCs are lysed by saponin, and released hemoglobin is reduced by sodium hydrosulfite in a phosphate buffer. Hemoglobin S is insoluble and will form a cloudy, turbid suspension, whereas other hemoglobins are more soluble and form a clear red solution. It is important to note that increased percentages of hemoglobin F may cause a false-negative test, and patients with abnormal proteins in their blood may have a false-positive test. In addition, Immucor HEA has an automated molecular bead chip test for hemoglobin S, which can be performed with common RBC genotyping.

### Screening donors for IgA deficiency

IgA levels are not routinely determined in donated blood. Some blood centers occasionally screen donors for a limited time to establish a file of rare donors known to be IgA deficient. The donor record can be annotated so that when the individual donates, the plasma from the unit can be frozen and saved for future use for IgA-deficient patients. Also, those donors can be called on to donate platelets if needed for IgA-deficient patients. In the setting of transfusion-related anaphylactic reactions, patients must be evaluated for severe IgA deficiency (<0.05 mg/dL) and anti-IgA antibodies.

## Summary

Laboratory testing of donated blood is composed of a wide variety of tests, focused primarily on blood group typing and tests designed to screen for relevant transmissible infectious diseases. With more widespread implementation of electronic crossmatching, the importance of proper ABO identification and labeling is paramount. Transmissible disease testing has almost eliminated the infectious risks of blood transfusion. The increasing complexity of these tests has led to the consolidation of the testing into larger laboratories.

## CHAPTER 6

# Acute adverse reactions after blood donation

Anne F. Eder

Center for Biologics Evaluation and Research, Food and Drug Administration, Silver Spring, MD; and Georgetown University Medical Center, Washington, DC, USA

A safe and adequate blood supply depends on healthy, altruistic volunteers who are willing to donate blood despite the potential risk of discomfort or an adverse reaction. Blood donation is generally considered safe and most donors have a good experience or have only mild symptoms after donation. About 7.3 million volunteer blood donors gave blood in 2019 in the United States (US), or 4% of the estimated 205 million individuals who are likely eligible to donate blood, to meet the annual demand for blood transfusion.<sup>1,2</sup> Considering the millions of donations each year, even a low risk of adverse reactions will negatively affect the health and well-being of many people and will influence their willingness to donate blood again. Consequently, prevention and mitigation strategies to reduce donor reactions and efforts to improve the donor experience are essential.

Adverse reactions occur immediately or soon after a blood collection procedure or become apparent only over a longer period of time, after several blood donations. Immediate or acute reactions after blood donation are typically minor symptoms such as dizziness and fainting or phlebotomy-related bruises, and less commonly, more serious injuries from resultant syncope-related falls or needle-related nerve injuries.<sup>3</sup> Blood collection agencies must inform prospective donors about the possible risks at each encounter and monitor adverse reactions during and after the collection procedure as part of ongoing continuous improvement efforts to reduce donation-related complications. Although blood centers cannot completely eliminate all risks associated with blood donation, they can systematically analyze their adverse reaction rates, which can lead to changes in collection procedures and policies to improve safety for the most susceptible groups of blood donors.

### Adverse reactions after blood donation

Most acute reactions (>90%) that occur immediately or within a few hours after donating blood are mild or minor symptoms such as dizziness, lightheadedness, or phlebotomy-related bruises and hematomas that resolve promptly but are still unpleasant for the donor. More serious complications are uncommon, but typically result from a loss of consciousness, from injuries after blood donation, or from a needle-related nerve injury.<sup>3</sup> Young (teenage) donors are much more likely to experience immediate adverse reactions after

blood donation than older donors, with loss of consciousness affecting about 4 in 1000 donations and injury resulting in 0.6 in 1000 donations among donors age 16–17 years.<sup>4,5</sup> Not surprisingly, blood donors who have an adverse reaction are less likely to return to donate blood again than those who have an uneventful donation.<sup>6–8</sup> Even minor reactions and transient symptoms discourage return donation by 36%, with more severe reactions further decreasing the likelihood by 66%, compared to the return rates of donors who do not experience reactions after blood donation.<sup>6</sup> The potential loss in annual donations resulting from donor attrition after adverse reactions has been estimated as 1.6% per year.<sup>7</sup> Donor retention has far-reaching implications for the blood supply, not only on availability but also on safety, because repeat donors account for about 75% of the US blood supply<sup>1</sup> and are less likely than first-time donors to have positive infectious disease markers, such as hepatitis and HIV.

Many studies of reactions after allogeneic blood donation published since the 1940s have reported various incidence rates and associated risk factors.<sup>9</sup> Published reaction rates from different blood centers span a wide range (e.g., <1% to >20%). Many factors contribute to this variability, including disparate donor demographics, different reaction definitions, subjective assessments of reaction severity, and various methods of data collection and analysis. Reactions may be captured at the site by collection staff or identified only after the donor calls the center back to report a reaction. Higher reaction rates are generally observed when blood donors complete surveys about mild subjective symptoms or are directly interviewed days to weeks after a donation.<sup>10,11</sup> Many studies of donor reactions are limited by methodological problems, including retrospective design, poorly controlled comparisons, or the use of univariate methods to detect associations of various factors with donor reactions. Consequently, statements about various risk factors should be evaluated in conjunction with an assessment of the study design and analytical methods.

In recent years, blood centers have focused on the practical application of donor hemovigilance, which is an effort to monitor, track, and trend reactions after blood donation, in order to design and implement preventive measures. An example of such a program in the American Red Cross is shown in Table 6.1, which captures immediate reactions managed by collection staff at the blood drives

Rate per 10,000 donations. LOC, loss of consciousness; small hematoma, 2 × 2 in. or less; large hematoma, more than 2 × 2 in. Prolonged recovery (>30 minutes) after presyncope. Automated collections include plateletpheresis, plateletpheresis with concurrent plasma or other cocomponent, two-unit red cell collections, and plasmapheresis procedures. Minor reactions (e.g., presyncope and small hematoma) are documented at the collection site. Major reactions are documented at the collection site or reported after donation, require follow-up with the donor, and receive a follow-up call, and are reviewed by a blood center physician.

and delayed reactions reported by the donor after whole blood and automated (apheresis) blood donation.<sup>3</sup> AABB also had a voluntary national program for donor hemovigilance in the United States (2012–2017), which encouraged blood centers to use common reaction definitions.<sup>12,13</sup> The general trends in adverse reactions have been consistent among blood centers and over time. The universal observation among all blood centers is that the youngest donors are consistently at the highest risk of reactions (Figure 6.1). According to AABB, young donors (age 16–22 years) accounted for 18% of the total donations, but consistently had the highest reaction rates each year, ranging from 41.41 per 1000 donations in 2017 to 49.09 per 1000 donations in 2013.<sup>13</sup> While the absolute incidence of donor complications varies dramatically among centers for all the reasons mentioned previously, the practical value of hemovigilance activities lies not in the casual comparison or “benchmarking” of reported rates across blood centers, but in the careful analysis of reactions rates within a blood system before and after implementation of measures designed to reduce the risk of reactions. Such efforts are described in greater detail in the following sections.

### Acute reactions after blood donation: immediate symptoms and delayed complications

Most (>85%) systemic reactions to blood donation are acute symptoms such as pallor, lightheadedness, dizziness, diaphoresis, and nausea, occurring in about 2–15% of whole blood donations.<sup>3</sup> The term *vasovagal* is often used to describe these reactions, to refer to physiologic changes that may be associated with syncope (i.e., increased vagal tone and bradycardia). The more general term *presyncope* captures the spectrum of reactions that result from various mechanisms involving not only peripheral baroreceptor activity, but also susceptibility to acute blood loss and orthostatic changes, as well as anxiety and psychological stress. Ultimately, syncope results from an insufficient supply of oxygen to the brain and a transient loss of consciousness. About 1 in every 20 presyncope reactions

**Figure 6.1** Total donations and reaction rates by age, 2012–2017. Reprinted from AABB donor hemovigilance, used with permission from AABB.<sup>13</sup>

(Table 6.1) progresses to loss of consciousness immediately or soon after the blood donation. Seizure-like movements or loss of bladder and/or bowel function might accompany some of these reactions.

Presyncope symptoms typically have rapid onset and short duration. Although most of these reactions are self-limiting and transient, they are still distressing for many donors and some require prolonged recovery periods of more than 30 minutes.<sup>3</sup> Syncope-related falls may be associated with serious injuries. Most (90%) fainting events occur with the phlebotomy or soon afterward at the blood drive, but delayed hypotensive reactions after the donor left the collection site comprised about 10% of the episodes in one center.<sup>13–15</sup> Young donors (16–17 years old) accounted for almost half of all injuries at collection sites among whole blood donors, and some of the injuries (e.g., concussions, lacerations, and dental injuries) required urgent medical care.<sup>4</sup>

## Risk factors associated with reactions after blood donation

Many studies have evaluated donor characteristics and other variables that influence the risk of immediate and delayed reactions after allogeneic blood donation. The strength of the studies' conclusions depends on the trial design and statistical analysis to control for confounding variables. An overview of risk factors and the strength of the available evidence that supports a possible association with syncopal reactions after allogeneic blood donation is summarized in Table 6.2.<sup>9</sup> The strongest, independent risk factors for both immediate and delayed reactions consistently identified in well-controlled studies of whole blood donation are young age (<23 years old), first-time donation status, total blood volume (<3.5 L), and estimated blood loss (>15%), and, in most studies, female sex.<sup>16–18</sup> Young age had the strongest association with complications even after controlling for first-time donation status in one study that showed 16- and 17-year olds were threefold more likely to experience an adverse reaction than older donors.<sup>3</sup> Although regulations in some countries restrict the upper age limit of blood donation, many studies have confirmed the lower observed rates of reactions among elderly donors compared to younger donors.<sup>19,20</sup> A multivariate analysis in 2010 concluded that young donors (<23 years) with low blood volume contributed about 3% of all donations but disproportionately accounted for about 10–15% of presyncope reactions and syncope-related complications after whole blood donation.<sup>18</sup> Many other variables related to the donor, environment, or staff have been reported to have weaker associations with immediate adverse reactions after blood donation, although the supporting data are generally weak and often not consistent among studies.<sup>9</sup> Finally, autologous blood donors might have significant medical conditions that potentially increases their risk for postdonation reactions compared to healthy, allogeneic blood donors.<sup>21</sup>

Most publications report on immediate donation-related reactions or reactions that occur soon after the blood donation; whereas, a few studies are available on delayed or longer-term complications. One such study showed that allogeneic blood donation did not have a long-term effect on the risk of cardiac ischemia.<sup>22</sup> Germain *et al.* compared a group of 50,889 eligible blood donors who made 0.36 donations/year to 12,357 donors disqualified for false-positive infectious disease markers as a control group of healthy donors

during a 17-year study in Canada.<sup>22</sup> There was no statistical difference in the incidence of hospitalizations or deaths attributable to coronary heart disease in the group of donors who remained eligible (3.60/1000 person-years) compared to the control group of disqualified donors (3.52/1000 person-years; rate ratio 1.02; 95% confidence interval, 0.92–1.13).

## Preventing syncopal reactions at blood drives

Focusing on the factors that most strongly predict immediate and delayed reactions, blood centers have reported strategies to improve safety for the youngest and most susceptible group of blood donors. In 2008, an AABB Task Force recommended that blood centers adopt one or more of the measures in Table 6.3 to reduce reactions among young donors and develop monitoring programs to continually assess donation safety.<sup>23</sup> Operational tactics to improve donation safety aim to recruit donors less likely to have reactions, to modify the drive environment, or to use automated (apheresis) procedures instead of whole blood collection. Physiologic strategies may reduce an individual blood donor's risk of a reaction, such as having the donor drink water shortly before the phlebotomy or perform applied muscle tension maneuvers.<sup>24</sup>

Psychological aspects of the donation experience may be addressed by gauging donors' fear and anxiety, providing donors with information about coping strategies before blood donation, or distracting their attention during the phlebotomy. Each measure is supported to varying degrees by controlled trials or by observational data and predictive models.

In 2009, the American Red Cross and Blood Systems Inc. independently made operational changes in their standard practice in an effort to reduce syncopal reactions among young whole blood donors.<sup>25,26</sup> Both centers introduced precautionary measures, which included new donor selection criteria that required individuals to have an estimated blood volume greater than 3.5 L to prevent loss of more than 15% of their total blood volume with a standard whole blood donation. Other preventive measures addressed donor education, drive environment and supervision, predonation water, and muscle tension during collection.

In the American Red Cross, full implementation of the new donor selection criteria and other preventive measures resulted in a 33%, 25%, and 18% reduction in reactions among 16-, 17- and 18-year-old donors, respectively, compared to the baseline rates before the operational changes.<sup>25</sup> The benefit was most pronounced for the youngest, most susceptible donors. Moreover, a significant 14% decrease in syncope was observed among 16-year-old donors with the new selection criteria. The rate of injuries at the collections sites was low in each year, but no consistent changes were observed over time for any age group. Similarly, Tomasulo and colleagues at

**Table 6.2** Variables Associated with Syncopal Reactions after Blood Donation

Independent variables strongly associated with increased risk (strong evidence based on multivariate analysis in multiple studies):
• First-time vs. repeat donation status
• Young (<23 years) vs. older age
• Low body weight/total blood volume (<3.5 L) with standard WB donation (~525 mL)
• Female vs. male sex
• Caucasian vs. African ethnicity
Variables associated with increased risk (weak or no association in some studies, inconsistent or low-quality evidence, and poorly controlled or univariate analysis)
• Admitted anxiety
• Collection volume
• Greater than 4 h since last meal
• Temperature/season
• Wait time
• Duration of phlebotomy
• History of fainting not related to blood donation
• Mobile blood drive
• History of prior reactions after blood donation
Variables not associated with reactions (strong evidence and multivariate analysis)
• Predonation blood pressure

**Table 6.3** Strategies to Reduce Reactions Among Blood Donors

Predonation education
Drive setup and environment
Staff supervision and phlebotomist skills
Selection criteria (e.g., estimated blood volume) for whole blood donors
Automated red cell collection
Interventions
• Water ingestion before donation and within 10–20 min of phlebotomy
• Distraction during phlebotomy
• Muscle tension during phlebotomy
Postreaction instructions to donors and parents

Blood Systems reported that using the new selection criteria to ensure an estimated blood volume of at least 3.5 L for 17–22-year olds and other interventions decreased the aggregate reaction rates in male and female donors by 24%.<sup>26</sup> In addition, the measures were associated with a 25% decrease in delayed reactions occurring more than four minutes after the phlebotomy was completed, and a 38% decrease in off-site reactions among female donors. Falls were infrequent in all donor groups, occurring at a rate of 1.4 per 1000 donations before the interventions.

These data from the American Red Cross and Blood Systems independently support the benefit of the selection criteria for estimated blood volume to mitigate reactions among young donors, largely to the extent predicted by statistical models.<sup>25,26</sup> In both reports, the aggregate effect of the selection criteria for estimated blood volume reduced reactions by at least 20% in susceptible groups. As expected, the measures did not eliminate the risk of reactions after whole blood donation. While the interventions decreased the occurrence of reactions in susceptible groups, the known risk factors (young age, first-time donation status) were still associated with relatively higher reaction rates than the comparison groups.<sup>25–27</sup> Both studies also documented a low rate of falls or injuries at the collection sites in all donor groups, which did not change after introducing the operational changes. These studies were large enough to detect a 20% reduction in these uncommon events but may have missed a smaller difference.

Alternate approaches to predict and prevent presyncopal reactions that show promise in small, uncontrolled trials have evaluated screening measures to identify and educate fearful donors, use of predonation water ingestion and applied muscle tension during collection, predonation measurements of hemodynamic responses to standing before and after water ingestion, collecting smaller volumes (350 mL rather than 450 mL) from young (16–18-year olds) first-time donors, and postdonation salty snacks.<sup>28–31</sup> Unfortunately, none of the preventive measures has been shown to have a consistent effect in practice or a significant effect on the uncommon but potentially serious falls and injuries resulting from syncope after whole blood donation. Future operational efforts should implement evidence-based approaches to reduce the risk of syncope after whole blood donation, especially among the most susceptible, young donors. Notably, AABB Blood Bank/Transfusion Medicine (BB/TS) Standards now require collection facilities to have a process to reduce the risk of adverse reactions in young donors (AABB BB/TS Standard 5.4.3.3, 32nd edition).<sup>32</sup>

### **Phlebotomy-related complications**

Whole blood and apheresis collections utilize large-bore (e.g., 16-gauge needles) for phlebotomy, which achieve rapid blood flow and minimize clotting and hemolysis but also introduce a risk of injury.<sup>33,34</sup> General guidelines for phlebotomy emphasize the importance of staff training, technique, and experience, as well as knowledge of the anatomy of the antecubital area and careful selection of the vein.<sup>34,35</sup> The median cubital vein, in the center of the antecubital space near the elbow crease, is typically prominent and well-anchored between muscles, making it a good first choice for phlebotomy. The basilic vein, located on the medial aspect (i.e., closest to the body) of the forearm, runs close to the brachial artery and nerve, is less likely to be visible or palpable, and more likely associated with a risk of nerve injury or arterial puncture with phlebotomy. Although these generalizations are useful guides, the anatomic relationships are more complex and variable than depicted in

textbooks. Cutaneous nerve branches are closely associated with veins, and anatomic variation is common, making it impossible to avoid them completely during phlebotomy. Needle adjustment after insertion should be limited to no more than one forward-to-backward maneuver, with careful attention to the donor's comfort level. The phlebotomy should be discontinued if the donor cannot tolerate the venipuncture, and the needle should be removed if it is readily apparent that the venipuncture was not successful. Despite adherence to these general guidelines and good technique, phlebotomy as with any invasive procedure carries an inherent risk that cannot be completely eliminated.

Adverse reactions such as sore arms, hematomas, or bruises are relatively common but usually self-limiting; rarely, more severe nerve injuries or chronic complications occur after phlebotomy.<sup>3,36</sup> Hematomas are raised areas of localized swelling, and bruises (contusions) are flat areas of discoloration. Both result from local injury and blood leaking from the punctured blood vessel that accumulates in the subcutaneous tissue and spreads along fascial planes. As the swelling subsides, the extravasated blood is broken down and reabsorbed, and the area can change in shape, size, and discoloration over a spectrum of blue, black, purple, yellow, and green before resolving completely within a few weeks.

Hematomas or bruises may be noted by the staff at the collection site, but more often develop soon after the donor leaves the drive, complicating about 1% of whole blood and 3.5% of apheresis donations (Table 6.1). When donors were questioned about bruises or other symptoms several weeks after a donation, additional information was elicited about minor complications and the rate of bruises reached 8–22%.<sup>10,11</sup> Although this suggests that some minor reactions are not routinely captured when reactions are recorded by staff at the collection site, these data still serve as a relevant gauge of the more severe or concerning reactions, and identify hematomas that cause discomfort, pain, or distress. About 1 in 10,000 whole blood and apheresis blood donors seek outside medical care for phlebotomy-related complications (Table 6.1).

Hematomas may be alarming to donors, especially if they extend along the arm and as they progress through the various stages of discoloration, but typically resolve completely within a few weeks. Treatment of the area with ice immediately and intermittently for 24 hours after the phlebotomy, followed by warm compresses or soaks, may provide symptomatic relief and promote healing. Over-the-counter medications such as acetaminophen may also be taken as directed for pain. In very rare cases, the phlebotomy site may show signs of infection or septic phlebitis (e.g., redness, swelling, or “red streaks” extending up the arm), which might resolve on its own or may be treated with antibiotics. In anecdotal reports, superficial venous thrombosis in the upper extremity has occurred after blood donation, although a causal relationship with the donation may not be clearly established.

Arterial puncture is suspected in about 1.4 in 10,000 whole blood donations (Table 6.1). Signs of an arterial puncture are rapid filling of the collection bag, often within three minutes, bright red blood, and pulsatile flow. All of these signs might not be present, making some arterial sticks difficult to distinguish from venous draws. Possible arterial punctures are more often reported in young, male donors, but can occur in other donors because of anatomical variation in the location of the artery in the forearm. Whenever a possible arterial puncture is suspected, staff should discontinue the collection, remove the needle, and apply direct pressure to the site for 10 minutes or more, until bleeding has stopped. Donors typically recover without rebleeding or further consequences, but about

7% of donors with a suspected arterial puncture sought additional medical care, likely related to the resultant hematoma or bruise (Table 6.1). In extremely rare cases, an arterial puncture has resulted in complications that required surgical intervention, such as pseudoaneurysm (three published reports), arteriovenous fistula (four published reports), or compartment syndrome (two published reports), after whole blood donation.<sup>36</sup>

### **Phlebotomy-related nerve injury**

Phlebotomy-related nerve injuries are uncommon and typically resolve without sequelae within weeks, but in rare cases have long-term debilitating consequences. Most patients experience characteristic symptoms when the needle is advanced in the arm suggestive of direct nerve trauma, often described as sharp, shooting pain or tingling that radiates to the hands or fingers. Donors may also report immediate numbness or tingling that persists after removing the needle or intense pain with burning, lancinating, or electrical sensations. The relationship of hematoma formation to the development of nerve damage and symptoms is unclear, and most hematomas do not cause symptoms suggestive of nerve irritation. However, hematomas may aggravate nerve dysfunction and pain possibly by impinging on damaged nerves or traumatized areas.<sup>35,36</sup>

Based on hemovigilance data from the American Red Cross, suspected nerve injuries occurred in about 3 in 10,000 whole blood donors; of those, 13% sought additional medical care after the event (Table 6.1). Almost all (>90%) donors who report symptoms of nerve injuries will recover completely within three months.<sup>36</sup> Some donors may report mild residual numbness that persists over an extended duration. Permanent nerve injury after phlebotomy is an extremely uncommon but potentially debilitating outcome, and reliable estimates on its incidence are not available because it is so infrequently encountered among blood donors. Given the close association of nerves with veins and the unavoidable possibility of direct injury to nerves with phlebotomy, factors other than direct nerve contact by the needle appear to be necessary for the chronic pain syndrome to occur. Chronic regional pain syndrome type 2 (CRPS II, previously called causalgia or reflex sympathetic dystrophy) describes neuropathic pain after confirmed nerve injuries. CRPS symptoms vary in severity and duration, but most cases are mild and individuals recover gradually with time. In more severe cases, individuals may have long-term disability. Treatment options for CRPS neuropathic pain include rehabilitation and occupational therapy, psychotherapy to treat associated depression and psychological symptoms, medications, sympathetic nerve block, and surgical sympathectomy. No drugs have yet been approved by the US Food and Drug Administration (FDA) to treat CRPS, but several different classes of drugs such as nonsteroidal anti-inflammatory drugs, corticosteroids, opioids, nortriptyline and other drugs for neuropathic pain, and botulinum toxin injections have also been used to effectively treat some patients, especially early in the course of disease.<sup>37</sup>

### **Reactions after automated collection of cellular blood components**

Advances in apheresis (automated) technology allow simultaneous collection of multiple standard blood components during a single procedure, yielding various combinations of plasma and blood components such as two units of red blood cells (double red cell collection [2RBC]) or two or three units of platelets (double or

triple plateletpheresis), often with a concurrent unit of plasma from one donation. Blood centers have increasingly relied on apheresis donors to optimize the collection process and reduce costs. As in prior years, apheresis platelets accounted for over 90% of the platelet units produced in the United States in 2017, with increasing trends in double- and triple-platelet collections.<sup>1</sup> Similarly, 2RBC collections continue to increase each year, now accounting for 15% of the total US supply of red cell units in 2017.<sup>1</sup>

Like whole blood donation, automated (apheresis) procedures are generally well tolerated, but some donors will experience phlebotomy-related or syncopal complications (Table 6.1). In addition, apheresis complications may result specifically from the device or anticoagulant (e.g., citrate reactions), preparatory regimens (e.g., G-CSF and/or corticosteroids for neutrophil collection), or frequency of procedures.<sup>38,39</sup> Hematomas are the most frequent complication and are more commonly reported after apheresis than WB donation because automated collections often use both arms for venous access (Table 6.1). The overall rate of minor complications at the collection site is higher for automated procedures than WB collections, reflecting primarily minor citrate reactions and small hematomas. Automated collection procedures had lower rates of presyncope and syncope than whole blood donation, which likely reflects donor demographics, more stringent selection criteria, and the use of saline replacement with automated procedures.

Medically serious complications are less likely after apheresis than WB collection, with observed rates of major complications at the collection site of 7.4, 5.2, and 3.3 per 10,000 donations for WB, plateletpheresis, and automated red cell procedures, respectively.<sup>3</sup> Similar rates of reactions requiring additional medical care occurred after WB donation (3.2 per 10,000) compared to automated procedures (2.9 per 10,000).<sup>3</sup> Hospitalization after donation was reported for 46 whole blood donors (1 in 130,749 donations) and eight apheresis donors (1 in 84,722 donations); a causal relationship between the donation and the hospitalization was not established in all cases.

As observed for whole blood donation, multivariate analysis reveals that young age, first-time donation status, female gender, and low weight are independently associated with the risk of reactions after automated red cell collection and plateletpheresis. Yuan *et al.* reported moderate to severe adverse events in 47 per 10,000 plateletpheresis or automated red cell collections over a 2-year period in a hospital-based donor center and found that small, female donors with lower predonation hematocrit were at higher risk of moderate to severe vasovagal-type reactions than other donors, especially when RBCs were collected.<sup>40</sup> Reactions had a similar dampening effect on return donation by first-time apheresis donors comparable to that observed for whole blood donors. Among experienced donors, however, reactions had less of an effect on retention and decreased the rate of return by about 28% for whole blood donors but only about 4% for 2RBC donors.<sup>8</sup>

### **Citrate reactions and other immediate complications during apheresis procedures**

Citrate is used as an anticoagulant during apheresis procedures because it effectively chelates divalent cations such as calcium to transiently and immediately inhibit the coagulation cascade. Citrate causes minimal side effects in donor plasmapheresis because the citrate is mostly in the retained plasma. Plateletpheresis, large-volume leukapheresis, and hematopoietic progenitor cell

collection are more likely to expose the donor to the effects of citrate toxicity. Greater exposure to citrate during triple plateletpheresis was associated with an increase in mild citrate reactions compared to double plateletpheresis, but did not substantially affect donor safety or product quality in one study.<sup>41</sup> Symptoms are usually transient and rapidly reversible because citrate metabolism occurs within minutes in the liver, kidneys, and muscles. In addition, the release of parathyroid hormone mobilizes calcium from body stores and increases its absorption from the kidney to restore calcium hemostasis. Despite these compensatory mechanisms, citrate infusion can acutely decrease the concentration of ionized calcium to cause symptoms such as perioral tingling and paresthesias, chills, nausea, twitching, and tremors during the apheresis procedure. If severe, citrate toxicity can progress to carpopedal spasm, seizures, tetany, and cardiac arrhythmia.

Prompt attention to mild symptoms usually requires only pausing the apheresis procedure, slowing the reinfusion rate, or decreasing the amount of citrate infused by increasing the whole blood-to-citrate ratio and allowing for dilution and clearance of citrate. The procedure should be stopped if symptoms persist or worsen. Intravenous calcium is rarely if ever needed to reverse the citrate effect during donor apheresis procedures and should not be used in routine practice. Donors who have had severe or unusual citrate reactions during automated procedures should be evaluated for possible underlying factors or medications such as loop diuretics that could predispose to these adverse events. The propensity for citrate reactions depends not only on donor characteristics but also on device-related factors, such as the citrate infusion rate or extracorporeal volume of the device.

Oral calcium supplementation (e.g., Tums) during automated collection procedures may reduce the severity of paresthesias and improve ionized and total calcium levels.<sup>42</sup> However, multivariate analysis revealed that oral administration of calcium was not associated with a reduction in overall symptom development and did not prevent the occurrence of more severe symptoms during donor apheresis procedures.<sup>42</sup> The possible significance of long-term metabolic effects of repeated citrate exposure on bone mobilization and calcium metabolism is not well characterized and remains an area of study.

Equipment and disposables used in apheresis collections may cause unusual reactions in rare cases, such as allergic reactions among repeat donors linked to plateletpheresis collection sets sterilized with ethylene oxide.<sup>38,39</sup> Preventive measures include avoiding use of certain disposables if sensitization is suspected or minimizing exposure to ethylene oxide by repeatedly priming the disposable collection set or using kits near their expiration dates. Air embolism is a very rare complication of apheresis procedures because the instruments have sensors to detect air within the extravascular circuit that stop the procedure. But symptoms of air embolism are still possible if more than 3–8 mL/kg of air enters the donor's venous system through either a leak in the access, instrument failure, or operator's error. These symptoms of air embolism include dyspnea, tachypnea, cyanosis, tachycardia, and hypotension as air enters the right ventricle and pulmonary artery with obstruction of the right ventricular output and pulmonary artery vasoconstriction. If collection staff expect air embolism, they should stop the procedure and place the donor in the Trendelenberg position (i.e., lay the donor on their back and raise their feet higher than their head) on their left side. If the air does not dissipate or symptoms worsen, surgical

intervention to aspirate the air through a pulmonary artery catheter may be necessary.

### **Procedure-related complications related to donation frequency or multiple component collection**

The high volume and efficiency of apheresis collection procedures, as well as the frequency and allowable interval for repeat donations, pose potential acute and long-term risks to donors, such as cellular depletion, iron depletion, and serum protein loss. The current regulations that govern donor selection define precautions for adequate pre- and postprocedure cell counts and serum protein values before donation, as well as limits on the donation interval and frequency for apheresis procedures. Immediately after plateletpheresis, a donor's platelet count may decrease by 20–30% but quickly returns to baseline within about four days.<sup>31</sup> Current FDA-approved apheresis devices have different methods to ensure that the donor's platelet count remains above a predefined set value at the completion of the procedure, typically 100 platelet/ $\mu$ L, which have been validated in practice by blood centers. The transient platelet count decrease and recovery after serial collection procedures are generally larger and last longer for female donors than male donors, but changes are typically transient and recovery occurs promptly after donation.

Frequent whole blood or double red cell donation is known to cause aggravate iron deficiency (see Chapter 7). Frequent apheresis donation has been associated with longer-term effects in some plasma and platelet donors. Progressive decreases in platelet counts, lymphopenia, and increased risk of infections have been associated with frequent plateletpheresis.<sup>43–46</sup> Serum protein, albumin, and IgG concentration are statistically lower in frequent plasmapheresis donors compared to nondonors; however, their levels may not correlate with the intensity of donation and typically remain stable over time in most donors.<sup>47,48</sup>

### **Special considerations: granulocyte collection**

Granulocyte collection (leukapheresis) poses unique risks to donors.<sup>3</sup> To collect sufficient numbers of granulocytes for an adequate therapeutic dose, healthy donors are given corticosteroids (e.g., dexamethasone) and/or granulocyte colony-stimulating factor (G-CSF) prior to the leukapheresis procedure. G-CSF may cause short-term side effects such as bone pain, myalgia, and headache in granulocyte donors. The rare complication of splenic rupture seen with hematopoietic progenitor cell collection has not been reported in G-CSF-stimulated granulocyte donors, likely because of the lower dose and shorter course of treatment. To date, the available data support the use of G-CSF stimulation in volunteer donors and have not detected long-term cardiac, inflammatory, or malignant consequences among granulocyte donors who received G-CSF on three or more occasions.<sup>49</sup>

The risk of subcapsular cataracts in granulocyte donors who received corticosteroids has been evaluated in two controlled studies. Differences between the treatment and the control (unstimulated) groups were not significant, but the tendency for bilateral occurrence of cataracts was observed exclusively among glucocorticoid-stimulated granulocyte donors. The relatively small size of both studies suggests that ongoing surveillance is

prudent to better define the prevalence of posterior subcapsular cataracts in this donor population.<sup>50,51</sup>

### Conclusion

Whole blood donation and apheresis procedures to collect blood components are generally considered safe, and most volunteer blood donors have uneventful donations and feel good about donating blood to help others. Still, blood donation is an invasive procedure that can cause discomfort and pain, and, in some cases, serious injury. Recent operational trials and research programs identify possible ways to reduce the risk of complications after blood donation, especially among the most susceptible, young donors. Ongoing efforts and continued vigilance are necessary to further improve safety for volunteer blood donors.

## Introduction

Stability of the blood supply depends on the ability of blood collectors to recruit new donors and to maintain return visits from established, volunteer donors. While the combination of motivations that inspires a person to donate blood will vary considerably, one consideration is surely an expectation for procedures that safeguard donor health and well-being. Many elements of blood collection, whether encoded in federal or state regulations or required by the blood collector's rules, are specifically designed for the protection of donor health. These include the brief physical exam, parts of the donor health history, minimum hemoglobin concentrations, and a mandated deferral period following a successful donation to allow for physiological recovery. The required minimum length of the interdonation interval is specific to the donation procedure, but for whole blood and apheresis collection of red blood cell components the interval is motivated by the need for hemoglobin recovery.

Donating blood has a remarkable safety record. Adverse reactions are generally uncommon, with low, single-digit rates of vasovagal or other systemic reactions in US donors, albeit higher in selected subpopulations of donors. Donors at higher risk have several identifiable features (younger age, lower body weight, first-time donor status, and female sex), and continuous improvements are made to donor intake and phlebotomy procedures to improve donor safety and comfort.<sup>1,2</sup>

In contrast to acute events, however, long-term outcomes attached to blood donation can be harder to recognize, measure, and ameliorate. The opportunity for blood donation to lead to deficits in hemoglobin and iron has been known for decades, and it informs key eligibility requirements in the United States and elsewhere. This chapter discusses potential chronic effects associated with blood donation, including those for apheresis donation of platelets and plasma.

## Prevalence of and risk factors for iron depletion in blood donors

Nominally a simple question, *How common is iron depletion in blood donors?* is a multivariegated inquiry that requires unpacking. One might reasonably interpret the question to mean any of the following:

- *What is the prevalence of iron depletion in people who present to donate?*
- *What is the prevalence of iron depletion in people who make a donation?*
- *What is the prevalence of iron depletion in blood donors (presenting or successful) that is caused by blood donation?*

From these questions follow several more:

- *How do you define "iron depletion?"*
- *How would you know, i.e., how do you measure it?*
- *What definition or what degree of iron depletion is tolerable, what is actionable, and does this vary for different groups of donors?*

Iron is an essential mineral involved in many important physiologic processes, including oxygen transport, energy production, immune and cognitive function, and support of numerous enzymatic reactions. Iron is found in all cells, and a deficit of iron is the most common nutritional deficiency worldwide. Most iron in the human body, about two-thirds, is found in hemoglobin in red blood cells. There is no active mechanism for iron excretion, so iron homeostasis is maintained by recycling of most of the body's iron and tightly controlled absorption in the gastrointestinal tract to balance what are ordinarily minimal basal losses.<sup>3</sup>

Evidence that hemoglobin recovery following donation varies considerably across individuals and especially by sex was recognized at least by the mid-twentieth century. A publication by Fowler and Barer in 1942 documented the interpersonal variability in regeneration of hemoglobin, the acceleration of recovery with administration of iron, and the average recovery period (in mostly male subjects) of about five weeks.<sup>4</sup> Following development of an assay for measurement of ferritin, the storage form of iron which varies directly with a person's iron stores, additional investigators focused on the relationship between blood donation and iron status. Finch and colleagues demonstrated that men donating three times annually had much higher prevalence of ferritin less than 12 ng/mL than those with one donation per year, 12.7% vs. 0.9%.<sup>5</sup> This threshold, considered the level below which one has exhausted iron stores, is still recognized as clinically relevant though alternate cutoffs of 10 or 15 (such as by the World Health Organization) are also used. Simon *et al.* reported similar findings in 1981, showing that female sex compounded the risk for ferritin less than 12 ng/mL associated with blood donation and that menstruation added

incremental risk.<sup>6</sup> Further, and importantly, they also showed that iron stores correlated strongly with lifetime donations, whereas hemoglobin levels did not; hemoglobin, accordingly, was also shown to be a poor indicator of iron status.

The limited information provided by hemoglobin levels with respect to a donor's iron status has been confirmed repeatedly,<sup>7</sup> and reliance on hemoglobin as an indirect proxy for donor iron status has been a long-term obstacle to developing a comprehensive assessment of the iron status of US donors. Regulatory and industry concern are longstanding, evidenced by multiple workshops and advisory committee meetings. One early meeting was a 2001 workshop focused on the need to maintain the iron status of female donors of childbearing age and how that could be done while maintaining adequacy of the blood supply.<sup>8</sup> Discussion noted the heavy preponderance of females in the 700,000 annual deferrals for low hemoglobin (95%) and the often permanent loss of donors who receive the deferral. Iron supplementation programs were indicated as a promising approach to improve female donor iron status and eligibility for donation, with attendant benefits for blood sufficiency.<sup>8</sup>

Over the subsequent two decades, widespread adoption of iron supplementation programs by blood centers did not materialize. There has been, however, considerable public discussion of blood donor iron depletion in parallel with public funding to elucidate the issue. Specifically, these conversations sought to better understand the prevalence of iron depletion in blood donors, to quantify the role of blood donation as a causal factor, and to identify strategies to mitigate risk for iron depletion while maintaining adequate blood supplies. The REDS-II (*Retrovirus Epidemiology and Donor Study*) Iron Status Evaluation (RISE) Study contributed importantly to these endeavors, demonstrating that the scope of the problem was considerable indeed.<sup>9,10</sup> Enrolling 2425 donors into a prospective cohort study, RISE investigators documented the trajectory of iron status and hemoglobin levels over a 15–24-month follow-up. The study population was balanced by sex and captured donors with distinct profiles, specifically those making their first blood donation ever (or alternately within two years) and those donating at high frequency (defined as two donations in a year for females and three times for males). Assigning ferritin less than 12 ng/mL to “absent iron stores” (AIS) and a ratio of ferritin and soluble transferrin receptor to represent “iron-deficient erythropoiesis” (IDE) or intermediate iron depletion, RISE showed that at enrollment 15% of donors were fully iron-depleted (had AIS) while

41% demonstrated IDE. These aggregate numbers masked notable variability by sex and donation history, ranging from 0% prevalence of AIS in first-time male donors to 67% prevalence of IDE in frequent female donors. Enrollment data also showed that how informative hemoglobin was for iron status varied by donation status. In first-time donors no association was seen, whereas in frequent repeat donors lower hemoglobin was associated with higher prevalence of iron depletion (Table 7.1). Because RISE did not enroll a representative sample of the donor population, it did not yield direct estimates of the overall prevalence of AIS or IDE in the US donor pool. But the data developed from statistical models allowed for a simulation study that projected that approximately 13% of donations in the United States come from a donor with ferritin less than 12 ng/mL, while another 21% are from donors with ferritin less than 26 ng/mL (which correlates strongly with the study's measure of IDE).<sup>11</sup>

The statistical models underpinning this simulation study helped identify and quantify the strongest determinants of blood donor iron status. Donation frequency was confirmed to exert a powerful effect, compounding the risks associated with female sex, while genetic markers for iron homeostasis were significant but of relatively modest predictive value.<sup>12</sup> Time itself was also a critical factor, with adjusted risk for AIS shown to last up to five months following donation, controlling for other risk factors.<sup>10</sup>

The REDS-III Hemoglobin and Iron Recovery Study (HEIRS) further sharpened the understanding of physiological recovery postdonation.<sup>13</sup> HEIRS was a randomized controlled trial of 215 subjects, all of whom had waited at least four months since their last donation, and who were assigned to either take 38 mg of elemental iron daily following a single unit of donated blood or to take no iron pill (unblinded treatment). Donor hemoglobin and ferritin were assayed at seven visits over 24-week follow-up, allowing for documentation of how exogenous iron mediates the effects of time in the regeneration of hemoglobin and the restoration of iron stores. In donors taking iron, the recovery of hemoglobin to preindex donation levels was uniformly quick, taking approximately one month. Ferritin recovery followed the recovery of hemoglobin, but was also considerably accelerated by daily iron. In contrast, in those not taking iron, recovery was highly variable and for two-thirds of participants neither hemoglobin nor ferritin had recovered to baseline levels by the end of 24 weeks. In sum, for donors taking a moderate dose of supplemental iron daily, the mandatory eight-week minimum interval between donations was easily sufficient to restore

**Table 7.1** Hemoglobin and Iron Status at Enrollment in REDS-II RISE Study

Sex	Donor Status	% with Low Iron	12.5–13.4	13.5–14.4	14.5–15.4	15.5–16.4	≥ 16.5 g/dL	All
Female	FT	N (%) Hb	267 (58%)	140 (30%)	46 (10%)	14 (3%)	3 (1%)	470
		AIS (%)	7%	7%	4%	7%	0%	7%
		IDE (%)	26%	26%	13%	43%	335	25%
	RPT	N (%) Hb	436 (59%)	212 (29%)	73 (10%)	18 (2%)	2 (0%)	741
		AIS (%)	32%	25%	12%	22%	0%	28%
		IDE (%)	69%	67%	62%	61%	50%	67%
Male	FT	N (%) Hb	61 (15%)	114 (29%)	105 (27%)	87 (22%)	29 (7%)	396
		AIS (%)	0%	0%	0%	0%	0%	0%
		IDE (%)	2%	3%	3%	4%	0%	2.5%
	RPT	N (%) Hb	172 (23%)	228 (31%)	207 (28%)	95 (13%)	35 (5%)	737
		AIS (%)	33%	15%	13%	3%	6%	16%
		IDE (%)	57%	50%	47%	39%	34%	49%

FT: first-time donor or “reactivated” donor (no donations in two years).

RPT: repeat frequent donor, two RBC units donated in one year (F) and three units (M).

AIS: absent iron stores (ferritin < 12 ng/mL).

IDE: iron-deficient erythropoiesis (log ratio soluble transferrin receptor/ferritin) ≥ 2.07.

physiological levels of iron stores and hemoglobin. For those not taking iron, an interval three times that length was still too short.

Research in other jurisdictions confirms the findings in the United States of a high prevalence of iron depletion in blood donor populations. In Canada, a representative sample of 12,000 blood donors was tested for ferritin, 17% of whom had ferritin less than 12 ng/mL and 42% (an additional 25%) had ferritin less than 25 ng/mL.<sup>14</sup> A smaller national sample of 3000 donors in Australia showed 13.6% had ferritin less than 15 ng/mL,<sup>15</sup> close to the prevalence in the US simulation study of advanced iron depletion.<sup>11</sup> A study in the Netherlands demonstrated another valuable lesson, namely, that the prevalence of iron depletion varies widely by how the investigator chooses to define it, based on the particular biomarker chosen and the relevant cutoff used to denote iron insufficiency. Depending on whether the definition was tied to ferritin, zinc protoporphyrin, hepcidin, or other markers, the estimated prevalence of low iron in both male and female donors varied fivefold, between approximately 5% and 25%.<sup>16</sup> Hence, while serum or plasma ferritin has generally emerged as a consensus biomarker for assessment of blood donor iron status, it is hardly the only one in use and cross-study comparisons require careful attention to tests performed and to terminology used to classify outcomes.

Two more large cohorts, the Danish Blood Donor Study and the UK Interval Study, provide further strong evidence that more frequent donation is associated with higher prevalence of iron depletion in blood donors.<sup>17,18</sup> A large cohort of French donors found subgroups of donors with prevalence of low ferritin (defined as <26 ng/mL) up to 72%.<sup>19</sup>

## **Regulatory considerations: Role of the Food and Drug Administration and AABB**

The US Food and Drug Administration (FDA) has engaged the transfusion medicine community multiple times to characterize the scope of iron depletion in blood donors and to solicit input for ways to best safeguard donor health and well-being. The FDA convened its Blood Products Advisory Committee in 2008, 2010, and 2016, and it sponsored a workshop in 2011.<sup>20-23</sup> These meetings spanned the period between 2007 and 2015 when FDA published proposed and final rules relating to salient donation eligibility requirements.<sup>24,25</sup> The proposed rule sought comment on the possible impact on blood availability and blood donor iron status of the following measures:

- Raising the minimum male donor hemoglobin level from 12.5 to 13.0 or 13.5 g/dL.
- Lowering the minimum female donor hemoglobin level from 12.5 to 12.0 g/dL.
- Extending the minimum interval between whole blood donations from 8 to 12 or 16 weeks.

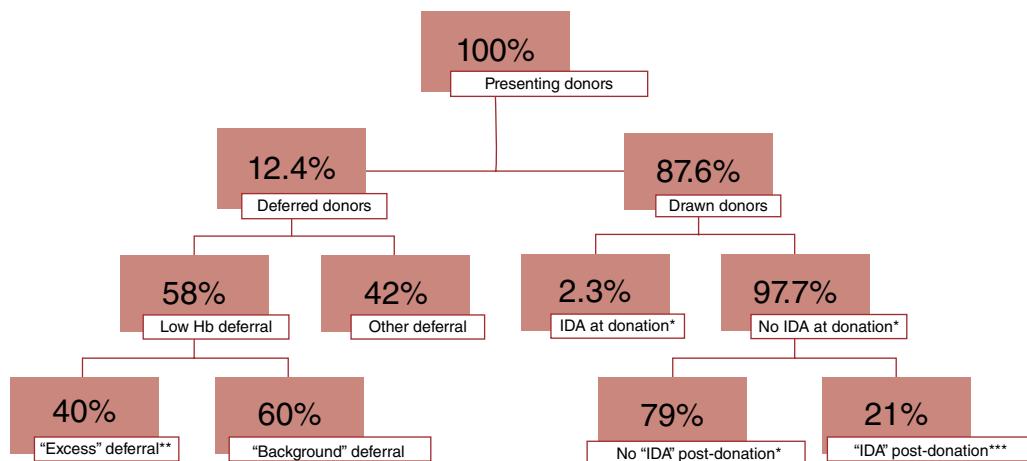

Consideration for increasing male donor hemoglobin acknowledged that the current standard was below the recognized lower threshold for anemia in adult males of 13.5 g/dL,<sup>3</sup> and the possibility of changing only to 13.0 g/dL was a tacit admission of the ever-present tension between eligibility requirements and blood sufficiency. The proposal to lower the female hemoglobin cutoff likewise sought to align donation requirements with the accepted definition of anemia, potentially offsetting diminished collections associated with increasing hemoglobin cutoff for males. The possibly lengthened interval intuitively allowed for additional physiological recovery, as amply documented by the RISE and HEIRS data emerging during this period. The Final Rule published in 2015 left donation intervals unchanged and increased the male donor

hemoglobin minimum by 0.5 g/dL. Female hemoglobin cutoffs were statutorily unchanged, but the text left the door open for blood centers to collect from females with hemoglobin levels of 12.0 g/dL as long as safety measures approved by FDA were implemented.<sup>25</sup> To date, no known approval has been issued for the collection of females with hemoglobin of 12.0 g/dL in the United States.

The AABB (Association for the Advancement of Blood & Biotherapies, formerly the American Association of Blood Banks), which provides accreditation for US blood collectors and publishes industry standards, has also engaged the issue. Communications with membership include bulletins that are often advisory, occasionally mandatory. In 2012, following publication of RISE enrollment data, AABB issued a bulletin to educate blood centers on the prevalence of iron depletion, recognized risk factors, and to suggest remediation measures.<sup>26</sup> Five years later, following presentation of preliminary data from a US study on high-school-aged blood donors at the 2016 BPAC meeting, an updated AABB bulletin was published.<sup>27</sup> Stronger in tone than the 2012 document's educational posture, the new bulletin advised that blood centers "should...take action" with all donors or those donor subpopulations shown to have greater risk for, or from, iron deficiency. Notably, for donors age 16–18 years old, the bulletin recommended limiting collections to a single unit of red cells per 12-month period, unless other mitigation measures were in place. As discussed below, this language helped stimulate a meaningful blood center response.

AABB dedicated further attention and energy to the issue by convening an expert work group that was tasked with evaluating iron depletion in blood donors under a "risk-based decision-making" (RBDM) framework developed by the Alliance of Blood Operators, a network of blood collectors from Europe, North America, and Australia.<sup>28</sup> The paradigm represents a systematic approach for managing complex risks that come up in the context of blood safety. The process seeks to define risks clearly, to assess whether each identified risk is tolerable, and if so under what contingencies. In addition, the process involves delineation of tradeoffs and it expressly seeks to identify and engage all relevant stakeholders. In the case of blood donation, the general public is integral to the process because it represents the source of volunteer blood donors, and public confidence in the institutions providing blood to patients is vital. Though intended as advisory and not an enforceable guideline, the committee's recommended mitigation measures were to encourage iron supplementation in blood donors and to encourage blood centers to conduct ferritin testing for at least higher-risk donor populations (discussed below).<sup>29</sup>

Another notable output from the RBDM workgroup's report was its discussion in the context of defining risk and stating the problem to be addressed. While the relationship between lower levels of iron stores and blood donation has been long evident, a systematic estimate of the occurrence of iron deficiency anemia (IDA) in a representative blood donor population was not available. This mattered because, as discussed more fully below, the adverse consequences associated with iron depletion are more consistently and more reliably observed when low iron is accompanied by anemia. As indicated in the three bulleted questions at the beginning of this chapter, this question could address any or all of the prevalence of IDA in presenting blood donors, the prevalence in donors who successfully donate (conceivably more important), and the prevalence of IDA in presenting blood donors that is caused by blood donation. Sufficient data has been developed in recent years that the RBDM committee was able to begin to characterize this phenomenon, as summarized in Figure 7.1.

**Figure 7.1** Association between iron-deficiency anemia and donation in presenting US donors.

\*Iron deficiency anemia (IDA) at donation is estimable from the proportion of males who donate with hemoglobin <13.5 g/dL and the share who are estimated to have low ferritin, which differs by donation frequency.

\*\*"Excess" hemoglobin deferrals are those attributed to the effects of blood donation and include most hemoglobin deferrals in males and postmenopausal females and a minority share of deferrals in premenopausal females. The "excess" of 40% of hemoglobin deferrals equals about 3% of presenting donors.

\*\*\*"IDA" postdonation represents male and female donors whose laboratory values are consistent with IDA given an assumed loss of 8% of hemoglobin in male donors and 12% in female donors making a whole blood donation and who had low ferritin at the time of donation.

Taking as the unit of analysis presenting donors, the committee assembled data that allowed for identifying a causal association between donation and IDA in a nontrivial share of the donor pool. Specifically, three groups were identified that include:

- 3% of presenting donors who are deferred for low hemoglobin that represents "excess deferral." This figure represents the product of the proportion of presenting donors deferred (12.4%), the proportion of donor deferrals attributed to low hemoglobin (58%), and the proportion of these deferrals attributed to the effects of prior donation (40%). This latter factor is complex and discussed separately below.
- 2% of presenting donors who make a donation despite having IDA. This figure is estimable by taking the proportion of male blood donors whose hemoglobin of record is below the recognized cutoff for anemia, 13.5 g/dL, and adjusting for the proportion of them estimated to have low ferritin, here defined as below 26 ng/mL.
- 18% of presenting donors whose postdonation lab values are consistent with both anemia and iron depletion. They represent the product of drawn donors (87.6%), those without IDA at donation (97.7%), and those whose values are consistent with IDA after donating; they are estimated to occur at a 3:1 ratio of female to male donors.

Identifying the first group, donors deferred for low hemoglobin that can be attributed to donation-associated IDA, leverages data from REDS-II studies including RISE and detailed analyses of donor presentation and deferral outcomes, and other efforts.<sup>9–11,30,31</sup> Data compiled to make these estimates includes the proportion of donations by sex, by menopausal status for females, by first-time or repeat donors, and the proportion of deferrals for males and females that are associated with iron depletion and anemia (below 12.0 g/dL in females and all low hemoglobin deferrals in males). The fact that blood donation contributes to deferral at subsequent visits is an unremarkable observation. However, the virtually identical low hemoglobin deferral rate for first-time and repeat donors (7.7% vs. 7.8%, respectively) reported by Custer and colleagues<sup>30</sup> would

ostensibly support the null hypothesis of no effect. Taking note of the four-time stronger disincentivizing effect of low hemoglobin deferral on first-time compared to repeat donors,<sup>31</sup> one must conclude that self-selection results in a donor pool enriched for donors with relatively lower risk for hemoglobin deferral, by a donor's second visit. With algebra and not terribly speculative assumptions, one derives an estimate that the ≈7.5% low hemoglobin deferral rate represents "background" low hemoglobin for 4% of presenting donors (almost entirely females) and donation-associated deferral for 3% of presenting donors. The clinical relevance of this is discussed below, but in aggregate that an estimated one out of every four or five blood donors presents to donate or leaves the donation site with IDA is indeed notable.

The spotlight on blood donor iron status seen in the United States is mirrored in many countries around the globe. As noted, large prospective studies were funded in the United Kingdom and Denmark, and the Netherlands also has research dedicated to reducing iron depletion.<sup>17,18,32</sup> Australia's study of iron status was cross-sectional rather than prospective, but it was nationally representative and followed by additional research efforts to identify optimal ways of encouraging iron supplementation.<sup>33</sup> More broadly, while virtually no country systematically monitors iron in all donors at each visit, attention and research are expanding in many locations.<sup>34,35</sup>

### Adverse outcomes potentially associated with iron depletion

Though the important causal role of blood donation for creating or sustaining iron depletion in many donors is uncontested, the documentation of serious adverse consequences is generally lacking. The number of clinical outcomes asserted to be due to iron deficiency even without anemia is considerable, including fatigue, lowered exercise tolerance, altered cognitive function, pregnancy-related outcomes, pica, and restless leg syndrome. To date, strong evidence exists only for pica.<sup>36–38</sup>

Expert opinion tends to more consistently find clinical outcomes associated with IDA rather than iron depletion alone, but what one finds in clinical populations might differ from what one documents with systematic examination in healthy blood donors.<sup>39</sup> The literature on the impact of iron deficits early in life is sizable and reflects decades of work, and there is strong documentation that fetal and neonatal deficits create cognitive, behavioral, emotional and metabolic changes that are enduring even if corrected.<sup>39</sup> More recent investigations have extended inquiry into whether iron deficits occurring in adolescence or adulthood have measurable effects, and a few studies have drawn attention with intriguing but not definitive data. In one RCT,<sup>40</sup> Bruner and colleagues studied adolescent females in Baltimore, MD, studying whether double-blinded oral iron treatment of nonanemic, iron-depleted ( $\text{ferritin} < 12 \text{ ng/mL}$ ) school girls impacted standardized test results. At study end, one measure out of three on a test for memory had a  $p$ -value of less than 0.05, and none of the three tests for attention showed a difference. The variability in outcomes attributed to iron was a mere 7%, with 93% ascribed to baseline differences in subjects. Moreover, while the subjects all had hemoglobin within the normal range at study onset, by study end the iron treatment group observed not only an increase in ferritin, but also an increase in hemoglobin of 0.8 g/dL compared to controls. Hence, any difference in memory tests observed, modest as they were, cannot be ascribed to the subjects' changes in iron status given the concurrent improvements in hemoglobin and ferritin levels. Another frequently cited study referenced in support of an association between adult iron status and cognitive function also has an issue with identifiability of the alleged effects.<sup>41</sup> Also an RCT, the study enrolled women into three strata classified as iron sufficient, iron deficient, and iron deficiency anemia, and within each stratum subjects were randomized to 16 weeks' oral iron treatment or placebo. The differences observed at baseline were statistically significant for the IDA group only, with the iron-deficient group being indistinguishable from controls. In longitudinal analysis, one measure (of many tested) was deemed statistically significant for "ferritin responders" while another reported improvement was attributed to "hemoglobin responders," but without disaggregating the IDA group from the iron-deficient-only subjects. This study and others have been discussed in a recent review,<sup>42</sup> and the interested reader can find more detail therein.

In blood donor populations, few studies have addressed whether donation-associated iron depletion affects neurocognitive function. Two large European studies have included the assessment of cognitive function, finding no association with iron status. In the INTERVAL study,<sup>18</sup> a large RCT in England designed to assess the safety implications of relaxing the prevailing minimum donation interval requirements, a battery of standardized tests were conducted at study onset and at the end of two-year follow-up. Expected associations were found between shorter donation intervals and prevalence of anemia and iron depletion, but none of five cognitive function assessments was associated with iron status or treatment group. The Danish Blood Donor Study indirectly addressed this question by evaluating the scholastic achievement of the offspring of female blood donors in comparison to children of nondonors.<sup>43</sup> This study documented the widely acknowledged "healthy donor effect," where donor populations have a favorable health status compared to the general population, but even controlling for that effect the authors found no association between academic outcomes and maternal donation behavior. A recent cross-sectional study in the United States has addressed this issue, also failing to

note any link between cognitive performance and iron status or blood donation in young women.<sup>44</sup>

Aside from concern for cognitive function, industry concern for pregnancy-related outcomes is the other potentially serious adverse outcome that has drawn scientific inquiry. Limited thus far, two large studies, one in Canada and one in Denmark, have not found a negative outcome associated with maternal blood donation. The integrated national health systems in both countries allow for close linkage of female donation behaviors and outcomes from subsequent pregnancies. In Canada, Germain and colleagues reported a lack of association between donation frequency prior to pregnancy and the occurrence of low-birth weight, preterm delivery, or stillbirth.<sup>45</sup> In Scandinavia, Rigas *et al.* did find a modestly lower birth weight from children born to women who were blood donors, but the magnitude was small and there was no difference in the clinically important low-birth weight incidence.<sup>46</sup>

Less serious consequences of donation-associated iron loss include fatigue, restless legs syndrome (RLS), and pica. The literature of fatigue and its relationship with iron and/or hemoglobin levels in blood donors is appreciable. Similar to the studies on cognitive function reported above, teasing out effects related strictly to iron depletion is challenged by the complexity of establishing identifiability of effects. The prevalence of fatigue in the postdonation period is not uncommonly reported,<sup>47,48</sup> but ascertainment would be conducted following loss of both hemoglobin and iron. One recent study evaluated changes in self-reported fatigue and changes in iron status in a prospective cohort of frequent blood donors.<sup>49</sup> Despite sizable changes in both iron and fatigue levels during the study period, fatigue and changes in fatigue were unassociated with iron or changes in iron in multivariable models. Similar findings were reported by Rigas *et al.* who found no association between iron status and self-reported physical or mental quality-of-life measures.<sup>43</sup> Findings from the INTERVAL study indicate a possible signal, with donors assigned to donate more frequently reporting greater levels of tiredness and lower levels of ferritin at study end.<sup>18</sup> Whether the results are derived from changes in red cell mass or from iron is hard to disentangle, however.

Restless legs syndrome (RLS) is a neurological condition with reported prevalence between 5 and 15% in European and North American populations. The most common feature is an irrepressible urge to move one's legs, particularly in the evening, and the condition can significantly compromise sleep and quality of life. The pathophysiology of RLS is complex and multifactorial, with an association with low iron reported 60 years ago and genetic associations being identified over the last 15 years.<sup>50,51,52</sup> Two studies in blood donors in the United States and one in Denmark found expected prevalence of RLS, but in none of the three studies was an association with iron status found.<sup>36,37,53</sup> The success of iron treatment in improving RLS<sup>54</sup> suggests a plausible association with donation that might prove elusive for investigators to confirm. It may be that donors who newly experience RLS as a consequence of blood donation take steps to remedy their condition. If they drop out of the donor pool, they would not be readily available to investigators; if they take iron they might eliminate symptoms and improve iron status, making their affliction short-lived.

Pica, the compulsive ingestion of non-nutritious substances, is one condition that has been clearly associated with iron in nondonor and donor populations. Investigation of pica has its own methodological challenges, in that it is a socially and culturally mediated phenomenon (in terms of what is considered appropriate to consume), it is often conflated with psychiatric conditions, and

eliciting disclosure of socially unusual behaviors is a formidable task. The most frequent manifestation in the United States appears to be consumption of large amounts of ice (pagophagia), but other common substances that are consumed include dirt, raw pasta, starch, or chalk. The association with iron and ice-related pica was identified 50 years ago, including the rapid reversibility of the behavior following treatment with iron.<sup>55</sup> Three studies in US blood donors have shown an association with iron, albeit often without great detail elicited on the specific substances consumed.<sup>36–38</sup>

### Potentially vulnerable populations

As noted above, awareness of the possibility for blood donation to adversely impact pregnancy is long-standing. The 2001 workshop offered solutions including suggestions for expanding iron supplementation,<sup>8</sup> but such programs remain few in number. Research to date does not show empirical support for worse outcomes in babies born to blood donor mothers. Abundant evidence exists that female donors are more prone to hemoglobin deferral than male donors, and that iron depletion is more prevalent in females.<sup>10,11,56</sup> The HEIRS study was not powered to assess differences by sex in the recovery kinetics of hemoglobin or ferritin, so whether sex differences exist in response to blood donation after controlling for menstrual loss remains an open question.<sup>13</sup>

Iron depletion in young blood donors has been a focus of concern for several years. The motivation for investigating whether younger donors might be more vulnerable derives from a couple of factors. First, blood collectors in the United States grew increasingly reliant on high school age donors (16–18 years old), with the share of RBC collections from this age group reaching 12–14% in recent surveys.<sup>57,58</sup> Donors this age show high levels of motivation to donate, and logically high schools represent an opportune locale to efficiently collect blood. State legislatures have accommodated mutual interest by the public and blood collectors to facilitate donation by younger donors, such that 37 states allow for donation by 16-year olds.<sup>57</sup> The second factor motivating the concern in teens is recognition that physical and neurocognitive maturation are ongoing in this population, with both processes requiring iron. The first bulletin issued by AABB in 2012 on iron depletion did not specify young donors as a risk population, but the one in 2017 did list them, given the public availability of a recent study on iron status in young donors.<sup>26,27</sup>

The REDS-III CHILL study (*Comparison of Donation History and Iron Levels in Teenage Blood Donors*) sought to determine the prevalence of iron depletion in young donors and to investigate whether their risk for iron depletion was greater than that for adult blood donors.<sup>59</sup> Two large blood centers systematically measured ferritin levels in 4265 blood donors over a single academic year, mostly subjects from high school blood drives. An adult control population and 1954 follow-up donations allowed for repeated measures, multivariable modeling of risk by age group. Sixteen-to-eighteen-year olds had two to three times the risk for ferritin less than 12 ng/mL compared to adults 19 to 49, after controlling for donation frequency and other factors, and progression to deferral for low hemoglobin was twice as likely in teen versus adult females.

### Potential measures for mitigation of iron depletion

Actions that might reduce the prevalence of iron depletion in blood donors are not hard to conceive. None, however, is cost free in terms of reducing donor availability with the possible exception of

enhanced educational materials. Raising the minimum hemoglobin level to the threshold for anemia would reduce iron depletion in male donors, but as shown previously with probable loss of several percentage points of RBC collections.<sup>11</sup> Extending the deferral period for a low hemoglobin deferral might represent a favorable cost–benefit approach, but despite reported variability in how blood centers manage low hemoglobin deferrals,<sup>60</sup> no systematic evaluation has been performed.

Explicit restrictions of donation frequency, whether by extending the minimum interval between donations, as proposed by FDA in 2007, or by limiting some or all donors to fewer donations on an annual basis, would by definition allow more time for recovery between donations. This was what AABB's 2017 bulletin recommended for teen donors, in fact, capping the donation frequency at a single unit per year unless other mitigation measures were in place. Compared to the current allowable donation frequency of every eight weeks (~6 times per year), this recommendation may seem unduly restrictive. In fact, it is consistent with the findings from HEIRS, which showed that two-thirds of donors not taking iron had not reached predonation levels for hemoglobin or ferritin after 24 weeks. Similarly, the simulation study based on RISE data found that extending the donation interval to 12 or 16 weeks would still leave 80% of prevalent iron depletion uncorrected. Finally, a recent study by Vassallo and colleagues reported that ~20% of male and ~40% of female donors age 16–18 years had insufficient iron stores 12 months after donation, and the share with adequate ferritin after a year was less than half in those whose index donation was also associated with low ferritin.<sup>61</sup> Clearly, longer recovery times in the absence of supplemental iron do not resolve the issue and place blood sufficiency at risk.

As recommended in the 2001 workshop focused on women of childbearing years, and consistent with findings from HEIRS, iron supplementation in donors would accelerate physiological recovery, reducing deferral for low hemoglobin and supporting blood availability. To date, very few blood centers actively distribute iron to blood donors,<sup>62</sup> the reasons for which are discussed at some length in the report from AABB's Risk-Based Decision-Making group on iron deficiency.<sup>29</sup> One consideration is a concern that distributing iron “medicalizes” the relationship between donor and blood center, imposing responsibility for tracking and follow-up that conceivably includes sophisticated hematologic workups. Relevant laws vary by state, and it is possible that in some jurisdictions distributing iron would indeed be considered the practice of medicine, with all the attendant implications for liability insurance and operations that such a transformation implies.

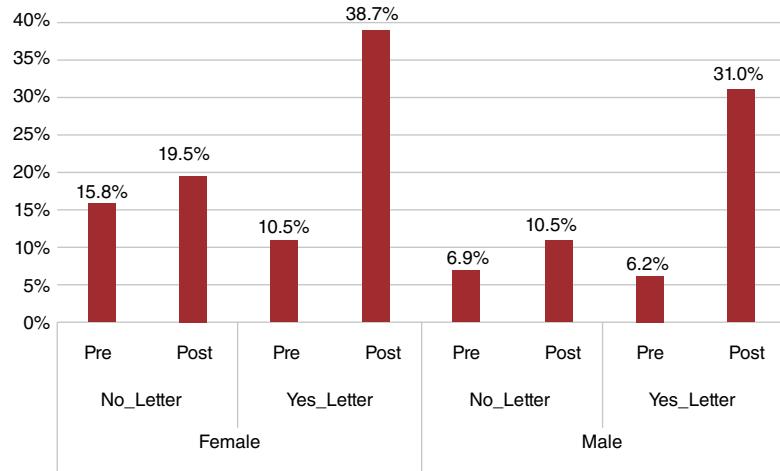

Remarkably, little is known about blood donor habits regarding iron supplementation. Outside of research studies, donors are not asked to report iron-taking behaviors. One study of 53,000 donors in a US blood center found that only 21% of donors reported taking iron in the form of multivitamins or iron supplements, with wide variation by sex, age, and donation history.<sup>63</sup> As little as 3% of first-time, young male donors reported taking iron, while up to 45% of frequent female donors age 50 years or older said they took iron. Motivations were evenly split between those who wanted to support general health and wellness and those who took iron specifically because they were blood donors, with the latter motivation being associated with greater use of separate iron supplements.

Ferritin testing to ascertain donor iron status is one recommendation in the AABB bulletin that is increasingly adopted by US blood centers for their teen donor population. One large center began testing in December 2016, and another large collector began

in January 2018, and unpublished estimates are that at present  $\approx$ 70% of US donors age 16–18 years have ferritin testing performed on their donations. Vitalant (then named Blood Systems, Inc.) was the first large collector to implement ferritin testing, and over the first 18 months they found 27% of tested donors received a low ferritin (LF) deferral, with cutoffs of  $<20$  ng/mL applied to females and  $<30$  ng/mL to males.<sup>64</sup> Their subsequent report showed that 12 months was insufficient for most donors to recover to those thresholds if their ferritin was below that cutoff at the first donation.<sup>61</sup> The experience of the American Red Cross helps explain why that may be the case, assuming comparable iron-taking behaviors across the two systems. In electronic survey of 25,000 teenage donors following donation, Red Cross found that only 11% reported taking iron at the time they donated, half as many as reported by Cable and Spencer.<sup>63,65</sup> Notably, the LF deferral triggered iron-taking, with about one in four deferred male and female donors reporting that they initiated supplemental iron postdonation

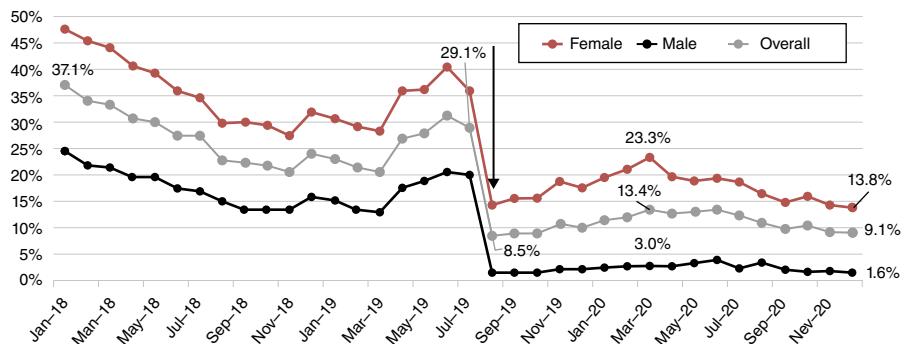

(Figure 7.2). The first 18 months of ferritin testing by the Red Cross was comparable to the experience of Vitalant, with a 6–7-month decline in deferrals followed by a 6–7-month nadir, followed by a climb in deferrals as, presumably, females previously deferred for low ferritin returned to donate after the 12-month deferral (Figure 7.3). Following a change in the deferral trigger to  $<12$  ng/mL in August 2019, deferral rates dropped by 70%.

Compared to restricting teen donation to one unit per year, many US blood centers concluded that ferritin testing provided a stronger balance of protections for donor health and impact on blood availability. Expectations for ferritin testing may, nonetheless, be a net negative contribution to blood collections, reflecting the aggregate impact of temporary removal from the donor pool with deferral, temporary or permanent self-exclusion from donation, and self-initiated iron supplementation. Experience from Canada and the Netherlands supports a decrement to collections as a consequence of ferritin testing.<sup>66–68</sup>

**Figure 7.2** Reported use of supplemental iron in donors 16–18 years old, American Red Cross, by sex and low ferritin deferral.

- “Pre” represents whether donor reported taking supplemental iron prior to most recent donation, as reported by electronic survey 4–8 weeks afterward.
- “Post” represents whether donor reported taking supplemental iron following their most recent donation, reported by the same electronic survey.
- “No\_letter” represents donors whose ferritin values were above the deferral threshold at their most recent donation.
- “Yes\_letter” represents donors whose ferritin values were below the deferral threshold at their most recent donation and who received a letter informing them of their ferritin value and 6-month (male) or 12-month (female) deferral.

**Figure 7.3** Low ferritin deferral rate for 16–18-year-old American Red Cross donors.

- Arrow denotes change in low ferritin deferral trigger in August 2019. Deferrable ferritin values changed from  $<20$  ng/mL (female) and  $<30$  ng/mL (male) to  $<12$  ng/mL for both sexes. Unpublished data.

### Long-term issues for platelet donors

Apheresis platelet donors in the United States can donate up to 24 times a year. While the average platelet donor has many fewer donations annually than the maximum allowable number (as with whole blood donors), a few issues relating to long-term effects of donation have surfaced for this population. Because they usually have a history of whole blood donation, are often recruited to platelet donation on the basis of a high platelet count (a marker for low iron), and can lose  $\approx$ 50 mL whole blood in sample tubes and tubing with each procedure, platelet donors may have unrecognized risk for iron depletion. One recent study in male plateletpheresis donors with borderline hemoglobin found high prevalence of iron depletion and a clear dose-response association with plateletpheresis donation frequency in multivariable models.<sup>69</sup> Another issue that has drawn attention is the possibility of higher risk for fracture in frequent plateletpheresis donors, based on the hypothesis that the citrate anticoagulant might chelate serum calcium and alter bone mineral density. Two studies have examined this question, finding no association between plateletpheresis donation and bone health or fracture.<sup>70,71</sup>

Concern for lymphopenia in frequent platelet donors has drawn renewed attention in recent years, after having been raised as a potential safety concern in the 1980s followed by reassuring findings associated with advancing apheresis technology.<sup>72,73</sup> The leukoreduction that occurs during the procedure has been associated with diminished CD4+ and CD8+ T-cell counts in healthy platelet donors. A recent study of 74,000 donors from Scandat documented potential clinical implications, finding increased risk for bacterial infection in a dose-dependent manner.<sup>74</sup> These results warrant further inquiry and raise questions about additional safety measures prospectively.

### Long-term issues for source plasma donors

Source plasma donors in the United States are permitted to donate twice per week with at least two days between donations with no long-term volume limits. Other countries are more restrictive in frequency and volume donated. Thus, there have been concerns voiced about the safety of source plasma donation in the United States. The long-term record of safety for this industry which has been collecting at this frequency for decades and with the allowed volume allowances since 1992 would seem to allay these concerns.<sup>75</sup> A number of specific issues have been investigated over the years.

When the focus began on iron depletion in blood donors, it was suggested this would be a possible issue for long-term plasma donors due to the accumulated loss of red cells with donation at the maximum frequency. The loss of 10–11 cc of red cells per donation with most of the automated equipment is reduced to about 5 cc when saline reinfusion is employed, as is standard practice. The saline infusion rinses some of the red cells in the tubing back into the donor. Theoretically, a plasma donor could have the equivalent loss of two units of red cells per year. The ferritin levels in plasma donors (FLIPID) study provided data that iron depletion is rare in source plasma donors and is not higher in frequent donors. This study compared male and female donors at different donation frequency to new donors.<sup>76</sup>

Protein depletion is of greater concern since proteins and immunoglobulins are removed with each donation along with other constituents of plasma. Multiple studies of this possibility have been completed since plasmapheresis began. In 1963, studies at NIH showed that chronic plasmapheresis for up to 23 weeks with the

maximum rates not exceeding 1.5 L of plasma withdrawn per week (slightly less than the currently approved maximum) produced no changes in formed elements and only minor changes in serum protein levels. By contrast, five donors subjected to 5 L of plasma removal in five days did have serum protein depletion.<sup>77</sup> A study at the University of Michigan in 1970 showed no major depletion with donations of plasma equivalent to four units of whole blood per week (somewhat less than the maximum currently allowed).<sup>78</sup> Investigators at UCLA and a commercial source of plasma products also showed no adverse effect on plasma protein homeostasis from long-term plasmapheresis at volumes somewhat less than allowed currently.<sup>79</sup> Similar low risk was found by Canadian investigators in 1993, but their protocol was weekly plasmapheresis at volumes about a third of what is currently allowed.<sup>80</sup>

There is clearly protein loss with each donation. In the United States, this is monitored by a protein level before each donation and a protein electrophoresis every four months. In Europe, IgG levels as well as protein levels are monitored. IgG has a delayed recovery after it is removed, which is the basis of this additional test. A comprehensive study of removal and recovery of normal plasma constituents after plasma exchange where much larger volumes are removed showed that immunoglobulin, complement, fibrinogen, and cholesterol have marked reduction in concentrations after high-volume plasma exchange. Interestingly, newly synthesized antibody after the exchange may have increased biologic activity, indicating the immunoglobulin depletion did not necessarily correspond to reduction in antibody activity. Since albumin replacement was used, neither albumin nor total protein declined.<sup>81</sup>

Subsequently, this was investigated in long-term plasma donors. A comprehensive study of proteins and lymphocyte subsets showed low levels of serum protein, globulin, and IgG accompanied by increased percentages of B cells and decreased percentages of suppressor T and natural killer cells.<sup>82</sup>

The evidence of IgG depletion led to concern that immune surveillance might be compromised in long-term plasma donors impacting general health. Industry conducted two studies: one a retrospective review of records of over 500 remunerated donors participating in plasmapheresis programs at various levels of frequency for 10 years or more and a second one determining the reasons for cessation of participation in serial plasmapheresis programs.<sup>83,84</sup> Both studies found no evidence that long-term plasmapheresis impacted the donor's health. The reasons for dropping out of plasmapheresis programs were not medically related.

A study in Austria found bone demineralization presumed to be due to long-term impact of citrate infusion in long-term apheresis donors.<sup>85</sup> Most of the data is related to plateletpheresis donors, but the authors extended their conclusions to plasmapheresis donors. In the plasma collection procedure, most of the citrate goes into the plasma collection bottle or bag and is not returned to the donor. An analysis of this data (unpublished by the Plasma Protein Therapeutics Association) did not support the conclusion, and no other data has indicated bone mineral density losses in plasmapheresis donors.

The concern about the health of source plasma donors, particularly in the United States, relates both to the frequency and amount collected at each donation and the fact that the donors are compensated in cash. The data available does not indicate that there are health-related issues with this donor population. However, the Plasma Protein Therapeutics Association is addressing this concern in the United States with short- and long-term studies of the donor

population's health similar to their FLIPID study mentioned above. These studies are ongoing, and no data have yet been presented or published.

## Summary

As demonstrated repeatedly in research studies, blood donors tend to enjoy stronger health by many measures than the general population. Blood centers and regulators collect data and deploy many measures to protect the health and safety of persons giving the "gift of life." The industry has a strong safety record but continues to evaluate the clear risk for iron depletion in many donors and whether that risk extends to actual health manifestations. Platelet and plasma donors enjoy robust safeguards for frequent donation, but risk for lymphopenia is a recent issue warranting further scrutiny for plateletpheresis donors.

## CHAPTER 8

# Global perspective: ensuring blood and blood product safety and availability through regulation and certification

Eva D. Quinley

Regulatory Affairs and Laboratory Operations, CSL Plasma, Knoxville, TN, USA

Blood and blood products are considered an essential part of medical therapies worldwide. National systems are seen in much of the developed world (e.g., Europe, Canada, Australia, and New Zealand), with the United States as an exception. In Canada, there is one national system and a second one for the province of Quebec. Less developed countries often have hospital-based systems (in some cases with a small national system, as in Mexico). Many are run by the International Red Cross and are government subsidized.

In the United States, a majority of the blood is collected and distributed by community blood centers that generally are part of a trade organization called America's Blood Centers (ABC). The American Red Cross, which is separate from ABC, collects and distributes about 40% of the blood, and a small percentage of blood is collected and processed by hospital-based blood banks.

A number of organizations impact blood product safety and availability. The AABB (formerly the American Association of Blood Banks) is a professional society of individuals in the field, community blood centers, and hospital transfusion services from around the world. It publishes the *AABB Technical Manual* and *Standards for Blood Bank and Transfusion Services* (as well as several publications containing standards for various specialized services) that both serve as voluntary guides to procedures and quality requirements and tend to establish a standard of care. The AABB through its accreditation program inspects blood banks and transfusion services to ensure that they provide quality care in line with that standard of care.

Plasma collection and manufacturing organizations are certified by the PPTA (Plasma Protein Therapeutics Association or PPTA Source for collections), which is the global and standard setting organization for plasma collection and fractionation. Their International Quality Plasma Program (IQPP) provides independent, third-party evaluation and recognition of a plasma center's adherence to global industry standards for source plasma.

There is also an international blood transfusion society, the International Society of Blood Transfusion (ISBT). Founded in 1935, the ISBT has grown into an international society where transfusion medicine professionals from across the globe come together and share knowledge to improve the safety of blood transfusion worldwide. In addition, the World Health Organization (WHO) has an

ongoing interest in blood availability and safety worldwide as part of its efforts to ensure quality health care is available worldwide.

Because of their importance as medical therapies, blood and blood products are heavily regulated throughout the world. The primary regulator for the United States is the Food and Drug Administration, although in addition there are applicable state and/or local regulations. Blood establishments are also regulated by other federal and state organizations such as the Department of Transportation (DOT), the Occupational Safety and Health Administration (OSHA), and the Nuclear Regulatory Commission (NRC). Europe has multiple regulatory groups within member states and outside Europe, and regulations are often country specific. Regulatory bodies outside the United States are discussed later in this chapter.

It is important to differentiate between regulation and accreditation/certification. Regulations are laws and must be followed whereas accreditation/certification is a choice and is achieved through adoption of voluntary standards. Regulations differ from country to country and even within a given country (e.g., state-specific regulations in the United States). When there are differences between regulations, the more stringent regulation usually applies so that there is full compliance. Many of the standards applicable to blood establishments are applicable worldwide.

It is important to note that blood centers, transfusion services, plasma centers, and laboratories that perform testing on donor blood are known collectively as blood establishments. Depending upon the activities that a blood establishment performs, differing regulations and standards apply.

## US perspective on ensuring blood and blood product safety and availability

### History of safety and efficacy requirements for drugs and biologics in the United States

Regulatory approval of drugs and biologics in the United States is subject to federal law. Safety and efficacy requirements related to drug and biologics approval have evolved through the twentieth and twenty-first centuries. In 1906, President Theodore Roosevelt, appalled by what he read in an Upton Sinclair novel, *The Jungle*, included a

recommendation for food and drug legislation in his annual message to Congress, which resulted in passage of the Pure Food and Drug Act (Public Law 59-384; 34 Stat. 768). The intent of the law was to prevent the manufacture, sale, and transportation of misbranded and adulterated foods and drugs. The passage of subsequent public health laws followed several therapeutic tragedies. In 1937, the S.E. Massengill Co. introduced sulfanilamide dissolved in diethylene glycol. Diethyl glycol, a chemical normally used as antifreeze, is a deadly poison. No drug safety testing was required by law at the time. The drug was promoted to treat streptococcal infections, and 633 shipments were distributed throughout the United States. Before its use could be stopped, more than 100 people in 15 states died.<sup>1,2</sup> This and similar incidents led to the enactment of the 1938 Food, Drug, and Cosmetic Act (FDCA) (Public Law 75-717; 52 Stat. 1040).<sup>3</sup>

The law, which became effective in June 1939 differed substantially from the 1906 Act that it replaced. It extended coverage to include cosmetics and therapeutic devices. It required clearance of new drugs for safety prior to distribution and provided authority to establish tolerances for potentially poisonous substances in foods and drugs. It added the sanctions of injunction and emergency permit control to the seizure and prosecution authority in the previous act. As the main purpose of the law was to prohibit the movement of mislabeled and adulterated food, drugs, devices, and cosmetics in interstate commerce, it authorized inspections of factories, warehouses, establishments, and vehicles used in manufacturing, processing, packing, storing, and transporting these products. The act also established a requirement that a new drug could not be introduced into interstate commerce unless an application was made. The application needed to include a full report of investigations to show whether or not the drug was safe for use; an explanation of the drug's composition; a description of the methods, facilities, and controls used in manufacturing, processing, and packing; as well as samples of the drug and label. Grounds for application rejection included inadequacy of tests, failure of test results, and other information to help determine the product safety, as well as inadequacy of facilities, methods, and controls used in manufacturing, processing, and packing for preserving the product's identity, strength, purity, and quality.

In the 1940s, the FDCA was amended with requirements of batch certification for certain drugs (e.g., penicillin; Public Law 79-139; 59 Stat. 463) to verify product identity, quality, purity, and strength, and thus try to ensure their safety and presumed effectiveness.<sup>4</sup> Thalidomide caused another public health disaster in the late 1950s and early 1960s.<sup>1,2</sup> Introduced in late 1957 to treat insomnia, colds, coughs, and headaches, the drug was found to relieve symptoms of so-called morning sickness, and was prescribed for this indication as well. At the time, drugs were not tested for their effects on the fetus. As a result, thousands of children, born in 46 countries, suffered severe congenital deformities. Although some pregnant women in the United States used this medication as it was distributed to physicians during the clinical testing program, the United States experienced fewer cases of birth defects, as the FDA refused to approve thalidomide. The enactment of the 1962 Amendments to the 1938 FDCA (Public Law 87-781, 76 Stat. 780; commonly known as the Kefauver-Harris Amendments) came as a response to the thalidomide disaster.<sup>1,2</sup> This law made regulatory approval a mandatory prerequisite for product marketing, strengthened safety regulations, and added the requirement for applicants to provide evidence of product effectiveness through adequate and well-controlled studies, including clinical investigations. Additionally, the Drug Amendments of 1962 stated that drug advertising should contain a label with the prominently printed established product

name, formula with ingredient quantification, as well as information related to side effects, contraindications, and effectiveness.

Biologics-related requirements also developed gradually and roughly in parallel with drug legislation. As defined in the PHSA Section 351(i), a biologic product means a virus, therapeutic serum, toxin, antitoxin, vaccine, *blood, blood component or derivative*, allergenic product, protein (except chemically synthesized polypeptide), or analogous product, or . . . applicable to the prevention, treatment, or cure of a disease or condition of human beings.<sup>5</sup> In 1901, 13 children in St. Louis, MO, and nine in Camden, NJ, died of tetanus after receiving contaminated diphtheria antitoxin and smallpox vaccine, respectively. In 1902, Congress passed the Biologics Control Act (Public Law 57-244; 32 Stat. 728), also known as the Virus-Toxin Law.<sup>1,2</sup> The law authorized the promulgation of licensing regulations for establishments involved in the production of toxins, antitoxins, viruses, sera, and similar products. The act also authorized inspections at manufacturing facilities. Companies needed to be licensed for the manufacture and sale of the products. Inspectors were required to study product purity and potency. In 1934, new regulations, published under the title "Regulations for the Sale of Viruses, Serums, Toxins and Analogous Products in the District of Columbia and in Interstate Traffic," explicitly indicated that licenses for new products would not be granted without acceptable evidence of therapeutic or prophylactic efficiency. In 1944, the Public Health Service Act (PHSA) was enacted (Public Law 78-410; 58 Stat. 682). Section 351 of this law incorporated, with few changes, the Biologics Control Act. The document stated that licenses would be issued only upon a showing that the establishment and the products for which a license was being sought met the standards intended to ensure the continued safety, purity, and potency of the products.<sup>5</sup>

As noted, regulatory approval of drugs and biologics in the United States is subject to federal law. Drugs are approved under Section 505 of the Food, Drug, and Cosmetic Act (21 U.S.C. 355), as amended. An order to approve an application is issued if none of the following applies: the investigations are found to be inadequate; the results either do not prove product safety or prove its unsafety; the data submitted as part of the application and other available information do not provide sufficient evidence of product safety and effectiveness; the methods, facilities, and controls used in manufacturing, processing, and packing are found to be inadequate to preserve the product's identity, strength, purity, and quality; and the application lacks the required patent information.<sup>5</sup> Although biologics are also considered to be drugs, because most of them meet the definition of the term drug in FDCA Section 201(g)(1) (21 U.S. C. 321), they are usually licensed under authority of Section 351 of the PHSA (42 U.S.C. 262), as amended. Under Section 351, which has been in effect since 1944, biologics license applications are approved following the applicants' consent to the inspection of the facilities and on the basis of a demonstration that the products are safe, pure, and potent, and the facilities in which the biologics are manufactured pass an on-site inspection.<sup>5</sup>

The FDCA of 1938 has been amended dozens of times. Major amendments include the FDA Modernization Act (FDAMA) of 1997, the Food and Drug Administration Amendments Act (FDAAA) of 2007, and the Food and Drug Administration Safety and Innovation Act (FDASIA) of 2012.

## FDA regulation of blood collection establishments

### Overview

Blood and blood components are used in the treatment of disease. Therefore, blood and blood components meet the definition of a drug in Section 201(g) of the FDCA; and blood products, including

source plasma, must meet all statutory requirements of the FDCA. FDCA sections applicable to blood include Sections 201, Definitions; 301, Prohibited Acts; 501, Adulteration; 502, Misbranding; 510, Registration; and 704, Factory Inspection.

The fundamental principles of the regulation of blood establishments are to ensure the safety, effectiveness, and availability of blood and blood products; protect the health of the donors and recipients; and ensure that the blood collected is safe for transfusion or further manufacture. The Food and Drug Administration is the primary regulator of blood establishments in the United States. The FDA has three major functions:

- 1 Development and promulgation of regulations.
- 2 Registration and licensure of blood establishments.
- 3 Inspection and compliance actions.

The FDA's Center for Biologics Evaluation and Research (CBER) works closely with other parts of the Public Health Service (PHS) to establish blood regulations and to identify and respond to potential threats to blood safety or supply. Regulations promulgated by the FDA are binding both on the agency and the blood establishment industry. The FDA also issues guidance documents that represent the FDA's current thinking on the handling of a particular subject. The FDA licenses and/or registers blood establishments, inspects them routinely, and monitors reports of errors, accidents, and adverse clinical events. If noncompliance is found during inspections, the FDA can take actions (sanctions) against blood establishments.

In addition to its major functions, the FDA conducts a wide range of compliance and surveillance activities during the "life cycle" of biological products. These include:

- Conducting prelicense and preapproval inspections as well as postlicensure and postapproval inspections of manufacturing facilities and products under clinical study.
- Monitoring the safety, purity, and potency of biological products through review of:
  - Biological product deviation reports,
  - Investigations into transfusion- and donation-related fatalities and other adverse events, and
  - Product recalls.
- Monitoring reports of biological product shortages.
- Initiating regulatory action to address noncompliance with FDA laws and regulations.
- Monitoring of research conducted on biological products and assessing the protection of the rights, safety, and welfare of human research subjects and the quality and integrity of research data.
- Monitoring import and export activities.
- Reviewing product advertising and promotional labeling.

### Good manufacturing practices

The requirements found in the current good manufacturing practices (cGMPs) are the major regulations that the FDA enforces on blood establishments. These represent the minimum requirements an establishment should follow. Applicable cGMP regulations are found in the US Code of Federal Regulations (CFR) within Title 21 Part 210, cGMP for Manufacturing, Processing, Packing, or Holding of Drugs; Title 21 Part 211, cGMP for Finished Pharmaceuticals; and 21 CFR 606, cGMP for Blood and Blood Components. Table 8.1 lists the subparts of 21 CFR Part 211, cGMP, and Table 8.2 lists the applicable sections for blood and blood products in 21 CFR Parts 600–640.

The PHSA requires licensure for biological products in interstate commerce. In this regard, each package of a biological product is clearly labeled; the biological product is required to be safe, pure, potent, and effective; the facility where the product is manufactured

meets or exceeds standards set in the regulations; and the applicant consents to inspection. Licensure is intended to ensure the safety, effectiveness, and availability of blood and blood products, thereby allowing shipment of product(s) in interstate commerce. It also protects the health of the donor and recipients.

FDA licensure is required to ship products in interstate commerce or internationally. Registration is required for all blood establishments, including those located in hospitals, that manufacture (collect, store, process, or distribute) blood components for transfusion or further manufacture. Registration requirements for manufacturers of human blood and blood products are outlined in 21 CFR Part 607; license requirements are outlined in 21 CFR Part 601. Elements of cGMP are listed in Table 8.3. The division into elements is arbitrary but is based on an analysis of commonality of the requirements of Title 21 as they apply to all aspects of blood establishment operations. Thus, it is irrelevant whether they are applied to blood collection or to infectious disease testing; each element is applicable for each discrete blood establishment operation. Because blood and plasma centers are required to follow their own standard operating procedures (SOPs), each SOP creates unique regulatory requirements for that operation. From a regulatory standpoint, this concept is significant in that compliance standards, and regulatory requirements are created by individual establishment SOPs. cGMP applies to both the production methods used by blood establishments to manufacture components and the manufacturing process controls in place. Each provision of an establishment's SOPs must be in line with the manufacturers' instructions for licensed or approved systems used in that organization.

Meticulous records of compliance with cGMP elements are required to ensure both executive management and the FDA that a

**Table 8.3** Elements of Current Good Manufacturing Practice

- Quality control and auditing
- Facilities and equipment
- Process and production change control

blood establishment's manufacturing processes are under control. Control, in this context, can be defined as compliance in every respect with the establishment's manufacturing SOPs and FDA requirements. It is worth emphasizing that if a firm's SOPs are more stringent than FDA requirements, it is not acceptable to deviate from the SOP, even if the FDA requirement is met, unless appropriate change control is applied, including appropriate approvals, communication of the change, and reporting to FDA of the change, if required. During inspections of blood establishments, whether by the private sector or regulatory bodies such as the FDA, the overriding investigational concern is whether an establishment has this control. Records should be designed to document and provide evidence of control of manufacturing systems and allow for complete trackability (follow logical steps of the process) and traceability of a process (details such as who, when, how, and where).

Although not required by the CFR, it is generally held that the quality function should organizationally be distinct from manufacturing to ensure its independence, and this de facto requirement appears in FDA guidance documents.<sup>6,7</sup> In many blood establishments, the director of the quality reports directly to the chief executive officer. The role of the quality function should be defined in writing as part of the Quality Management System. All matters that relate to quality should funnel to a single person or group with broad knowledge of the blood establishment's operations and access to the information necessary to assess the impact of proposed changes. These principles emphasize the importance with which the FDA views both quality and SOPs. However, case law holds that upper management cannot avoid adverse consequences of noncompliance with regulatory requirements because a lower ranking employee is designated the authorized official (the individual(s) designated to speak for the organization in regulatory matters and to work with the FDA).<sup>8</sup> Quality staff can be deployed to enhance the quality of blood establishment operations in a variety of ways. They can assume responsibility for personnel training, especially in cGMP, maintain calibration and validation records, design validation protocols, and identify trends through statistical analysis. A well-directed quality function can be of enormous value to both the authorized official(s) and the staff of the facilities in which it is established. However, quality staff should not review their own work as their objectivity cannot be ensured. Table 8.4 lists selected responsibilities of the quality function. Although internal audits are also not specifically required by regulations, procedures to detect problems are required and internal audits are an important means of ensuring that processes remain in control. Internal audits are considered confidential by the FDA and the results of such audits are generally not available to FDA investigators unless fraud is suspected or there appears to be an imminent threat to public health. The reason for this policy is to encourage audits that are complete and detailed with no information withheld.

**Table 8.4** Quality Function Responsibilities

**Quality Function Responsibilities Should Include, but Not Be Limited to, the Following:**

- Approve specifications
- Approve test procedures, including process controls
- Approve validation plans, protocols, or equipment
- Review changes in product, process, or equipment, and determine if revalidation is required
- Approve specification changes, sampling plans, and test procedures
- Approve sampling procedures
- Approve reference standards
- Conduct analytic investigations and evaluate results
- Approve testing materials
- Provide analytical reports
- Approve or reject intermediates and active pharmaceutical ingredients manufactured, processed, packed, or held under contract by another establishment
- Gather data to support retest dates (stability testing)
- Evaluate and approve contractors
- Review batch records
- Review complaints
- Perform internal and external audits
- Perform periodic assessments of procedures, policies, and responsibilities within the establishment's manufacturing and control operations

The FDA also respects supplier audits as confidential internal audit information. However, it is critical that the blood establishments have readily available SOPs for audits, schedules demonstrating that all elements of operations are reviewed regularly (at least annually), processes for ensuring and documenting corrective and preventive action and follow-up, and formal closure notices to complete the records. It is also essential that any deviations discovered in the course of audits be properly documented in records that are available to FDA investigators. The Quality Management System, including a review of internal audits and their outcomes, must be assessed for effectiveness by management at regular intervals.

**FDA structure: Office of Blood Research and Review (OBRR)**

FDA regulatory review of devices, drugs, and biologics is conducted by the Center for Drug Evaluation and Research (CDER), the Center for Devices and Radiologic Health (CDRH), and the Center for Biologics Evaluation and Research (CBER). All submissions and applications (including combination products) are assigned to one of these centers for review. The Office of Blood Research and Review (OBRR) within CBER regulates blood and blood products while the Office of Tissues and Advanced Therapies (OTAT) regulates plasma derivatives (except for albumin) and their recombinant analogues. OBRR is also responsible for the regulation of blood donor screening assays and retroviral diagnostic tests. There are two divisions within OBRR, the Division of Emerging and Transfusion Transmitted Diseases (DETTD) and the Division of Blood Components and Devices (DBCD). DETTD has oversight of blood donor screening and supplemental tests, source plasma donor screening tests, and retroviral diagnostic tests. The DBCD has oversight of blood grouping reagents; reagent red cells; anti-human globulin; molecular erythrocyte typing tests; HLA, HNA, and HPA antigen and antibody test kits; and bacterial detection tests.

**FDA guidance documents**

Guidance documents represent FDA's current thinking on a topic. They do not create or confer any rights for or on any person and do not operate to bind FDA or the public. A firm can use an alternative approach if the approach satisfies the requirements of the applicable statutes and regulations. These documents usually discuss specific

products or issues that relate to the design, production, labeling, promotion, manufacturing, use, and testing of regulated products. Guidance documents may also relate to the processing, content, and evaluation or approval of submissions as well as to inspection and enforcement policies.

### FDA inspections

Section 704 of the FD&C Act authorizes FDA to conduct inspections at reasonable times, within reasonable limits, and in a reasonable manner. Facility inspectors are instructed that the facility must have knowledgeable and trained staff, appropriate equipment, and adequate procedures to ensure that, as applicable, donors are screened appropriately and units are collected, stored, and shipped in accordance with FDA regulations. The establishment's procedures must address all manufacturing steps. For example, in a blood collection facility, SOPs should cover donor screening; blood collection; unit identification; operation of all screening and collection equipment; handling of donor reactions; management of post donation information reports; storage of product and supplies; quality control of reagents, supplies, and equipment; transport of collected units; and documentation and follow-up of any unexpected incidents. Inspections should include observations of the manufacturing process and an examination of the physical layout of the facility to ensure that there is limited public access to biohazardous areas, proper disposal of biohazardous materials, accessible restrooms and handwashing equipment, and clean and organized storage areas. Supplies should be examined to make certain they are appropriately licensed and used within their expiration date.

Inspections may be conducted for several reasons: routine, pre-license, for cause, and follow up. Upon arrival at a blood establishment, the inspector presents credentials and an FDA Form 482 that explains the reason for the inspection.

Observations during an inspection are recorded on an FDA Form 483. These are presented to the blood establishment being inspected, and normally the blood establishment writes a written response to each observation and may write responses to any discussion points. The observations represent an inspector's observation of noncompliance. Following the inspection, an Establishment Inspection Report that provides a full narrative of the inspection results is prepared by the inspector(s) and forwarded to the establishment for review.

### FDA reportable deviations

Apart from the requirement to report and investigate adverse reactions, as stipulated in 21 CFR 606.170, an organized error management process is not specifically required by the provisions of Title 21, although 21 CFR 606.171(c) mandates the reporting within 45 days of all biologic product deviations on distributed products. It is important to note that for something to be reportable it must meet the criteria in Table 8.5.

The investigation and follow-up of deviations is critical to the successful and continuing improvement of blood establishment quality. In fact, appropriate management of deviations forms the centerpiece of continuous improvement. Each blood establishment deviation should be treated as an opportunity to be used to improve processes. All facilities must develop SOPs for detecting, reporting, managing, and correcting deviations, including errors and accidents. Error management efforts and results should be documented as quality records. Monitoring corrective action outcomes to ensure effectiveness is an essential part of the system for addressing corrections.

Although error management systems are not defined in Title 21, some attributes of good systems include:

**Table 8.5** Reportable Event Criteria

**For a Deviation Event to Be Reportable, It Must:**

1. Either
  - (i) represent a deviation from current good manufacturing practice, applicable regulations, applicable standards, or established specifications that may affect the safety, purity, or potency of that product; or
  - (ii) represent an unexpected or unforeseeable event that may affect the safety, purity, or potency of that product.
2. Occur in your facility or another facility under contract with you.
3. Involve *distributed* blood or blood components.

- 1 Employees at all levels in the organization are encouraged to report errors. Punitive policies discourage reporting, resulting in lost opportunities for systems improvements.
- 2 Employees involved in the process in which an error was made should be involved with the investigation and resolution of the error and corrective actions taken. It is essential that the investigation be sufficient to determine the underlying root cause for the error rather than identifying mere "symptoms" of the root cause. The FDA also requires that staff are educated concerning the effect their errors have or potentially have on product quality, that is, it is required that they understand how their responsibilities have an effect on ensuring that only safe products are released.
- 3 Confirmation of the effectiveness of the corrective action is vital to ensure that the improved process continues to yield the expected results. Post change monitoring is essential, and long-term evaluation should be performed at appropriate intervals (e.g., 3–6 months after a process improvement is completed).

Deviations must be reported only if the product was distributed. This is defined as having left the control of the establishment. If the product was not distributed, the incident still must be recorded in internal records [21 CFR 606.160(b)(7)(iii)]. If the product was distributed, a report must be submitted to CBER within 45 calendar days from the date information is acquired that reasonably suggests a reportable event occurred. The incident must also be recorded [21 CFR 606.160(b)(7)(iii) and 21 CFR 211.198] and investigated [21 CFR 606.100(c) and 21 CFR 211.192]. The FDA has stated that the purpose of this reporting system is to provide early warning of faulty processes as an indicator for potentially immediate problems that may be related to recalls and as surveillance for improving training and establishing guidance.<sup>9,10</sup> Table 8.6 contains a synopsis of the final rule for reporting.

**Table 8.6** Synopsis of Final Rule on Reporting Biological Product Deviations

- The rule applies to all establishments: donor centers, blood banks, transfusion services.
- Reporting time is not to exceed 45 days.
- Report by mail: Director, Office of Compliance and Biologics Quality, Food and Drug Administration, 10993 New Hampshire Avenue, Silver Spring, MD 20993, USA; or electronically via CBER's website: [www.fda.gov/cber/biodev/biodev.htm](http://www.fda.gov/cber/biodev/biodev.htm).
- If the answers to the questions below are affirmative, the event is reportable:
  - Was the event associated with manufacturing?
  - Did the deviation affect safety, purity, or potency?
  - Did it occur in a licensee's or a contract facility?
  - Did the facility have control over the product when the deviation occurred?
  - Was the product distributed?

## Device regulatory controls

All classes of medical devices are subject to what are known as general controls. General controls are the basic provisions of the May 28, 1976, Medical Device Amendments to the FDCA. They provide the FDA with the means of regulating devices to ensure their safety and effectiveness. General controls in the FDCA apply to all medical devices. They include provisions that relate to adulteration; misbranding; device registration and listing; premarket notification; banned devices, including repair, replacement, or refund; records and reports; restricted devices; and good manufacturing practices. The FDA considers three classes of devices.

- Class I devices are subject to general controls and are typically exempted from submission of a premarket 510(k) notification. They are viewed as posing the lowest risk to the patient and/or user.
- Class II devices are subject to what are known as special controls in addition to the general controls provision of the FDCA. Special controls may include compliance with a recognized standard, warning statements in the instructions for use, specific performance requirements, and/or other controls necessary to ensure a reasonable assurance of safety and effectiveness. Class II devices typically require FDA clearance of a premarket 510(k) notification to permit the device to be marketed and sold in the United States.
- Class III devices are viewed as presenting a higher level of risk. They may be first-of-a-kind devices for which general and special controls are not adequate to ensure safety and effectiveness. Class III devices require FDA approval in the form of a premarket approval application prior to marketing, as well as compliance with device general controls.

The 510(k) premarket notification is a submission made to the FDA to demonstrate that the device to be marketed is at least as safe and effective as (i.e., is substantially equivalent to) a legally marketed Class I or II device of that same generic type. When determined to be substantially equivalent, the subject device may be legally marketed and sold in the United States.

The legally marketed device to which substantial equivalence is determined is known as the predicate device. A predicate device can be a preamendments device (legally marketed prior to the May 28, 1976, Medical Device Amendments to the FDCA) or a postamendments device that is, or was, legally marketed in the United States following the device amendments. A claim of substantial equivalence does not mean the new device must be identical to the predicate device. Substantial equivalence is based on a comparative assessment with respect to intended use, design, energy used or delivered, materials, performance, safety, effectiveness, labeling, biocompatibility, standards, and other applicable characteristics that would demonstrate the device is as safe and effective as the predicate device.

## Blood establishment computer software

Blood establishment computer systems (BECS) are currently subject to the 510(k) premarket notification provisions of the FDCA. Currently, these devices are regulated as Class II devices, subject to 510(k) premarket notification requirements.

Medical device data systems (MDDS), regulated under Section 880.6310, are Class I medical devices exempt from 510(k) premarket notification and were not included for consideration under the BECS and BECS accessories classification. By definition, Medical Device Data Systems (MDDS) are hardware or software products intended to transfer, store, convert formats, and display medical device data. The MDDS does not, in any way, manipulate or alter the data.

## Regulation and accreditation of hospital transfusion services

### Overview

The Clinical Laboratory Improvement Act and Amendments (CLIA) stipulate requirements for the qualifications of staff who perform or supervise the testing conducted within a transfusion service. AABB standards and FDA cGMP regulations also require that the transfusion services have a process for personnel training and competency evaluation.<sup>11</sup>

Written SOPs are required by the FDA in 21 CFR 606.100. A system must be in place to ensure process control for the validation of processes and procedures, introduction and change of processes and procedures, proficiency testing, quality control, and the use of materials and other aspects of performance of procedures. A defined system of documentation and record retention is required by 21 CFR 606.140 and 21 CFR 606.160 and also may be found within the AABB standards.<sup>12</sup>

AABB standards state that the blood bank or transfusion service shall have a medical director who is a licensed physician and qualified by education, training, and/or experience. The medical director shall have responsibility and authority for all medical and technical policies, processes, and procedures—including those that pertain to laboratory personnel and test performance—and for the consultative and support services that relate to the care and safety of donors and/or transfusion recipients. The medical director may delegate these responsibilities to another qualified physician; however, the medical director shall retain ultimate responsibility for the medical director duties. However, the standards do not require that overall executive management to be under the control of the medical director. The Joint Commission (discussed later in this chapter) also does not require that the overall direction of the laboratory be performed by a physician but does state that “a pathologist or physician qualified in immunohematology, hemotherapy, and blood banking directs blood transfusion services” (HR 1.15).<sup>13</sup> Thus, the medical director may or may not have authority in personnel (other than policies and procedures), purchasing, budgeting, and other administrative matters. The regulation states that the laboratory director must be a doctor of medicine or doctor of osteopathy licensed in the state where the laboratory is located (42 CFR 493.1443).

The FDA, AABB, and the College of American Pathologists (CAP) all have requirements regarding the evaluation and reporting of adverse effects of blood transfusion. CAP is an organization of board-certified pathologists that serves patients, pathologists, and the public by fostering and advocating excellence in the practice of pathology and laboratory medicine worldwide. The FDA requires that records be maintained of any reports of adverse reactions to blood transfusion and that a thorough investigation of each reported reaction be conducted. All transfusion services must report deaths confirmed as being caused by a transfusion. The applicable regulation [21 CFR 606.170(b)] reads

When a complication of blood collection or transfusion is confirmed to be fatal, the Director, Office of Compliance and Biologics Quality, CBER, must be notified by telephone, facsimile, express mail, or electronically transmitted mail as soon as possible. A written report of the investigation must be submitted to the Director, Office of Compliance and Biologics Quality, CBER, by mail, facsimile, or electronically transmitted mail (for mailing addresses, see 600.2 of this chapter), within seven days after the fatality by the collecting facility in the event of a donor reaction, or by the facility that performed the compatibility tests in the event of a transfusion reaction. (<http://www.fda.gov/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/Guidances/Blood/ucm074947.htm>)

The AABB requires that a transfusion service has a process for the detection, reporting, and evaluation of suspected complications of transfusion and that all suspected transfusion complications are evaluated and reviewed by the medical director. CAP requires that all transfusion reactions or incidents be reported immediately to the laboratory, that documented procedures exist for actions to be taken in the event of a transfusion reaction, and that the results of the investigation be recorded in the patient's chart.

### FDA regulation of hospital transfusion services

Total quality systems have been required for blood establishments since 1975 when the FDA incorporated cGMP into the Code of Federal Regulations. Although the regulations were aimed primarily at blood and plasma centers, many of the provisions apply to transfusion services as well. In 1995, the Center for Biologics Evaluation and Research produced a Guidance to assist establishments in developing quality programs in accord with applicable regulations.<sup>6</sup>

In laboratories where clinical samples are tested, the Clinical Laboratory Improvement Amendments (CLIA) requirements for quality control (QC), listed in 42 CFR Part 493, must also be followed. All personnel shall be trained in its application. The quality system shall be under the supervision of a designated person who reports to executive management. For reagents for which there are no QC requirements in Title 21, the QC testing described in the manufacturer's package insert must be followed. It is mandated that "each laboratory establish and follow written policies and procedures for a comprehensive quality assurance program. . . . The laboratory's quality assurance program must evaluate the effectiveness of its policies and procedures; identify and correct problems. . . . All quality assurance activities must be documented."<sup>11</sup>

For any hospital quality program to work successfully, physicians must give priority to the process, and hospital administration must make the necessary resources available to ensure its development, implementation, refinement, and continuation.

The FDA requirement that errors or accidents affecting the safety, quality, integrity, purity, or potency of a blood product be reported extends to all blood establishments, including the transfusion services (21 CFR 606.171). However, this statutory authority extends only to the blood product itself and does not permit FDA oversight of the actual transfusion episode. Although FDA MedWatch provides a voluntary venue for reporting adverse events, most hospitals do not voluntarily report errors to MedWatch (<http://www.fda.gov/Safety/MedWatch/default.htm>). Therefore, the FDA's purview extends only as far as the laboratory door, and there is no requirement to report a patient misidentification error unless it results in a death. (A transfusion-related death, however, must be reported to CBER within 24 hours.)

The FDA considers establishments that perform certain activities that it defines as manufacturing steps to be hospital blood banks, which are required to register annually using Form FDA 2830. A hospital blood bank is an entity that routinely collects or processes whole blood or blood components. These components may be collected by means of apheresis or prepared from whole blood. Processing includes freezing, deglycerolizing, washing, irradiating, rejuvenating, or removing leukocytes from components. However, the collection and processing of blood and blood components in an emergency situation, therapeutic collection of blood or plasma, preparation of recovered plasma for further manufacture, or preparation of red blood cells for transfusion do not require registration (21 CFR 607.65(f)).

Because blood and blood components are drugs under the Federal FDCA, the FDA cGMP regulations (21 CFR Parts 210 and 211) apply to the manufacture of these products. All of these regulations apply to FDA-defined hospital blood banks. FDA registration allows the agency to plan and perform routine cGMP inspections.

Although the FDA does not routinely inspect hospital transfusion services, these services also engage in manufacturing in the view of the FDA because compatibility testing, blood storage, labeling, and recordkeeping are considered steps in the manufacturing process. Thus, transfusion services are also subject to cGMP regulations. Inspection of hospital transfusion services is overseen by the Centers for Medicare and Medicaid Services (CMS) through a 1980 memorandum of understanding with the FDA that addresses inspection of these establishments. In an effort to reduce duplication of inspections, it was agreed that inspection of hospital transfusion services that are approved for Medicare reimbursement and that engage in compatibility testing but that neither routinely collect nor process blood components would be subject to inspection by the CMS. This agreement pertains to responsibility for inspection only. No statutory authority transferred between the agencies. As part of the agreement, the CMS adopted FDA regulations in 21 CFR Part 606 titled "Current Good Manufacturing Practice for Blood and Blood Components" and 21 CFR Part 640 titled "Additional Standards for Human Blood and Blood Products." These are the FDA requirements that have been incorporated into the CLIA regulations. Observations made by the CMS may be communicated to the FDA, which has the authority to directly inspect a hospital transfusion service if deemed necessary.

All transfusion services, registered or unregistered and regardless of FDA nomenclature, must also comply with the regulations in 42 CFR Part 493 in accord with CLIA 1988. For the purposes of CLIA certification, CMS retains responsibility for inspection of all transfusion services.

Many transfusion services may not be surveyed directly by the CMS. Some are in an exempt state or have been accredited by an organization that has been granted deemed status (discussed in the subsections below on AABB, the Joint Commission, and CAP).

### FDA and transfusion service error reporting

Both registered and unregistered blood establishments, including transfusion services, must report errors and accidents in manufacturing to the FDA. As defined in 21 CFR 600.3(u), manufacture means "all steps in propagation or manufacture and preparation of products and includes but is not limited to filling, testing, labeling, packaging, and storage by the manufacturer." The term includes packaging, labeling, repackaging, or otherwise changing the container, wrapper, or labeling of any blood product package in furtherance of the distribution of the blood product from the original place of manufacture to the person who makes final delivery or sale to the ultimate consumer (21 CFR 607.3(d)). Errors and accidents (termed biologic product deviations) and unexpected events in manufacturing that can affect the safety, purity, and potency of a product are deemed reportable (21 CFR 606.171 and 21 CFR 600.14). Form FDA 3486 is used for reporting these deviations. The requirement to report applies only to manufacturing errors and not to transfusion errors occurring in clinical areas outside of the transfusion service.

The deviation or unexpected event must occur in the facility or another facility under contract with the controlling facility. If a facility under contract to the hospital blood bank or transfusion service is responsible for a deviation, the hospital blood bank or

transfusion service is responsible for reporting the problem if the product is distributed. The contract facility must perform an investigation but is not required to report. For example, if a test laboratory under contract to a hospital blood bank fails to provide viral marker testing and the unit is subsequently distributed, the blood bank must report this. If a transfusion service discovers that a unit is mislabeled with an extended outdate, the transfusion service must notify the blood center responsible for reporting to the FDA. The transfusion service would report this incident only if it further distributed the unit without correcting the label.

Deviations and unexpected events occurring within the facility or a facility under contract must be reported if they may affect the safety, purity, or potency of either licensed or unlicensed products that have been distributed. However, as noted, an error occurring after a product has left the facility need not be reported. Examples of events that would not require a report include a unit not being held at the appropriate temperature before transfusion after release from the blood bank, transfusion of a unit to the wrong patient, or failure by hospital staff to use a filter issued by the transfusion service. Reportable, unexpected events may occur even if all established procedures are followed within the transfusion service itself. An example of this would be a patient sample used for compatibility testing that was collected from the wrong patient.

### FDA and defective product reporting

If the transfusion service determines that the transfused blood or blood component was at fault in causing the adverse event, a summary of the transfusion services' investigation and conclusions must be sent to the manufacturer or blood collection establishment, who must then maintain such copies (21 CFR 606.170(a)).

### AABB

The AABB assessment incorporates evaluation of the quality system at an institution and of each operational system. The quality system assessment is based on the same criteria for every facility. The operational systems, however, are identified by the activities performed within an individual facility. This voluntary assessment is conducted every two years. AABB Standards for Blood Banks and Transfusion Services apply equally to member blood establishment. AABB policy includes the provision that although some requirements are based on the FDA's regulations, a committee with international expertise can review requests for variance from facilities both in and outside the United States that involve a departure from US regulations.

In May 2014, AABB was granted deemed status for CLIA to meet CMS requirements. This status means that the CMS has determined that the AABB accreditation process provides assurance that facilities meet or exceed conditions required by federal law and regulations. A laboratory accredited by the AABB that designated AABB as its CLIA provider does not need to be inspected routinely by the CMS. However, these facilities are subject to validation surveys and surveys performed in response to complaints to the CMS or state agencies on behalf of the CMS. This deemed status applies to the following AABB Standards: Blood Banks and Transfusion Services; Cellular Therapy Services; Immunohematology Reference Laboratories; and Molecular Testing for Red Cell, Platelet, and Neutrophil Antigens.

The AABB works with CAP to coordinate the AABB assessment and CAP inspection at the same time if the institution falls under both AABB and CAP, but the activities are still separate and each organization makes their own determination of accreditation.

AABB does not work with the Joint Commission in the area of accreditation. Many hospital transfusion services, especially if they are in smaller hospitals, are not members of AABB, but nearly all fall under the Joint Commission.<sup>13</sup>

### The Joint Commission

Founded in 1951, the Joint Commission (TJC) is a global driver of quality improvement and patient safety in health care. It is the oldest and largest standards setting and accrediting body in health care in the United States. Since 1961, review of blood use has been an element of the accreditation process of the Joint Commission which is voluntary but widely used. By 1970, the Joint Commission required review not only of blood utilization but also of transfusion reactions. The 1986 Standards were more comprehensive, mandating review of transfusion policies and procedures, ordering practices, and adequacy of the transfusion service generally. The standards also required evaluation of all transfusions. After repeated blood utilization reviews consistently documented appropriate blood use, sampling became acceptable. Although only a minority of hospitals complied with this requirement for 100% evaluation, this standard was nevertheless the driving force behind blood utilization review in the United States.

Since 1991, the Joint Commission has made a series of modifications to this standard, and 100% review is no longer required. The actual number of transfusions to be reviewed is not mandated, although recommendations are provided. Additionally, as part of an effort to reduce medical errors, the Joint Commission has developed National Patient Safety Goals; the number one goal is to "improve the accuracy of patient identification." Although this safety goal was implemented because of the recognition that patient misidentification affects all aspects of medical care, its relevance to transfusion therapy was clearly recognized by the Joint Commission. One of the implementation expectations for the goal clearly states that "Two patient identifiers are used when administering medications or blood products" and "when collecting blood samples . . . for clinical testing."<sup>13</sup> There are also explicit statements that specimens collected from a patient must be labeled at the bedside and that the patient's location may not be used as an identifier. The patient safety goal is reiterated in the body of the standards themselves.

The Joint Commission views transfusion services from a dual perspective. Standards are devoted both to the entire process of blood transfusion from blood ordering through infusion and to the laboratory procedures and practices. Two accreditation manuals have standards regarding blood transfusion. The *Comprehensive Accreditation Manual for Hospitals* provides specific standards for hospitals that transfuse and monitor blood components. The *Comprehensive Accreditation Manual for Pathology and Clinical Laboratory Services* contains technical standards that are patterned after the CLIA 1988 requirements and AABB standards. This dual approach provides the Joint Commission with the opportunity to assess the entire spectrum of clinical and laboratory blood transfusion practices. The Joint Commission Laboratory Accreditation Program has deemed status for CLIA to meet CMS requirements.

Standards related to blood transfusion are included in the *Comprehensive Accreditation Manual for Hospitals* in those sections addressing the medical staff, provision of care, treatment and services, management of information, improvement of organization performance, environment of care, and sentinel event review. Among the salient standards, MS 3.10 states that the medical staff must have "a leadership role in hospital performance improvement activities to improve quality of care."<sup>13</sup> One of the specific elements

of performance for MS 3.10 requires that the medical staff be “actively involved in measurement, assessment and improvement in the use of blood and blood components.”<sup>13</sup> A similar provision, PI 1.10 in the section on performance improvement, states that the hospital must “collect data to monitor its performance,” and this requirement includes collecting data on blood and blood product use. PI 2.20 requires that “undesirable patterns and trends in performance are analyzed,” including all confirmed transfusion reactions.<sup>13</sup> In addition, hemolytic transfusion reactions involving the administration of blood having major blood group incompatibilities are identified as reviewable sentinel events subject to specific review by the Joint Commission.

The *Comprehensive Manual for Laboratory and Point of Care Testing* contains more specific provisions governing transfusion services. HR 1.15 requires that the director of the blood bank must be a physician, either a pathologist or other physician qualified in immunohematology and hemotherapy. Sections QC 5.10 through QC 5.260 provide guidance on what the Joint Commission regards as critical elements comprising an acceptable transfusion service. Section QC 5.10 requires that the transfusion services have written policies and procedures that “are acceptable in format, content, review process and availability.” These policies and procedures must be consistent with AABB standards and must be reviewed annually. There must also be policies and procedures governing transfusion reactions and adverse events. Every adverse event must be evaluated by the medical director and documented in the patient’s medical record.

### College of American Pathologists

CAP has an established accreditation program for transfusion services. This program examines preanalytical, analytical, and postanalytical aspects of quality management in the laboratory. These include the performance and monitoring of general quality control, test methodologies and specifications, reagents, controls and media, equipment, specimen handling, test reporting and internal performance assessment, and external proficiency testing. In addition, personnel requirements, safety, document management, and other administrative practices are included in the inspection process. The CAP laboratory accreditation program expects a participant laboratory to demonstrate that it is in compliance with the CAP standards for laboratory accreditation. These standards relate to requirements for laboratory direction, physical facilities and safety, quality control and performance improvement, and inspection. Assessment of whether a laboratory meets the standards is accomplished through a series of checklists. Any applicable question that cannot be answered “yes” is considered a deficiency and must be corrected within 30 days with the submission of supporting documentation for accreditation to be achieved. The inspector does not grant or deny accreditation but makes a recommendation for the outcome. The accreditation decision is made by the CAP Accreditation Committee. In addition to the on-site inspection program, the CAP laboratory accreditation program monitors the proficiency testing performance of its participant laboratories. The CAP has deemed status with the Joint Commission and for CLIA to meet CMS requirements. As requested, CAP assesses hospital blood banks and transfusion services as well as blood collection establishments every two years.

Inspection of transfusion services is not limited to the contents of the Transfusion Medicine Checklist but includes the All Common Checklist (COM) and all applicable portions of the Laboratory General Checklist (GEN). All sections of the laboratory must be familiar with and in compliance with the requirements of the COM

and GEN Checklists. The Transfusion Medicine checklist contains the following: “Note: Many of the requirements in this Checklist reflect United States regulatory requirements, particularly those of the US Food and Drug Administration (FDA). These requirements may not be applicable in other countries for purposes of CAP accreditation.”<sup>14</sup>

### Transfusion Medicine Committee

A clinical staff committee concerned exclusively with practices and policies related to transfusion and the transfusion service is not mandated by federal regulation, the Joint Commission, or other accreditation entities. However, it has become routine to have such a committee in most hospitals because a standing transfusion committee is an efficient way of meeting QA and peer review requirements. In fact, one of this committee’s principal activities in many institutions has been the utilization review of transfusion: both over transfusion and under transfusion. Assessment of transfusion practices has the potential to enhance the knowledge and judgment of health-care professionals; provide significant information about patient care; reduce the risk of litigation; decrease costs; ensure compliance with regulatory and accreditation requirements; conserve the blood supply; provide an opportunity to demonstrate quality and value to the public; and help create, sustain, and document excellence in patient care. Many committees have also been engaged in developing informed consent practices for transfusion as well as policies related to “lookback” to find patients who may have previously been infected by a blood transfusion at the committee’s institution.

This committee typically reports to the health-care evaluation office or committee, or directly to the medical policy committee of the institution.

### Conclusion: US structure

FDA and the voluntary accrediting agencies seek to advance and protect public health. Federal regulations that carry the force of law, federal guidance documents that contain nonbinding recommendations, and voluntary accreditation standards issued by the organizations addressed in this chapter are the instruments used to achieve these goals. Blood donor qualification and the collection of blood and blood components as well as their processing, storage, transport, and subsequent manufacturing at hospital transfusion services and plasma manufacturing facilities are FDA-regulated activities to which certain biologic and drug laws apply.

The regulations, guidance documents, and standards are crafted so that compliance by the affected institutions is feasible while providing the greatest protection possible to blood donors and patients.

### International perspective on ensuring blood and blood product safety and availability

From a global perspective, WHO, the European Union (EU), the Council of Europe (CoE), and the FDA are the most prominent organizations that develop guidance documents, regulations, directives, and standards, used nationally or internationally to ensure the quality, safety, efficacy, and availability of blood and blood products. Although these organizations do not codevelop their regulations, they do collaborate on common initiatives, comment on each other’s public documents, and exchange ideas, all of which promote a general convergence of their regulatory and advisory activities. The information and standards that these organizations provide are employed by many developed and developing

countries to establish their own national blood programs. International trade associations, patient and professional organizations, and professional societies also contribute to global blood and blood product safety. This section describes the international programs and the organizational structures related to the regulation and/or accreditation of blood establishments and cite other major international organizations that advance global blood and blood product safety and availability.

### **WHO programs for blood and blood component transfusion safety**

WHO is the authority within the UN system that is responsible for the coordination of health policy. It has a mandate for “providing leadership on global health matters, shaping the health research agenda, setting norms and standards, articulating evidence-based policy options, providing technical support to countries and monitoring and assessing health trends.”<sup>15</sup> WHO is in the forefront of providing guidance for safe blood collection and transfusion. “The objective of the WHO program on Blood Transfusion Safety is to ensure provision of universal access to safe, quality and efficacious blood and blood products for transfusion, their safe and appropriate use, and also ensuring blood donor and patient safety.”<sup>16</sup>

WHO has a 50-year history of involvement in improving blood safety and availability. In 1975, a World Health Assembly resolution urged member states to promote the development of national blood transfusion services based on voluntary nonremunerated blood donations and to take other actions to promote and protect the health of blood donors and recipients of blood and blood products. These objectives are further elaborated in WHO’s strategic directions for 2008–2015 to build a conducive political, social, and economic environment for the effective integration of sustainable national blood programs in health systems; respond to country needs to enhance national blood programs and improve clinical transfusion practice; build effective collaboration and partnerships for coordinated action; and strengthen systems for assessing, surveillance, alerting, monitoring, and evaluating.<sup>17</sup>

WHO has developed an extensive program to promote access to safe blood transfusion products, particularly to address the needs of less developed and transitional countries. This includes giving advice on improving blood systems by establishing a national blood system recognized through a national blood policy. Functions of the national blood system should include “policy formulation and standard setting, strategic and operational planning, provision of sufficient resources and national coordination and management to ensure an adequate supply of blood and blood products and safe clinical transfusion.”<sup>17</sup>

WHO recommends the implementation of a quality system that provides a framework within which activities are established, performed in a quality-focused way, and continuously monitored to improve outcomes. The risk associated with blood transfusion can be significantly reduced through the introduction of quality systems, external quality assessment, and education and training for staff.

Other programs supported by WHO include voluntary blood donation, donation testing, blood processing, proper clinical use of blood transfusion products, and hemovigilance.

### **Implementation of WHO programs for access to safe blood transfusion**

WHO has established a number of collaborations and partnerships to share knowledge, coordinate technical support to increase blood donations, support blood system strengthening, and promote universal

access to blood transfusion. One means that WHO uses to coordinate activities related to blood is through the work of WHO Collaborating Centers (WCCs) on Blood Transfusion Safety and Blood Products, whose members currently (2014) include Iran, Thailand, the United Kingdom, China, Slovenia, Brazil, Tunisia, and Germany.

Another WHO partnership is through the WHO Global Safety Network comprised of members of the WHO Expert Advisory Panel on Blood Transfusion Medicine, the WCCs on Blood Transfusion, nongovernmental officials in official relations, key developmental and implementing partners for blood safety, WHO regional focal points for blood safety, and WHO Blood Transfusion Safety staff. This group shares information from the WCCs and develops mechanisms of working together to enhance WHO strategies and objectives in the area of blood transfusion safety.

In 1998, WHO established a Global Data Base on Blood Safety to address global concerns about the availability, safety, and accessibility of blood for transfusion. The database reports the number of blood transfusions and donations in countries throughout the world and provides information that can be used to assess where deficiencies lay and identify where progress is being made. A fact sheet from June 2020 provides examples of the information contained in this database.<sup>18</sup>

Of the 118.5 million blood donations collected globally, 40% of these are collected in high-income countries, home to 16% of the world’s population.

In low-income countries, up to 54 % of blood transfusions are given to children under five years of age; whereas in high-income countries, the most frequently transfused patient group is over 60 years of age, accounting for up to 75% of all transfusions.

Based on samples of 1000 people, the blood donation rate is 31.5 donations in high-income countries, 15.9 donations in upper-middle-income countries, 6.8 donations in lower-middle-income countries, and 5.0 donations in low-income countries.

An increase of 7.8 million blood donations from voluntary unpaid donors has been reported from 2013 to 2018. In total, 79 countries collect over 90% of their blood supply from voluntary unpaid blood donors; however, 56 countries collect more than 50% of their blood supply from family/replacement or paid donors.

Only 55 of 171 reporting countries produce plasma-derived medicinal products (PDMP) through the fractionation of plasma collected in the reporting country. A total of 90 countries reported that all PDMP are imported, 16 countries reported that no PDMP were used during the reporting period, and 10 countries did not respond to the question.

### **WHO QA and safety programs for blood products and related biologicals**

In addition to programs focused on ensuring safe blood components for transfusion, WHO has an interest in providing technical guidance and QA tools to regulatory authorities, national control laboratories, and manufacturers to support implementation of quality and safety systems for the production and control of blood products and related in vitro diagnostic devices worldwide. Input for the development of these tools is provided by technical experts from academia, industry, national regulatory authorities, professional societies, and WHO’s Collaborating Centers for Biological Standards and Standardization (i.e., the National Institute of Biological Standards and Control [NIBSC], United Kingdom; the Paul Ehrlich Institute [PEI], Germany; and the Center for Biologics Evaluation and Research [CBER], Food and Drug Administration [FDA], United States).

As an example of these resources, WHO has issued a document entitled *Assessment Criteria for National Blood Regulatory Systems* to assist “capacity building of national regulatory authorities for the regulation of blood and blood products. The document is intended to help Member States identify gaps and priorities when developing capacity building programs, and to support the introduction of regulation of blood products.” This document outlines “elements and functions which may support the creation of an appropriate blood regulatory system where none exists so far, and which may also be used as a tool to assess strengths and gaps of established systems.” It “identifies the essential elements and core regulatory functions that should be present in an effective national regulatory authority to assure the quality, safety and efficacy of blood and blood products, as well as associated substances and medical devices including in vitro diagnostics.”<sup>19</sup>

In addition to this document, WHO has produced a series of technical reports that give guidance on topics such as GMPs for blood establishments; recommendations for the production, control, and regulation of human plasma for fractionation; and guidelines on viral inactivation and removal procedures intended to ensure the viral safety of human blood plasma products.

#### **Major WHO advisory groups relevant to blood product safety, quality, and standardization**

The Expert Committee on Biological Standardization (ECBS) and the WHO Blood Regulators Network (BRN) are two advisory groups associated with WHO whose work directly promotes blood product safety and quality.<sup>19,20</sup>

ECBS was established in 1947 to provide detailed recommendations and guidelines for the manufacturing, licensing, and control of blood products and related in vitro diagnostic tests, biotechnology products, and vaccines along with the establishment of WHO Biological Reference Materials. The ECBS meets annually and reports directly to the Executive Board, the executive arm of the World Health Assembly.

Members of the ECBS are scientists from National Regulatory Agencies, academia, research institutes, and public health bodies. The decisions and recommendation of the committee are based entirely on scientific principles and considerations of public health.

Written guidelines and recommendations submitted to the ECBS are drafted through a consultative process during which WHO brings together experts from around the world on a given topic. Written guidelines and recommendations describe procedures for the manufacture and quality control testing of biological medicinal products to ensure safe and effective products. Guidelines provide more general information on a range of topics of interest to National Regulatory Authorities (NRAs) and manufacturers, whereas recommendations establish the technical specifications for manufacturing and quality control of specific products. By adopting these guidance documents in their pharmacopoeias or equivalent legislation, national governments ensure that the products produced and used in their country conform to current international standards. Regulatory guidance documents also advise NRAs and manufacturers on the control of biological products, with the aim of establishing a harmonized regulatory framework for products moving in international markets.

In addition to guidelines and recommendations, WHO has played a key role for over 50 years in establishing the WHO

Biological Reference Materials necessary to standardize biological materials. Reference materials are required to standardize potency, purity, and identity measurements for complex biological materials. “The WHO Biological Reference Materials provide a global standard against which experimental values can be compared and expressed, thereby allowing direct comparisons between products and measurements across different methodologies and assays in use around the world.”<sup>20</sup> Reference materials are established through scientific studies involving participation of a large number of laboratories worldwide.

The proceedings of the meetings of the ECBS are published in the WHO Technical Report Series (TRS). They provide information on the establishment, discontinuation, and replacement of the WHO Biological Reference Materials as well as on the adoption of Guidelines and Recommendations. The TRS are available electronically as well as publications, and relevant topics can be searched either by the TRS number or by topic.

The WHO Blood Regulators Network (BRN) is a group whose work helps to ensure blood product safety in a timely manner. BRN was established in 2006 and is composed of leading international regulatory authorities that have responsibility for the regulation of blood, blood products, and related in vitro diagnostic (IVD) devices.

Members of the BRN exchange information and opinion on blood-related issues. The BRN focuses on scientific assessment of current and emerging threats to the safety and availability of blood and blood products, assesses the impact of new blood-related technologies, and also explores opportunities for regulatory cooperation and collaboration, where possible.

Member organizations have legal standing and well-established, demonstrated institutional capacity to regulate blood and blood products, and the necessary expertise to address emerging global public health challenges.

BRN recommendations and considerations are communicated to the ECBS through WHO. Documents published by the BRN contain the collective views of members and do not necessarily represent the decisions or the stated policy of WHO or of the participating regulatory authorities.

Examples of the work of BRN are the publications *Position Paper on Collection and Use of Convalescent Plasma or Serum as an Element in Filovirus Outbreak Response* and *Potential for Use of Convalescent Plasma in Management of Ebola*. These documents were published in August and September 2014, respectively, and demonstrate BRN’s ability to respond quickly to emerging threats to the blood supply.

#### **Regulation of and guidance on blood products in Europe**

The regulation of blood components for transfusion, and blood plasma derivatives and analogous recombinant analogs, in Europe is complex because of historical considerations and the balance that is needed between the role of a centralized authority and the involvement of the many independent member states that have their own medicines regulatory authorities. The functionality of the system depends on the exchange of information among the member states and their acceptance of common standards and practices. The standards, guidance documents, and authorized medicines produced within the European framework stretch beyond its borders and have been adopted in many other parts of the world.

Organizations involved in European regulatory processes include the following (see Figure 8.1).

### The European Union and associated organizations

**European Union:** The European Union was founded in 1948 to promote stability and economic cooperation among member states. It consists of 27 member states and operates through a system of supranational independent institutions and intergovernmental negotiated decisions by EU Member States. The European Union has developed a single market through a standardized system of laws, and the same rules and harmonized procedures apply to all the 27 Member States regarding the authorization of medicines and the supervision of the safety of medicines.

**European Commission:** This executive arm of the European Union proposes legislation, sets objectives and priorities, and grants centralized marketing authorization.

**European Economic Area (EEA):** This includes the European Union plus Norway, Iceland, and Liechtenstein.

**European Medicines Agency (EMA):** The agency within the European Union is responsible for the scientific evaluation of applications for marketing authorizations for human and veterinary medicines in the centralized procedure. Its main responsibility is the protection and promotion of public and animal health through the evaluation and supervision of medicines for human and veterinary use.

**Committee for Medicinal Products for Human Use (CHMP):** The committee at the EMA that is responsible for preparing opinions on questions concerning medicines for human use. The members and alternates of the CHMP are nominated by EU member states in consultation with the Agency's Management Board. They are cho-

sen on the strength of their qualifications and expertise with regard to the evaluation of medicines.

### Council of Europe and associated organizations

The Council of Europe (CoE) is an international organization founded in the wake of World War II to uphold human rights, democracy, and the rule of law in Europe.<sup>21</sup> It has 47 member states.<sup>22</sup> The organization is distinct from the 27-nation European Union (EU), although it is sometimes confused with it, partly because the EU has adopted the original European Flag that was created by the Council of Europe in 1955, as well as the European Anthem. No country has ever joined the EU without first belonging to the Council of Europe. The Council of Europe is an official United Nations Observer. The CoE regularly reviews and updates technical requirements in its Guide to the Preparation, Use and Quality Assurance of Blood Components and Good Practice Guidelines for blood establishments. In addition, it prepares ad hoc guidelines on different topics, in regard to the safety and quality, including a Directive last amended in 2004 that sets requirements for blood collection and processing. The Council of Europe cannot make binding laws, but it does have the power to enforce select international agreements reached by European states on various topics. Organizations associated with the COE are briefly described below.

**European Directorate for the Quality of Medicines (EDQM):** The EDQM is a Directorate of the CoE. Its mission is to establish and provide official standards that apply to the manufacture and quality control of medicines to member states of the CoE. As it specifically relates to blood, it serves to propose ethical, safety, and quality standards for blood transfusions, including the collection, preparation, storage, distributions, and appropriate use of blood components.

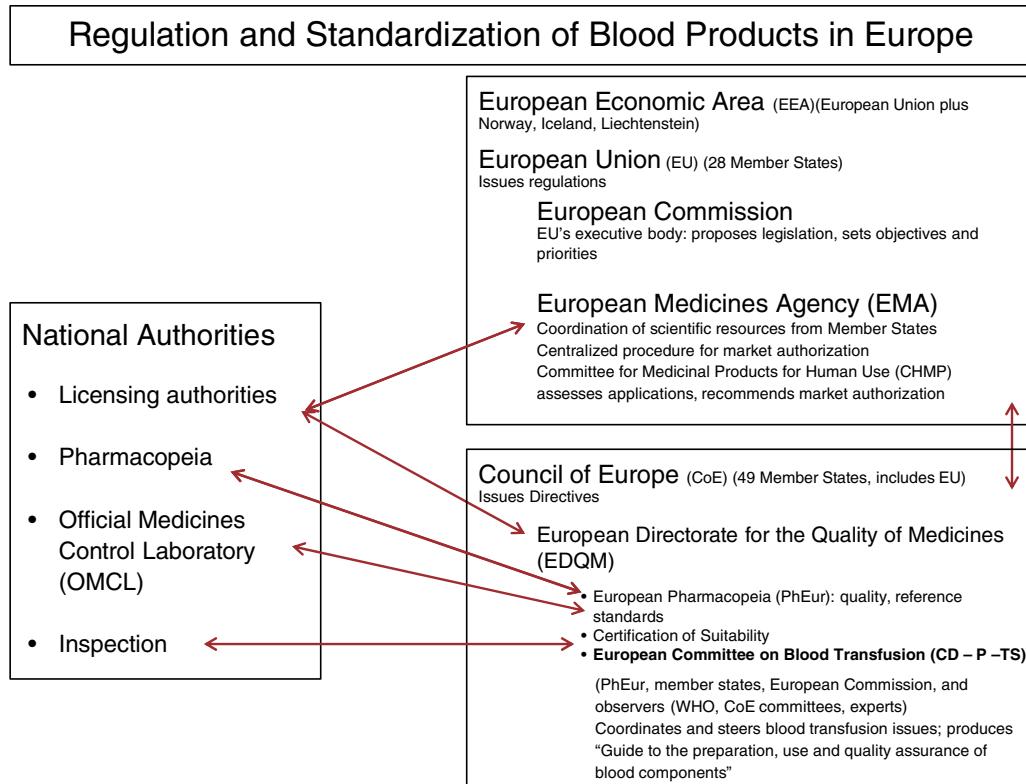

Figure 8.1 Regulation and standardization of blood product in Europe.

**European Pharmacopeia (PhEur):** Within the EDQM, the PhEur sets common standards for all the national pharmacopoeias of the member states. It provides standardization of analytical methods used for the control of substances used in medicines for human and/or veterinary use. The Expert Group 6B is the entity within the PhEur that is involved with standards for blood products. Importantly, the European Pharmacopeia standards are legally binding for member states.

**Official Medicines Control Laboratory (OMCL):** OMCLs support regulatory authorities in controlling the quality of medicinal products for human and veterinary use available on the market. Within Europe, OMCLs are nominated by the national authority responsible for the quality control of medicines in their country. OMCLs test products in the EEA, where appropriate, and are independent of manufacturers.

**European Committee on Blood Transfusion (CD-P-TS):** This coordinates and steers blood transfusion issues, and produces a publication entitled *Guide to the Preparation, Use and Quality Assurance of Blood Components*. Its members include PhEur, member states, the European Commission, and observers (WHO and CoE committees).

**European Medicines Agency (EMA):** The European Medicines Agency is an agency of the European Union in charge of the evaluation and supervision of medicinal products.

**Committee for Medicinal Products for Human Use (CHMP):** The CHMP plays a vital role in the authorization of medicines in the European Union (EU). The CHMP is responsible for:

- conducting the initial assessment of EU-wide marketing authorization applications;
- assessing modifications or extensions (“variations”) to an existing marketing authorization;
- considering the recommendations of the Agency’s Pharmacovigilance Risk Assessment Committee on the safety of medicines on the market and when necessary recommending to the European Commission changes to a medicine’s marketing authorization, or its suspension or withdrawal from the market.<sup>23</sup>

**Paul Ehrlich Institute (PEI):** German regulatory authority that has a major influence on the development of blood products in Europe and is a WCC.

## Authorization in Europe of plasma derivative and analogous recombinant products

The regulation and authorization of manufactured blood products in Europe involve an interplay among the EMA, national competent authorities (NCAs), CHMP working parties, and the EDQM that includes the PhEur and OMCLs. There are three pathways for authorizing medicines in Europe. In the “centralized” procedure, pharmaceutical companies submit a single marketing-authorization application to the EMA. For blood products, the EMA’s CHMP carries out a scientific assessment of the application and gives a recommendation on whether or not to grant a marketing authorization. Once granted by the European Commission, the centralized marketing authorization is valid in all EU member states. Most innovative medicines go through this procedure.

Most medicines are not authorized through the centralized procedure. Instead, they are authorized by NCAs in member states. When a company wants to authorize a medicine in several member states, it can use one of the following procedures:

- The decentralized procedure, through which companies can apply for the simultaneous authorization of a medicine in more than one EU member state if it has not yet been authorized in any EU country and it does not fall within the mandatory scope of the centralized procedure; or

- The mutual-recognition procedure, through which companies that have a medicine authorized in one EU member state can apply for this authorization to be recognized in other EU countries.

This process allows member states to rely on each other’s scientific assessments. Rules and requirements applicable to pharmaceuticals in the European Union are the same, irrespective of the authorization route for a medicine.

## Safety monitoring of medicines in Europe

EudraVigilance is an EU web-based information system within the EMA that collects, manages, and analyzes reports of suspected side effects of medicines, including blood. Information is obtained from EEA members, and these data are continuously monitored in order to identify any new safety information.

The EMA has a committee dedicated to the safety of medicines for human use—the Pharmacovigilance Risk Assessment Committee (PRAC). If there is a safety issue with a medicine that is authorized in more than one member state, patients and health-care professionals in all member states are given the same guidance by the committee, and the same regulatory action is taken across the European Union.

The PRAC has a broad remit covering all aspects of pharmacovigilance. In addition to its role in risk assessment, the committee provides advice and recommendations to the European medicines regulatory network on risk management planning and postmarketing benefit–risk assessment for medicines.

## Activities to promote blood component safety in Europe

The CoE has been actively contributing since the 1950s to the implementation of standards for blood transfusion. In 2007, the secretariat responsible for blood transfusion activities was transferred to the EDQM. Within the EDQM, the European Committee on Blood Transfusion (CD-P-TS) is in charge of steering and coordinating the actions of the CoE in this area. The membership of CD-P-TS includes the CoE member states and parties to the Convention on the Elaboration of a European Pharmacopoeia. The European Commission, WHO, and other CoE Committees (European Public Health and Bioethics Committees) are special observers to the CD-P-TS.

Activities of the CD-P-TS include, among others, addressing issues about quality and safety standards for blood transfusion, including collection, storage, distribution, and use of blood components; improving blood transfusion services; promoting the principle of voluntary nonremunerated donations; and establishing good practices in transfusion medicine and monitoring their use in Europe. These objectives are attained by setting standards and preparing guidance on professional practices (e.g., *Guide to the Preparation, Use and Quality Assurance of Blood Components*); organizing and evaluating surveys on blood components; and using resolutions to promote continuous improvement of an ethical, organizational, and regulatory approach to blood transfusion.

## Other major international organizations involved in the regulation or standardization of blood, blood products, and their biotechnology analogs

**America’s Blood Centers/European Blood Alliance (ABC/EBA):** This works to harmonize requirements and decision-making processes to promote safe and high-quality blood products in North America and Europe.

*World Federation of Hemophilia (WFH)*: This works on issues involving hemophilia and other bleeding disorders, including supply, affordability, safety, and regulatory harmonization.

*European Hemophilia Safety Surveillance (EUVASS)*: This is a pharmacovigilance program to monitor the safety of treatments for people with inherited bleeding disorders in Europe.

*Plasma Protein Therapeutics Association (PPTA)*: This is the international trade association and standards-setting organization for the world's major producers of plasma-derived and recombinant analog therapies, collectively referred to as *plasma protein therapies*.

*International Plasma Fractionation Association (IPFA)*: This is an international association for nonprofit organizations involved in the manufacture of blood products made from blood collected from nonremunerated donors.

*International Society of Blood Transfusion (ISBT)*: The ISBT promotes research, new developments, and changing concepts in blood transfusion medicine.

### FDA role in the global regulation of blood and blood products

The activities of the FDA have a large impact on the global regulation of blood and blood products. FDA's international standing is bolstered by the substantial medical and scientific resources that it devotes to ensuring the safety, efficacy, and availability of blood and blood products.

FDA is strongly supportive of harmonization efforts that will maximize national and global health. A convergence of thinking on regulatory and guidance issues is important for trade as well because many of the companies involved in blood product manufacture are international in scope; the US market for these products is extensive; and a large amount of plasma, intermediates, and manufactured products are distributed abroad.

FDA influences global regulatory and guidance norms for blood and blood product safety, through its interactions with all of the organizations cited in this chapter. For example, FDA representatives

are members of the WHO's ECBS and the BRN, have Observer status with EDQM's Expert Group 6B, and routinely communicate with the EMA and Health Canada through Blood Cluster meetings. In addition to interacting with organizations that are composed of multiple international partners, FDA has bilateral memoranda of understanding and confidentiality arrangements with a number of individual countries. All of these relationships facilitate cooperative activities and the sharing of information, which support the common goal of enhancing the global safety and availability of blood and blood products.

# **Blood groups and pretransfusion testing**

## CHAPTER 9

# Carbohydrate blood groups

Laura Cooling

Department of Pathology, University of Michigan, Ann Arbor, MI, USA

Blood group antigens of the H, ABO, Lewis, and historical “P” blood groups are defined by small carbohydrate epitopes expressed as posttranslational modifications on glycoproteins, mucins, and glycolipids. Their synthesis is complex and dependent on several distinct glycosyltransferases and interrelated biosynthetic pathways. In many cases, carbohydrate antigens share features of more than one blood group (e.g., ABO and Lewis).

### ABO system

Discovered in 1900 by Karl Landsteiner, the ABO blood group system remains the most important blood group system for blood transfusion and transplantation. ABO antigens are widely expressed on human tissues and fluids, leading to their designation as *histoblood group* antigens.<sup>1</sup> ABO antigens are differentially expressed during cellular development and can be detected as early as human embryonic stem cells.<sup>2</sup> This can be observed in bone marrow, where hematopoietic progenitor cells strongly express H-antigens (H, Le<sup>y</sup>), but not A/B antigens, which are restricted to developing erythroblasts and megakaryocytes.<sup>3,4</sup> ABO can also be detected on vascular endothelium, skin, and tissues arising from embryonic endoderm and mesoderm, including epithelial cells of the respiratory, gastrointestinal, and genitourinary tracts.<sup>1</sup>

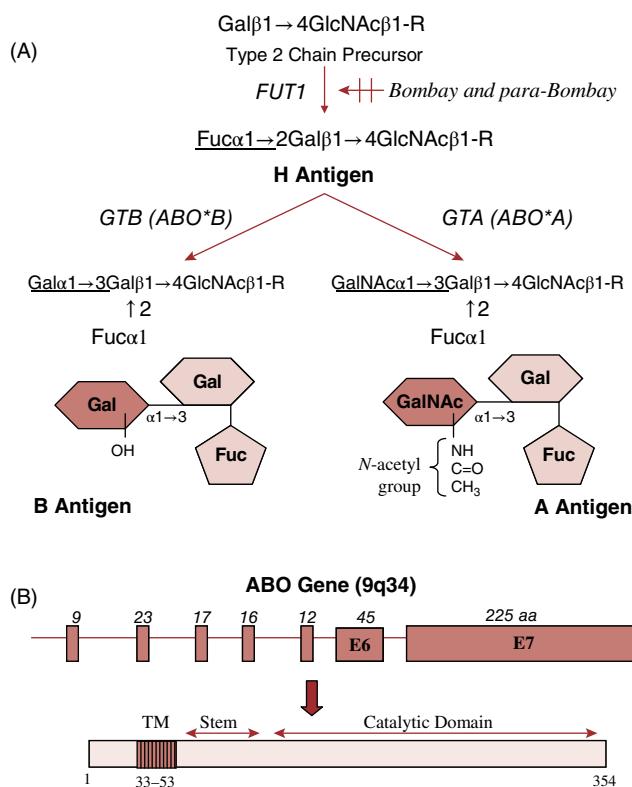

### Chemistry and biosynthesis

The ABO system (ISBT 001) contains two structurally related carbohydrate antigens, A and B. The O or H antigen is the biosynthetic precursor of A and B antigens and is listed under a separate blood group system (ISBT 018). All three antigens consist of 2–3 terminal oligosaccharides on glycoproteins and glycolipids. As shown in Figure 9.1, the minimum A-antigen epitope is a trisaccharide composed of a subterminal  $\beta$ -galactose (Gal) bearing both an  $\alpha 1 \rightarrow 2$ fucose and  $\alpha 1 \rightarrow 3$  *n*-acetylgalactosamine (GalNAc). The B antigen resembles the A antigen except for the presence of an  $\alpha 1 \rightarrow 3$ Gal. Not surprisingly, group A red cells can be converted to group B-active cells through loss of the acetyl group. Clinically, this is observed in the acquired B phenotype, in which group A patients transiently type as group B due to infection by deacetylase-producing bacteria.<sup>5</sup>

In red cells, the synthesis of H and A/B antigens proceeds in a stepwise fashion from a type 2 chain or lactosamine (Gal $\beta 1 \rightarrow 4$ GlcNAc-R) precursor (Figure 9.1). Initially, the H-enzyme, FUT1, adds an  $\alpha 1 \rightarrow 2$  fucose to the terminal galactose to make type 2 H-antigen. H-antigen can then serve as a substrate for A and B synthesis. In group A individuals, A-transferase (GTA) recognizes UDP-GalNAc to transfer an  $\alpha 1 \rightarrow 3$ GalNAc to H-antigen. Likewise, B-transferase (GTB) recognizes UDP-Gal to transfer an  $\alpha 1 \rightarrow 3$ Gal to synthesize group B antigen. Group AB, in which both A and B antigens are expressed, reflects coinheritance of GTA and GTB. The group O phenotype, on the other hand, reflects the complete absence of ABO enzyme activity due to ABO-null alleles. As a result, these individuals only express the H-antigen precursor. Because A/B expression is dependent on H-antigen synthesis, the absence of FUT1 activity due to mutations (e.g., Bombay phenotype) or transcriptional repression is also associated with absent A/B expression.

On red cells, it is estimated that 65–75% of ABH antigens are expressed as N-linked glycans on glycoproteins, especially Band 3 (Diego blood group, AE1).<sup>6</sup> At one million copies, Band 3 is the major glycoprotein on red cells and accounts for 50% of all ABH antigens.<sup>7</sup> The remaining ABH antigens are present on O-linked glycans (10%), glycosphingolipids (GSL, 5%), and polyglycosylceramides (10–15%), also known as *erythroglycans*.<sup>6</sup> The latter are massive, branched, multivalent type 2 chain glycolipids composed of 40 or more oligosaccharides and potentially 4–6 ABH epitopes.<sup>8</sup>

ABH antigens can be expressed on different oligosaccharide scaffolds, which often demonstrate developmental and tissue specificity (Table 9.1). Furthermore, the oligosaccharide backbone can influence ABH valency and spatial presentation, as well as contribute to the immune epitope. On red cells, platelets, and endothelium, ABH is primarily expressed on type 2 chain or lactosamine-based structures. Genitourinary and gastrointestinal tissues, on the other hand, are rich in type 1 chain ABH antigens.<sup>1</sup> Type 1 chains are structurally similar to type 2 chains except for linkage of the galactose residue (Gal $\beta 1 \rightarrow 3$ GlcNAc-R). In addition, the synthesis of type 1 chain H-antigen is dependent on *Secretor* or *FUT2*, a related  $\alpha 1,2$ -fucosyltransferase. Secretor-positive (Se) individuals also secrete type 1 ABH antigens in body fluids, including saliva and plasma.

**Figure 9.1** (A) Synthesis of group A and group B antigen. (B) Structure of the ABO gene and ABO glycosyltransferase.

**Table 9.1** Group A Structures in Humans

Name	Structure

Fuc, fucose; Gal, galactose; GalNAc, *n*-acetylgalactosamine; Glc, glucose; GlcNAc, *n*-acetylglucosamine; GlcCer, glucosylceramide or Glcβ1-1Ceramide.

Type 3 and type 4 chain structures share a terminal  $\text{Gal}\beta 1 \rightarrow 3\text{GalNAc-R}$  (Table 9.1). Type 3 chain A, also known as *mucinous A*, is a polymer of repeating A motifs. Type 4 chain ABH, or *globo-ABH*, is a GSL-specific antigen related to the GLOB blood group system (see the “P Blood Group System” section). Although both type 3 and 4 ABH antigens are found in trace amounts on red cells, their synthesis is relatively tissue-restricted to gastrointestinal and/or genitourinary epithelium.<sup>1</sup> There is evidence that both FUT1 and FUT2 are able to recognize type 3 and type 4 chain substrates;<sup>9</sup> however, it is believed that FUT2 is primarily responsible for type 3 and type 4 ABH synthesis in epithelial tissues.<sup>10</sup>

### ABH antibodies

The ABH system is unique for the presence of naturally occurring antibodies against missing ABH antigens (Table 9.2). Specifically, a group A individual will possess anti-B, whereas anti-A will be produced by group B individuals. These antibodies are not present at birth but gradually develop after 4–6 months of age, with adult titers reached by 5–10 years of age.<sup>11</sup> Bacteria in the diet and the gastrointestinal microbiome appear to be the primary immune stimulus for the development of anti-A and anti-B: many bacterial species express ABH-like structures on lipopolysaccharide that can crossreact with ABH antibodies and lectins.<sup>12</sup>

Antibodies against ABH and other carbohydrate antigens are considered to arise via a thymic-independent mechanism.<sup>13</sup> Specifically, carbohydrates presented as multivalent, repetitive epitopes can directly stimulate B-cells, independent of accessory T-cells, with the production of IgM antibodies. More recent studies in mice also implicate invariant natural killer cells (iNKTs) in ABH antibody formation.<sup>14</sup> Finally, the absence of ABH antibodies against self-antigens may occur through antigen–antibody complexes with specific deletion of antibody-producing B splenocytes.<sup>15</sup>

### Serology of the ABO system

The ABO system contains four major phenotypes, based on the inheritance of A and B antigens: A, B, AB, and O (or none).<sup>11</sup> ABO is unique among all other blood groups in that both red cells and plasma/serum testing are required (Table 9.2). The forward-type or red cell grouping is performed by directly testing red cells for the expression of A and B antigens with commercial antisera. The back-type or serum grouping involves testing plasma or serum against commercial A<sub>1</sub> and B red cells for the presence of anti-A and anti-B. Both the forward and back type must agree for a valid ABO phenotype.<sup>11</sup>

### Weak ABO subtypes

The ABO system contains several weak subtypes. All are characterized by decreased A/B and a parallel increase in H-antigen expression. Weak subtypes can be associated with ABO typing

**Table 9.2** ABO Serology

ABO Type	GT Genes*		RBC Grouping (Forward/Antigen Type)			Serum Grouping (Reverse/Back Type)		
	FUT1	ABO	Anti-A	Anti-B	UEA-1†	A <sub>1</sub> RBC	B RBC	O RBC
A <sub>1</sub>	+	+	++	0	0	0	+	0
A <sub>2</sub>	+	+	+	0	+	+/0	+	0
B	+	+	0	++	0	+	0	0
O	+	0	0	0	++	+	+	0
O <sub>1</sub> (Bombay) (hh)	0	+	0	0	0	+	+	+

\* Inheritance of at least one functional FUT1 or ABO gene.

† Testing for H-antigen with lectin *Ulex europeus* (UEA-1). Not routinely performed except to resolve ABO typing discrepancies.

discrepancies during serum grouping due to the presence of unexpected anti-A or anti-B activity. In some instances, A/B expression is so weak that red cells can forward type as group O.

The most common ABO subtype encountered is A<sub>2</sub>, which occurs in 20% of group A donors in the United States and Europe. A<sub>2</sub> red cells have 75% less A antigen than A<sub>1</sub> cells and can possess an anti-A.<sub>1</sub> Because of the inefficiency of the A<sub>2</sub>-glycosyltransferase (GTA), A<sub>2</sub> red cells also differ in the type of A antigen synthesized. Specifically, A<sub>2</sub> red cells lack globo-A.<sup>16</sup> These differences are more pronounced in other tissues such as platelets and endothelium, where there is little or no A-antigen.<sup>17,18</sup> Studies in A<sub>weak</sub> subtypes confirm a profound decrease in the array and complexity of A-antigens synthesized with weak GTA activity.<sup>19</sup> A<sub>2</sub> and A<sub>weak</sub> red cell subtypes are serologically distinguished from A<sub>1</sub> red cells by their lack of reactivity with the lectin *Dolichos bifloris* (DBA).<sup>11</sup> Weak A/B subtypes have increased reactivity with *Ulex europeaus* (UEA), an anti-H lectin.

### Bombay and para-Bombay

Bombay and *para*-Bombay are autosomal-recessive, H-deficient phenotypes due to homozygous inheritance of amorph *FUT1* alleles (*hh*). As a result, these individuals are unable to synthesize type 2H antigen, the precursor of A and B antigens. Serologically, red cells are negative for H, A, and B antigens, accompanied by the presence of naturally occurring anti-A, anti-B, and anti-H in plasma. In routine testing, these individuals may initially type as an apparent group O but will have a strong positive antibody screen due to allo-anti-H, which recognizes group O screening cells.

The Bombay and *para*-Bombay phenotypes are distinguished by the presence or absence of soluble type 1 ABH substance, which is under the control of *FUT2/Secretor*. The classic Bombay phenotype is an H-deficient nonsecretor (*hh, se/se*), with an absence of both type 1 and type 2 chain ABH antigens. As nonsecretors, these individuals will also type as Le(b-) (see the “Lewis Blood Group” section). In contrast, *para*-Bombay individuals are typically H-deficient secretors (*hh, Se/Se*, or *Se/se*) and retain synthesis of type 1 H antigen on mucosa and in secretions. Unlike Bombay cells, *para*-Bombay red cells may have trace amounts of ABH antigen on red cells due to adsorption of soluble type 1 ABH from plasma. There are also examples of *para*-Bombay arising from an H-deficient, weak Secretor (*hh* and *Se<sup>w</sup>/se*) as well as an H-weak nonsecretor (*H<sup>w</sup>/h* and *se/se*).<sup>20</sup>

## Molecular biology

### ABO gene

The ABO system contains two autosomal, codominant consensus alleles, A<sup>1</sup> (ABO'A1) and B (ABO'B), responsible for GTA and GTB, respectively. The active enzyme is encoded over seven exons, spread over a 19 kb region on chromosome 9q34.1.<sup>20,21</sup> This is in stark contrast to most blood-group-related glycosyltransferases (H, Secretor, Lewis, P1PK, and GLOB), in which the active enzyme is located within a single exon. Most mutations effecting ABO activity arise within exons 6 and 7, which account for 75% of the active enzyme. Exon 6, which encodes the stem region, is a hot spot for recombination. ABO'A1 is generally considered the ancestral gene, with ABO'B and ABO'O alleles arising through convergent evolution.<sup>22</sup> A more recent study, however, suggests that ABO is an ancient balanced polymorphism originating early in hominid history and maintained in multiple primate lineages.<sup>23</sup>

ABO belongs to the GT6 family of glycosyltransferases, a large family (184) of animal and bacterial α-galactose/α-galactosaminyltransferases that includes the enzymes for Forssman antigen and linear B—two histo-blood group antigens found in animals. The enzyme is a 354-amino-acid, type II transmembrane glycoprotein with a short amino-terminal cytosolic (amino acids 1–32) and transmembrane (33–53) domains, followed by a “stem region” and a large, globular catalytic domain (64–354).<sup>21</sup> The enzyme has a single N-glycan site (Asn<sup>113</sup>), five cysteines, and a DxD motif (Asp<sup>211</sup>–Val<sup>212</sup>–Asp<sup>213</sup>). DxD motifs are found in many glycosyltransferases that require Mn<sup>2+</sup> or other cations for catalysis.<sup>24</sup> Crystallography of the ABO protein shows it has a complex secondary and tertiary structure, composed of two functional domains separated by a catalytic cleft that contains the DxD motif and a highly conserved Glu<sup>303</sup>.<sup>25</sup> The H-antigen acceptor binds to the carboxyterminal half, whereas the UDP-nucleotide sugar donor binds to the more amino-terminal half of the enzyme. Initial binding of the UDP-nucleotide sugar leads to conformational changes in the enzyme necessary for H-antigen acceptor binding and catalysis.<sup>25,26</sup>

A comparison of GTA and GTB enzymes shows they are virtually identical, differing by only four amino acids at 176, 235, 266, and 268 (Table 9.3).<sup>21</sup> Using recombinant enzymes, Yamamoto *et al.* demonstrated that only three polymorphisms define whether the enzyme has GTA or GTB activity: Gly235Ser, Leu266Met, and Gly268Ala.<sup>21</sup> Because both GTA and GTB recognize and transfer a

\* Gene type refers to amino acid positions 235, 266, and 268. These three positions strongly influence substrate specificity and differ between A (AAA) and B (BBB) alleles. Amino acids that differ from the ABO'A.01 consensus allele are highlighted in bold.

<sup>†</sup> Deletion mutant (261ΔG) leading to a frameshift and premature stop codon.

sugar to H-antigen, any differences in the two proteins must reflect binding of the nucleotide sugar donor. The mechanism underlying how these three amino acids differences determine whether the enzyme will utilize UDP-Gal or UDP-GalNAc appears to be the size and geometry of the UDP-binding pocket. In general, the amino acids associated with GTA are biochemically “smaller” than those in GTB and are thus able to accommodate the larger UDP-GalNAc donor.<sup>25</sup> Evidence to support the latter includes crystallography studies, where Leu<sup>266</sup> in GTA directly interacts with the GalNAc acetoamido group, whereas no binding or interaction is observed with Met<sup>266</sup>.<sup>25</sup> The adjacent Gly268Ala polymorphism is also believed to be critical for UDP-donor preference,<sup>21</sup> however, this has been challenged. Crystallographic data show both Ala<sup>268</sup> and Gly<sup>268</sup> interacting with galactose hydroxyl groups of the H-antigen acceptor regardless of UDP-donor specificity.<sup>25</sup> Other amino acids interacting with the H-antigen acceptor include Tyr<sup>126</sup>, Glu<sup>303</sup>, and amino acids 233–245, which includes the Gly235Ser polymorphism. The DxD motif near the nucleotide binding pocket binds Mn<sup>2+</sup>, which helps coordinate the UDP-phosphate group.<sup>25</sup>

Mutations in *ABO* are responsible for weak ABO phenotypes. To date, over 100 *ABO* weak alleles have been identified.<sup>20</sup> Most weak alleles possess missense mutations affecting enzyme activity; however, mutations affecting transcription, mRNA processing, translation, and Golgi trafficking are also known.<sup>20,27–30</sup> The most common mutant allele is *ABO'A2.01* associated with the A<sub>2</sub> phenotype.<sup>20</sup> *ABO'A2.01* has a single nucleotide deletion (1061ΔC) near the carboxy terminus that leads to a frameshift and translation of an additional 20 amino acids. Some alleles contain mutations within or proximal to the DxD motif (Val212Met, Met214Arg, and Phe216Ile) and highly conserved Glu<sup>303</sup> (Asp302Gly). A few alleles contain mutations affecting amino acids directly interacting with the H-antigen acceptor (amino acids 233–245: Arg241Trp), including mutations at amino acid 268 (*ABO'AW.08*; Table 9.3). *ABO'AW.08* is a common cause of ABO discrepancies due to extremely weak GTA activity.<sup>31</sup>

The ABO system also contains hybrid *ABO* alleles able to synthesize both A and B antigens. The *cisAB* phenotype was initially identified following apparent anomalous inheritance of both A and B antigens. These individuals typically type as A<sub>2</sub>B with unusually weak B expression, often accompanied by an allo-anti-B.<sup>32</sup> For many years, it was assumed that *cisAB* was the result of unequal crossover events, leading to a hybrid A–B gene. It is now clear that *cisAB* is a consequence of polymorphisms at or near key amino acids (234, 235, 266, and 268) necessary for UDP-donor and H-antigen acceptor binding.<sup>20,21</sup> As shown in Table 9.3, *cisAB* alleles share features of both GTA and GTB enzymes. Similar features are observed in *ABO'BA* alleles responsible for the B(A) phenotype. The B(A) phenotype is observed in rare group B individuals who have small amounts of A antigen when tested with certain anti-A monoclonal antibodies.

Group O, on the other hand, is an autosomal-recessive phenotype due to inheritance of amorph *ABO* alleles. There are several group *ABO'O* alleles documented, but most can be classified as belonging to either the O<sup>1</sup> (*ABO'O.01*) or O<sup>2</sup> (*ABO'O.02, O03*) families (Table 9.3).<sup>20</sup> O<sup>1</sup> accounts for 95% of group O alleles and is characterized by a nucleotide deletion (261ΔG, fs88stop118), leading to a nonfunctional truncated protein. O<sup>2</sup> alleles share a missense mutation at amino acid 268 (Arg<sup>268</sup>), which profoundly impacts enzyme activity. As noted, this same mutation is present in two weak A and B alleles. In general, heterozygous inheritance of an *ABO'O* allele (ex. A<sup>1</sup>/O) does not impact expression on red cells but may be associated with weaker ABO expression on other tissues.<sup>33</sup>

Given the complexity and number of allelic variants, molecular typing is not used for routine donor or recipient ABO typing. Molecular testing is used, however, in genome-wide association (GWA) testing. For these studies, 3–4 single nucleotide polymorphisms (SNPs) are used as a surrogate for ABO typing (Table 9.3). The most common SNPs cover the three amino acid polymorphisms that distinguish GTA from GTB (235, 266 and 268) plus the O<sup>1</sup> allele (261ΔG). Any O<sup>2</sup> alleles should also be identified using this scheme. SNP rs8176704 is sometimes added to screen for the common A<sub>2</sub> allele.

Finally, *ABO* mRNA expression shows evidence of tissue-specific regulation.<sup>34</sup> Like many genes, the *ABO* 5' UTR is CpG rich (82%) and is highly susceptible to transcriptional regulation by methylation.<sup>35</sup> In fact, the loss of A/B expression in leukemia patients is frequently attributed to hypermethylation of the *ABO* promoter region.<sup>36</sup> Methylation patterns are heterogeneous between different tissues; however, the methylation of the core proximal promoter region (-117 to +31) strongly suppresses *ABO* transcription in both epithelial and erythroid cell lines.<sup>34,35</sup> A second CpG island is located over intron 6 and exon 7.<sup>34</sup>

The CpG-rich, proximal promoter contains sites for SP1, which is required for transcription, as well as other transcription factors.<sup>34,37</sup> Mutations affecting the Sp1 site lead to decreased transcription in all cell lines.<sup>34</sup> In erythroid cells, transcription is significantly enhanced by GATA and RUNX1 sites located within intron 1 (+5.8 kb site).<sup>30,34</sup> The weak B<sup>m</sup> phenotype has been associated with mutations within this 5.8 kb site. Likewise, RUNX1 mutations may lead to weakened ABO expression in myeloid leukemia patients.<sup>34</sup> An N-box containing a Hes-1 site is adjacent to the proximal promoter region and is reported to repress ABO expression.<sup>38</sup>

Binding by Sp1 and RUNX1 appears necessary for transcription in erythroid cells but not in other tissues. In epithelial cells, ABO transcription is dependent on Sp1 and ELF5, which is located downstream of exon 7 (+22.6 kb site).<sup>34</sup> This can lead to discrepant expression of ABO on red cells and secreted molecules. For example, the B<sup>m</sup> phenotype has extremely weak B expression on red cells but normal levels of B antigen in secretions. Finally, a CBF/NF-Y minisatellite enhancer region composed of 1–4 copies of a 43-bp sequence is located nearly 4 kb upstream of the translation start site (-3650 to -3931).<sup>39</sup> In some tissues, there is a correlation between the number of tandem repeats, ABO type, and transcriptional activity.<sup>29,39</sup> There is conflicting evidence as to whether this enhancer region plays a role in red cell ABO expression.<sup>34</sup>

## H gene

The *H* gene or *FUT1* resides on chromosome 19q13 in conjunction with the *Secretor* gene and *Sec1*, a pseudogene.<sup>20</sup> *FUT1* contains four exons with the active enzyme located within exon 4. *FUT1* is highly specific for type 2 chain polylactosamine substrates and is solely responsible for H antigen synthesis on red cells.<sup>40</sup> In hematopoietic lines, *FUT1* is expressed by stem cells and erythroid-megakaryocytic progenitors but is classically absent from lymphoid and myeloid cells.<sup>3,41</sup> *FUT1* mRNA is commonly expressed in epithelial tissues and other tissues.<sup>42</sup> *FUT1* is not expressed by salivary and parotid glands, which exclusively utilize *FUT2/Secretor*.<sup>42</sup> This is the basis for testing saliva for *secretor status*.

The H enzyme is a 365-amino-acid glycoprotein composed primarily of a large 240-amino-acid catalytic domain containing two conserved N-glycans, two cysteines, and three α-fucosyltransferase motifs.<sup>40,43</sup> Motif I resides at amino acids 214–224 and is likely involved in recognition of the GDP-fucose donor. Motifs II and III

may be involved in the recognition of the galactose acceptor and are located at 256–269 and 309–318, respectively. The enzyme shares 80% homology with FUT2/Secretor, especially along the catalytic domain.<sup>44</sup>

Loss of FUT1 activity and ABH expression is associated with the Bombay and *para*-Bombay phenotypes.<sup>20</sup> The International Society for Blood Transfusion (ISBT) currently lists 25 null alleles (*h*) and 34 weak-H alleles (*H<sup>w</sup>*) due to missense, frameshift, and nonsense mutations. Several mutations occur at conserved fucosyltransferase and N-glycan motifs or introduce new cysteine residues with the potential for aberrant folding. Nearly all missense mutations involve amino acids conserved between *FUT1* and *FUT2*.<sup>44</sup> In several instances, mutations in the same homologous amino acids in *FUT2* are associated with weak and null *FUT2* alleles.

Although widely expressed, *FUT1* is transcriptionally regulated with evidence of tissue-specific promoters and alternate splicing. In erythroid cell lines, up to four different mRNA transcripts can be identified from two different, developmentally regulated transcription initiation start sites.<sup>3,41,45</sup> In undifferentiated K562 cells, an early pluripotent hematopoietic cell line, *FUT1*, is transcribed primarily from exon 1A. In bone marrow and more differentiated erythробlastic cell lines (HEL, TF1), however, transcription proceeds from exon 2. Several transcription factor binding sites are located immediately upstream of exon 2 (AP-2, Sp1, Ets-1, c-Rel, and Elk), including a retroviral long-terminal repeat sequence that lies within the basal promoter region.<sup>45</sup> Retroviral-type sequences have been shown to regulate other glycosyltransferases and may be susceptible to methylation.<sup>46</sup>

*FUT1* transcription has also been studied in other cell lines and cancer. In general, *FUT1* transcription occurs from exon 1A in epithelial cells, whereas in vascular endothelium transcription starts at exon 3.<sup>45</sup> In colon carcinoma, there is the upregulation of *FUT1* mRNA and Le<sup>y</sup> expression due to Elk-1, which promotes transcription from the E1A start site.<sup>47</sup> In ovarian cancer lines, *FUT1* is upregulated by c-jun, a member of the AP-1 transcription factor activator protein complex.<sup>48</sup>

## Transfusion and transplantation

### Transfusion

Anti-A, anti-B, and anti-A,B are clinically significant IgM antibodies, capable of fixing complement and causing intravascular hemolysis.<sup>11</sup> In contrast, anti-H is typically a low-titer, clinically insignificant cold autoantibody in most individuals. On occasion, group A<sub>1</sub> and B individuals possess an allo-anti-HI that can react with group O red cells at 37 °C. In contrast, the allo-anti-H observed in Bombay and *para*-Bombay individuals is always significant, and requires the transfusion of rare H-negative red cells. In cold autoimmune hemolytic anemia, autoantibodies with I and ABH activity are not uncommon (e.g., auto-HI and auto-sialyl-A).

For transfusion, red cells and plasma must be ABO compatible with the recipient to avoid acute hemolytic transfusion reactions.<sup>11</sup> Patients whose ABO type is unknown or cannot be resolved due to typing difficulties should receive group O red cells. In emergent situations requiring plasma transfusion support, patients without a valid ABO type should receive group AB or group A plasma. Due to the scarcity of group AB plasma, thawed group A plasma is increasingly used as the initial plasma replacement in the military and large trauma centers, with no discernable increase in adverse events.<sup>49</sup>

ABO compatibility is not required for platelet and cryoprecipitate transfusion, although most transfusion services attempt to dispense ABO type-specific and ABO-compatible components, if

possible. Transfusion of ABO-incompatible platelets can adversely affect the posttransfusion increment, especially in group O recipients.<sup>50</sup> Two studies have shown that A<sub>2</sub> platelets are group O compatible and are as effective as type-specific platelets when transfused to either group A or O patients.<sup>51,52</sup>

### Hemolytic disease of the fetus and newborn (HDFN)

ABO major incompatibility between the mother and fetus is not uncommon given the incidence of blood groups O and A in the population. Severe HDFN due to ABO incompatibility, however, is relatively rare, with a reported incidence of 0.04%.<sup>53</sup> One reason is the inability of IgM antibodies to cross the placenta. In addition, A/B antigens are poorly expressed on fetal red cells and may not efficiently support complement fixation by maternal immunoglobulin G (IgG) antibodies. HDFN due to ABO incompatibility is most commonly observed in group O mothers, especially with a history of a prior, non-O pregnancy and immune-stimulated anti-A/B IgG antibodies.

### Transplantation

#### Solid organ transplantation

In general, organs selected for allotransplantation are ABO compatible with the recipient's isoagglutinin profile. Transplants of ABO-incompatible organs are at risk for acute and hyperacute rejection due to immune recognition of A/B antigens on endothelium and epithelial tissues of the transplanted organ. To improve the availability of organs, group A organ donors are now screened to identify non-A<sub>1</sub> (A<sub>2</sub>, A<sub>weak</sub>) donors.<sup>54</sup> Because of the relative absence of A-antigen on endothelium and epithelium, these organs can be transplanted successfully into group O and B recipients.<sup>54</sup>

Protocols have been developed to permit transplantation of other types of ABO incompatible organs in selected patient populations. Due to their naive immune state, infants and neonates can be transplanted with ABO incompatible hearts with good outcomes, minimal risk of acute rejection, and a decreased incidence of HLA antibodies.<sup>55</sup> Unlike adults, neonates lack preformed ABO antibodies and memory B cells, eliminating the need for splenectomy and aggressive immunosuppression. Over time, infants who received ABO-incompatible transplant appear to develop a broad donor-specific tolerance to ABO and other antigens.<sup>55</sup> Likewise, there is evidence of equivalent outcomes for ABO-incompatible liver transplantation in infants and young pediatric patients.<sup>56</sup>

Unlike infants, ABO incompatibility is a significant barrier in adult transplantation. Several protocols have been developed for ABO-incompatible kidney transplantation. Recipients often undergo a series of presurgery plasma exchanges, coupled with immune suppression that may include steroids, ATG, rituximab, basiliximab, daclizumab, eculizimab, or alemtuzumab.<sup>57</sup> Nonetheless, ABO-incompatible kidney transplants are associated with a higher rate of postoperative bleeding, infection, graft loss and death.<sup>58</sup> ABO-incompatible liver transplantation is usually reserved for emergent situations in which an ABO-compatible organ is unavailable. Historically, ABO-incompatible liver transplants were associated with high rates (50%) of graft failure and retransplantation. More recent studies using aggressive immunosuppression have reported improved graft survival, although the risks of venous thrombosis and graft loss are still higher than with ABO-compatible transplants.<sup>54,56</sup>

#### Stem cell transplantation

Unlike solid organ transplantation, human progenitor or stem cell transplants are frequently ABO incompatible. It is estimated that 30–50% of all allotransplants are ABO mismatched.<sup>59</sup> ABO

incompatibility has no impact on white cell engraftment but can lead to hemolysis, delayed red cell engraftment, pure red cell aplasia, and increased transfusion requirements.<sup>59</sup> There are also reports linking ABO mismatched transplants with an increased incidence of venous occlusive disease, severe graft-versus-host disease, and transplant-related mortality.

Several variables influence the impact of ABO incompatibility in stem cell transplantation, including the type of stem cell product, whether the donor is ABO major or minor incompatible, the conditioning regimen (myeloablative versus reduced conditioning), and the type of post-transplant immunosuppression.<sup>59,60</sup> In general, ABO major-incompatible marrow transplants have more significant delays in red cell engraftment and pure red cell aplasia than peripheral blood stem cell transplants.<sup>60</sup> Loss of recipient ABO antibodies and donor red cell engraftment is often faster in matched unrelated donors, especially in the presence of graft-versus-host disease and increased transfusion requirements.<sup>60</sup> It is hypothesized that the loss of ABO antibodies may reflect a graft-versus-plasma cell effect as well as the impact of passive infusion of soluble ABH antigens, which could both adsorb recipient ABO antibodies and promote selective B-cell depletion.<sup>15,60,61</sup> Finally, ABO minor-incompatible transplants may be complicated by hemolysis due to donor lymphocyte syndrome.<sup>59</sup>

## Biological role

### ABO, cancer, and possible biological role

The biological role of ABH antigens is still unclear; however, the influence of ABH antigens in cancer biology may provide some insight. It is well known that the loss of A and B expression in lung, esophageal, and bladder cancers is associated with a poorer prognosis.<sup>62–65</sup> In immortalized colon carcinoma cell lines, the absence of A or B is associated with increased chemotactic and haptotactic cell migration in vitro, which can be blocked by transfecting cells with GTA or GTB transferases.<sup>66</sup> Because integrins are sensitive to changes in glycosylation, it is hypothesized that A/B antigens on  $\alpha$ - and  $\beta$ -integrins sterically interfere with heterodimer formation, integrin-mediated adhesion, and/or cell signaling.<sup>66,67</sup> In addition, ABH is a terminal glycan modification and competes with sialyltransferase for reactive nonreducing  $\beta$ -galactosyl residues on glycoproteins. As a result, ABH has the potential to modulate cellular interactions with galactins, siglecs (sialic acid-binding lectin glycoproteins), cadherins, and growth factors.<sup>68</sup>

ABH may also influence cell sensitivity to apoptosis and immune regulation. Increases in H-antigen and  $\alpha$ 1,2-fucosyltransferase activity are associated with decreased overall survival in colon cancer.<sup>69</sup> Furthermore, the induction of H-activity can increase resistance to apoptosis by heat shock and serum deprivation.<sup>65</sup> Finally, H-antigen neoexpression may make tumors less antigenic, allowing tumors to escape immune surveillance.<sup>65</sup>

There are associations between specific blood types and the incidence of cancer. The incidence of gastric and pancreatic cancer is higher among group A individuals, where A > B, AB > O.<sup>70,71</sup> When examined by A subtypes, the risk of pancreatic cancer is higher among A<sub>1</sub> individuals whereas no increase is observed for A<sub>2</sub>.<sup>71</sup> In lung cancer, blood group O has a higher mortality.<sup>62</sup> There is some evidence that many of these associations reflect differences in the upregulation of inflammatory mediators.<sup>62,69</sup>

### ABO and coagulation

There is a strong association between non-group O blood types and thrombosis risk. Two recent systematic reviews and meta-analysis

calculated that non-group O individuals have a twofold higher risk of thrombotic events than group O people.<sup>72</sup> In European studies, non-group O was the single most important population risk factor for venous thrombosis, including both deep venous thrombosis and pulmonary embolism. Non-group O blood types also have an increased risk of coronary heart disease, increased LDL, and total cholesterol.<sup>72</sup>

The observed linkage between ABO and thrombotic events appears to be multifactorial. GWA studies have found associations between ABO and serum levels of ICAM1, TNF $\alpha$ , P-selectin, E-selectin, LDL, and cholesterol levels.<sup>72</sup> More importantly, there is a clear correlation between vWF levels and ABO type, where AB > A, B > A<sub>2</sub> > O > O<sub>h</sub> (Bombay).<sup>72</sup> The lower vWF levels in group O individuals reflect accelerated vWF clearance relative to non-O individuals. Group O vWF is also more susceptible to proteolysis by ADAMTS13. In addition, there is evidence of accelerated vWF uptake by macrophages in those with blood group O.

## ABO and malaria

ABO is considered a major host susceptibility factor in malaria.<sup>73,74</sup> In fact, there is evidence that selection pressure by *Plasmodium falciparum* may underlie the high prevalence of blood group O in malaria-endemic populations located along the equator.<sup>73</sup> Why blood group O provides a survival and reproductive advantage against malaria is multifactorial and a subject of ongoing intensive investigation. Studies in Africa suggest that blood group O may protect against placental malaria through higher fetal birth weights and hemoglobin levels.<sup>74</sup> One critical mechanism appears to be protection against red cell resetting by some *P. falciparum* species.<sup>75</sup> The ability to rosette red cells is a major virulence factor associated with severe malaria, microvascular ischemia, thrombosis, and cerebral malaria.<sup>73–75</sup> The increased thrombotic risk in non-group O may also contribute to excess morbidity and mortality in malaria-endemic regions (see above). Finally, group O may provide an advantage in parasite clearance. Infected group O red cells appear more susceptible to oxidative damage as evidenced by the carbonylation of cytoskeletal proteins, hemichrome formation, and Band 3 clustering.<sup>76,77</sup> These senescent changes may facilitate phagocytosis and clearance of infected red cells, thereby decreasing the level and severity of parasitemia.<sup>78</sup>

## ABO, cholera, and other enteric infections

Group O is a host risk factor for the development of severe cholera by *Vibrio* strains carrying the El Tor and Bengal cholera toxin subtypes.<sup>74</sup> These two strains have been shown to bind difucosylated H antigen (Le<sup>Y</sup>) but not ABH-modified structures (BLE<sup>Y</sup>).<sup>79</sup> It is hypothesized that Le<sup>Y</sup> captures and concentrates cholera toxin, bringing it within close proximity to ganglioside GM1, the physiologic toxin receptor on small intestine epithelium. The result is increased cellular toxicity and secretory diarrhea in group O individuals. ABO has no impact on classical O1 cholera toxin infections.

Several other enteric pathogens also recognize ABH epitopes on intestinal epithelium. *Campylobacter jejuni* recognizes type 2 chain H and Le<sup>Y</sup> antigens on jejunal epithelium.<sup>80</sup> Norovirus and rotavirus, two highly infectious nonenveloped viruses, recognize type 1 ABH and/or Lewis antigens in the upper small intestine.<sup>73</sup> Norovirus G1 strains prefer type 1 H antigens, whereas GII strains are more promiscuous, recognizing a host of fucosylated structures.<sup>74,81</sup> Individuals lacking type 1 antigens (nonsecretors) are resistant to most norovirus infections.<sup>82,83</sup> Most human rotavirus strains (P4, P6, and P8)

also recognize type 1 H and Le<sup>b</sup>;<sup>84</sup> however, a few strains belonging to the PIII family (P9, P14, P25) have evolved to recognize the GalNAc $\alpha$ 1 → 3 Gal epitope present on group A antigen.<sup>85</sup>

### ABO and respiratory infections

ABO type may affect the course of COVID-19 (SARS-CoV-2 infection). Several large GWAS studies have identified the ABO locus as a host risk factor.<sup>86</sup> Although clinical studies have specifically linked group A with increased susceptibility, other studies have shown little or no correlation between ABO and COVID-19.<sup>87</sup> The primary receptor for COVID-19 is the ACE2 receptor; however, there is evidence that the viral spike protein also has lectin properties that might be important for host cell invasion.<sup>88</sup> Using recombinant COVID-19 spike protein, the Stowell laboratory showed a clear preference of spike protein for binding type 1 chain A antigen.<sup>88</sup> In addition, the COVID-19 spike protein is heavily glycosylated and able to express host ABO antigens, and ABO antibodies may protect against infection (see below).<sup>87,89</sup> The course of COVID-19 disease may also be impacted by the known association between ABO and thrombosis (see above).

### ABH antibodies and innate immunity

ABH antibodies, particularly anti-B, may play a role in the innate host defense against bacterial infection. As discussed in this chapter, ABH-like glycoconjugates are found on the LPS of many enteric bacteria.<sup>12</sup> In animal and in vitro studies, anti-B have been shown to bind bacteria with complement activation and increased phagocytosis.<sup>74</sup> Clinically, the absence of anti-B in group B and AB individuals has been linked to increased incidence of infection by *Escherichia coli* and *Salmonella*.<sup>90,91</sup>

ABH antibodies are also implicated in the susceptibility to infection by enveloped viruses and schistosomiasis.<sup>74</sup> HIV, SARS-CoV-1, and COVID-19 (SARS-CoV-2) viruses express host ABH antigens on viral glycoproteins and the lipid envelope.<sup>88,89,92,93</sup> Infection by HIV and SARS-CoV-1 can be blocked by monoclonal and/or human ABH antibodies in vitro, suggesting that ABO incompatibility at the time of primary viral exposure could offer some protection.<sup>92,93</sup> This was observed during a SARS-CoV-1 virus outbreak involving a single index patient in China.<sup>94</sup> Most infections (68%) occurred among non-group O health-care workers, whereas group O individuals were relatively resistant (OR = 0.18).

Due to widespread community spread during the Covid-19 pandemic, there is no clear data that ABO antibodies were beneficial in blocking infection or preventing severe disease in exposed individuals.<sup>87,89,95</sup> However, more recent data suggest that anti-Tn antibodies, a naturally occurring antibody directed against terminal GalNAc, may play a role. Anti-Tn antibodies were significantly

lower in COVID-19 patients, with the lowest levels observed in group A patients.<sup>96</sup> The Tn antigen is widely expressed on tracheal and bronchial epithelium regardless of ABO type.

Finally, group B and O individuals may have an increased resistance to schistosoma infections due to anti-A.<sup>74</sup> Anti-A is hypothesized to bind and block GalNAc epitopes on female flukes necessary for fluke chemoattraction and mating.<sup>97</sup>

### Lewis blood group

The Lewis blood group system was discovered shortly after World War II (1946–1948) and currently contains six antigens.<sup>20</sup> Serologically, Lewis status is defined by the expression of two main antigens, Le<sup>a</sup> (LE1) and Le<sup>b</sup> (LE2). Four additional antigens—Le<sup>ab</sup> (LE3), Le<sup>bH</sup> (LE4), ALe<sup>b</sup> (LE5), and BLe<sup>b</sup> (LE6)—reflect the biosynthetic and immunologic interaction of Le<sup>a</sup>, Le<sup>b</sup>, and ABO antigens. Unlike ABH, Lewis antigens are not of erythroid origin but are passively adsorbed onto red cells from a pool of Lewis-active GSL present in plasma. Adsorbed Lewis antigen is also found on platelets, lymphocytes, and endothelium. Cells synthesizing Lewis antigens are typically of endodermal origin and include gastrointestinal, urogenital, and respiratory epithelium. Soluble Lewis antigen can be found in plasma, saliva, breast milk, and urine.

### Serology

There are four possible Lewis phenotypes, although only three are commonly encountered in adults (Table 9.4): Le(a+b−), Le(a+b+), and Le(a−b−). The Le(a+b+) is unusual but can be observed in neonates and up to 20% of Japanese, Chinese, and Polynesians.<sup>20</sup> There are racial and geographic differences in the distribution of Lewis phenotypes and alleles. Because Lewis antigens are adsorbed and not synthesized on red cells, Lewis phenotype is sensitive to changes in red cell turnover and plasma volume.<sup>32</sup> Lewis antigens can be transiently decreased in chronic hemolysis. Pregnancy, cirrhosis, and chronic renal failure can lead to decreased Lewis expression due to an expanded blood volume and changes in circulating lipid concentration.

### Synthesis and biochemistry

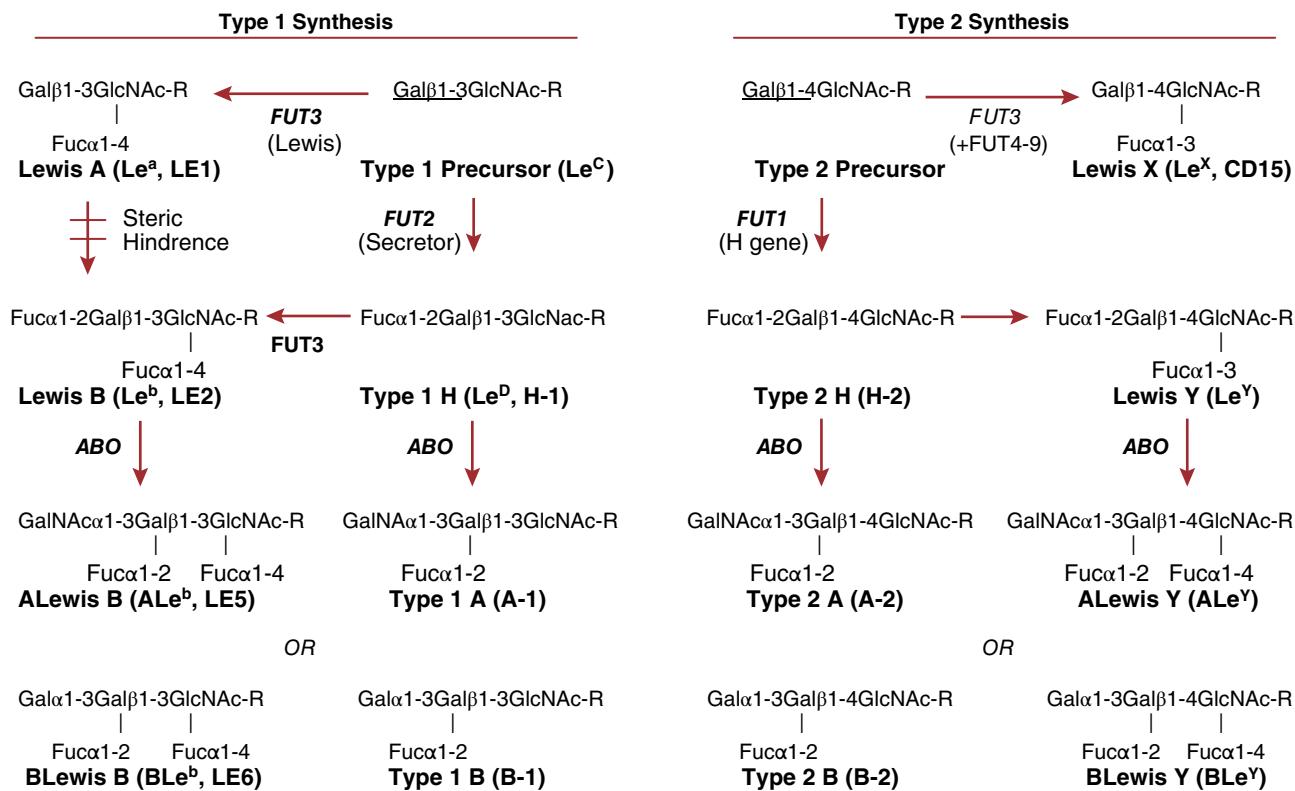

Le<sup>a</sup> and Le<sup>b</sup> are fucosylated type 1 chain antigens and reflect the interaction of two autosomal-dominant fucosyltransferases: Lewis (FUT3) and Secretor (FUT2). As discussed earlier in this chapter, FUT2 is an H-type  $\alpha$ 1,2-fucosyltransferase-specific for type 1 chain substrates, whereas FUT3 is considered an  $\alpha$ 1,3/1,4-fucosyltransferase, able to utilize both type 1 and type 2 chain substrates. As a result, FUT3 can synthesize type I Lewis antigens as well as type II chain Le<sup>X</sup> and Le<sup>Y</sup> antigens (Figure 9.2). This is

**Table 9.4** Lewis Serology and Genetics

Lewis Type	Incidence		Genes*			Secreted Antigens†		
	White	Black	FUT2	FUT3	ABH Secretor†	Le <sup>a</sup>	Le <sup>b</sup>	ABO
Le (a+b−)	22%	23%	se/se	Le	N	+	0	0
Le (a+b+)	72%	55%	Se	Le	Y	+	+	+
Le (a+b <sup>w</sup> )	Rare	Rare	Se <sup>w</sup>	Le	Y	+	↓	↓
Le (a−b−)	6%	22%	Se	le/le	Y	0	0	+
			se/se	le/le	N	0	0	0

\* Inherited at least one functional allele of FUT3/Lewis (Le) and FUT2/Secretor (Se). Lewis null and nonsecretors are homozygous for FUT3 (le/le) and FUT2 (se/se) amorph alleles, respectively.

† Presence of secreted ABH substances in saliva and body fluids.

**Figure 9.2** Biosynthetic pathways for Lewis, and type 1 and type 2 chain ABO antigens.

observed in gastrointestinal mucosa, where deep glandular epithelial stem cells express FUT3 and type 2 chain precursor with synthesis of Le<sup>x</sup> and Le<sup>y</sup>, but switch to type 1 chain synthesis upon further differentiation, with expression of Le<sup>a</sup> and Le<sup>b</sup> structures on villus epithelium.<sup>1,74</sup>

Synthesis of Le<sup>a</sup> and Le<sup>b</sup> proceeds from type 1 chain precursor, historically known as Le<sup>C</sup>, along two different pathways. Le<sup>a</sup> is a monofucosylated antigen and requires only FUT3, whereas Le<sup>b</sup>, a difucosylated antigen, requires the action of both FUT3 and FUT2 for its synthesis. To synthesize Le<sup>a</sup>, FUT3 transfers an α1 → 4 fucose to the subterminal *n*-acetylglucosamine (GlcNAc) of type 1 precursor. To synthesize Le<sup>b</sup>, type 1 precursor is initially fucosylated by FUT2 to form type 1 H (Le<sup>D</sup>), which then serves as a substrate for FUT3 to form Le<sup>b</sup>. Le<sup>b</sup> cannot be synthesized directly from Le<sup>a</sup> due to steric blocking by the subterminal fucose. Once formed, Le<sup>b</sup> can be further modified by ABO to form ALe<sup>b</sup> (LE5) and BLe<sup>b</sup> (LE6). In A<sub>1</sub> individuals, ALe<sup>b</sup> is the predominant Lewis- and A-active GSL in plasma.<sup>98</sup> Because Le<sup>b</sup> requires FUT2 for synthesis, it is accompanied by the synthesis and secretion of type 1 chain ABH antigens.

It is now clear how FUT2 and FUT3 determine Lewis phenotype (Table 9.3). The Le(a+b-) phenotype reflects inheritance of at least one functional FUT3 gene and homozygosity for FUT2-null alleles (*se/se*). As a result, Le(a+b-) individuals also fail to express type 1 chain ABH and are considered ABH “nonsecretors.” Only type 1 chain precursors (Le<sup>C</sup>) and Le<sup>a</sup> are found in saliva and secretions.

The Le(a+b+) phenotype has inherited at least one functional FUT3/Lewis and FUT2/*Se* allele with secretion of Le<sup>a</sup>, Le<sup>b</sup>, and type 1 ABH antigens. The apparent absence of Le<sup>a</sup> on red cells is deceptive because both Le<sup>a</sup> and Le<sup>b</sup> are synthesized. It appears that FUT2 outcompetes FUT3 for type 1 precursor, leading to predominantly Le<sup>b</sup> synthesis.

Decreases in FUT2 activity account for the Le(a+b+) phenotype. In neonates, it is believed that there is a developmental delay in FUT2 expression in gastrointestinal mucosa. In contrast, mutations leading to weak FUT2 activity underlie the Le(a+b+w) phenotype commonly encountered in Japanese, Chinese, and Polynesians.<sup>20</sup> Weak FUT2 activity permits FUT3 to successfully compete for type 1 precursor, tipping the balance toward Le<sup>a</sup> synthesis.

The Le(a-b-) phenotype is a FUT3/Lewis-null phenotype. Le(a-b-) may be either ABH nonsecretor or secretors, depending on the inheritance of FUT2. Le(a-b-) does not secrete Lewis-active substances.

### Molecular biology of Lewis and secretor genes

#### Lewis gene (FUT3)

FUT3 is located on chromosome 19p13.3 as a tandem cluster of three homologous glycosyltransferases: FUT5–FUT3–FUT6.<sup>20</sup> All three genes belong to the GT10 family of α1,3-fucosyltransferase, which is widely conserved in vertebrates and bacteria.<sup>43</sup> The gene consists of three exons, although only exon 3 encodes the active enzyme. The translated protein is a 361-amino-acid, type II glycoprotein with five cysteines and two N-glycan sites.<sup>99</sup> Detailed analysis indicates that the globular catalytic domain starts around residue 86 and extends through the carboxy-terminus of the enzyme. FUT3 shares two highly conserved α-fucosyltransferase motifs in the GDP-nucleotide donor (motif I, amino acid 152–171) and acceptor domains (motif II, amino acids 239–272) of the enzyme, respectively.<sup>43</sup> Motif I includes an N-glycan site and the DxD motif that interacts with divalent cations (Mn<sup>2+</sup>). The region immediately adjacent to motif I has been identified as critical for transferring fucose to type 1 substrates (amino acids 105–151).<sup>100</sup> This region contains two highly conserved cysteines (Cys<sup>81</sup>, Cys<sup>91</sup>) that are

believed to form disulfide bridges with the formation of a small loop structure necessary for enzyme activity.<sup>101</sup> An additional conserved disulfide bond pair is located toward the carboxy-terminus (Cys<sup>338</sup>, C<sup>341</sup>). The enzyme is believed to reside in the *trans*-Golgi.

*FUT3* is tissue-restricted and correlates fairly well with *FUT2* expression.<sup>42</sup> The strongest *FUT3* expression is observed in trachea, intestine, bladder, and lower female reproductive tract.<sup>42</sup> Depending on tissue, up to four different mRNA transcripts can be produced due to differential splicing.<sup>102</sup> A basal promoter in the 5' UTR that is active in intestinal mucosa was located –636 to –674 bp upstream of exon 1 and contains AP-1 and c/EBPβ transcription binding sites. The 5' UTR also contains multiple c-Myc sites that can upregulate *FUT3* and an enhancer region (–674 to –854).<sup>102,103</sup> Gene suppression can occur by methylation and a negative regulatory region located between –855 and –1220.<sup>102,104</sup>

There are nearly 50 *FUT3* null (*le*) alleles associated with a Le(a–b–) phenotype.<sup>20,105</sup> A majority of alleles (89%) have at least two mutations, and many alleles contain four or more SNPs. Several null alleles show distinct geographic and ethnic distributions. In whites and Pakistanis, alleles containing T202C (Trp68Arg) and C314T (Thr105Met) are common (*le*<sup>202,314</sup>), whereas *le*<sup>59</sup>, *le*<sup>59,508</sup>, and *le*<sup>59,1067</sup> predominate in Japan, China, Korea, Northern India, Asia, and Brazilian Amazon.<sup>74,105</sup> In African and US black populations, several additional mutations have been identified, including G13A (Gly5Ser), G484A (Asp162Asn), G667A (Gly223Arg), and A808G (Val270Met). In blacks, the most common alleles are *le*<sup>13,484,667</sup>, *le*<sup>484,667</sup>, and *le*<sup>59,308</sup>.

Some mutations have an apparently greater effect on Lewis-GSL expression, leading to Lewis-type discrepancies between saliva, tissues, and red cells. A mutation in the transmembrane domain (Leu20Arg; *le*<sup>59</sup>) is associated with marked loss in Lewis-GSL synthesis but retains Lewis expression on intestinal glycoproteins.<sup>106,107</sup> It is believed this mutation leads to mislocalization and trafficking of the enzyme within the Golgi.<sup>98</sup> *FUT3* also displays gene dosage with reduced enzyme activity in heterozygous individuals (*Le/le*).<sup>108</sup> Heterozygous individuals can be red cell type as Le (a–b–) but retain Lewis expression on gastrointestinal and other tissues.<sup>99,100</sup>

### Secretor gene (*FUT2*)

Like *FUT1*, *FUT2*/Se is a galactoside-2-α-L-fucosyltransferase, catalyzing the addition of an α1 → 2 linked fucose to a terminal galactose. Unlike *FUT1*, which is specific for type 2 chain precursors, *FUT2* recognizes type 1 chain substrate with the synthesis of type 1 chain ABH and Le<sup>b</sup> antigens. *FUT2* is primarily responsible for the synthesis of type 3 and type 4 ABH antigens, which also share a terminal Galβ1 → 3HexNAc acceptor.<sup>9,10</sup> *FUT2* resides on chromosome 19q13.3 as part of a 100-kb gene cluster that includes *FUT1* and *Sec1*, an inactive *FUT2*-like pseudogene.<sup>44</sup> The *FUT2* gene contains two exons, with exon 2 encoding the active enzyme.<sup>20,44</sup> The translated protein is 343 amino acids long and shares 68% sequence homology with *FUT1*.<sup>44</sup> It shares three motifs common to eukaryotic and prokaryotic α1,2-fucosyltransferases at amino acids 184–204 (motif I), 226–239 (motif II), and 278–288 (motif III).<sup>43</sup> The *Sec1*-*FUT2*-*FUT1* gene cluster is susceptible to mutation and genetic recombination due to the high homology of the three genes and their proximity to several *Alu* sequences, including nine *Alu* repeats in exon 1.<sup>101</sup>

*FUT2* is highly expressed in trachea, parotid, salivary gland, gastric and intestinal mucosa, uroepithelium (bladder and kidney), and female reproductive tract (vagina, cervix, and ovary). Little or no *FUT2* mRNA is observed in placenta, bone marrow, or spleen

which uses *FUT1* almost exclusively.<sup>42</sup> Intestinal *FUT2* expression can be induced by commensal bacteria that utilize fucose as a nutrient<sup>109</sup> and could theoretically account for the developmental delay in Le<sup>b</sup> expression observed in newborns. Babies slowly acquire *FUT2*-inducing bacteria through ingestion of breast milk and other foods, only achieving a normal “adult-type” intestinal microbiome by 1 year of age.<sup>110</sup>

The minimal basal promoter for *FUT2* is located at 109 to 56 and includes several GC-rich regions. Multiple transcription factor binding sites are present, including those for CDX2 (8 sites), GATA, Sp1, AP2 (5 sites), and E2A.<sup>103,111</sup> CDX2 binding appears critical for *FUT2* expression in human intestinal cell lines.<sup>103</sup> Animal studies suggest that demethylation and Sp1 may also play a role.<sup>112</sup> An SNP located at approximately 190 is associated with decreased transcription in colon cell lines and is unique to African populations.<sup>113</sup> Finally, *FUT2* mRNA has a long 3' UTR that can form a large stem-loop structure, which could affect mRNA stability and translation. It also contains a binding site for microRNA (miRNA-15b) which can downregulate *FUT2* transcription.<sup>109,114</sup>

Individuals homozygous for two *FUT2*-null alleles (*se/se*) are considered nonsecretors and express only Le<sup>a</sup> and/or type 1 precursor substance (Le<sup>C</sup>) in their secretions and tissues (Table 9.3). ISBT currently lists 27 *FUT2* weak and null alleles, many with distinct geographic and ethnic distributions ([www.isbtweb.org](http://www.isbtweb.org)). Most null alleles are the result of nonsense mutations leading to the synthesis of a truncated protein.<sup>20</sup> The most common null mutation is *se*<sup>428</sup> (Trp143stop and *FUT2*'01N.02), an ancient mutation that arose nearly three million years ago. The *se*<sup>428</sup> allele is the most frequent nonsecretor allele in whites and is common among Africans, Iranians, and Turks. As a consequence, it is frequently included in genetic studies (G428A: rs601338). Unusual *se* alleles due to *Alu*-mediated deletion and recombination have also been identified in India and Asia.<sup>20</sup> Six missense mutations involve highly conserved amino acids often within or adjacent to conserved motifs.

*FUT2* variants with weak activity (*Se<sup>W</sup>*) are common in Asia and tend to be missense mutations. In China and neighboring Asian countries, *Se*<sup>385</sup> (Ile129Phe; *FUT2*'01W.02) is the predominate *Se<sup>W</sup>* allele.<sup>115</sup> *Se<sup>W</sup>/Se<sup>W</sup>* and *Se<sup>W/se</sup>* individuals can type as Le(a+b<sup>W</sup>), Le(a+b–), or Le(a–b–). Individuals with a *Se<sup>W/se</sup>* genotype are particularly at risk for phenotyping as nonsecretors.<sup>115</sup>

### Blood transfusion and transplantation

Lewis antibodies are generally low-titer, IgM saline agglutinins and are clinically insignificant.<sup>11</sup> Lewis antibodies can display ABO reactivity, reacting stronger with group O (anti-Le<sup>bH</sup>), A (anti-ALe<sup>b</sup>), or B (anti-BLe<sup>b</sup>) red cells. With rare exceptions, they are not associated with HDFN or hemolytic transfusion reactions. There is a single small report linking a Le(a–b–) phenotype with an increased risk of rejection in kidney transplantation.<sup>116</sup>

### Biological roles

#### Cancer

Sialyl-Le<sup>a</sup> (sLe<sup>a</sup>; CA19.9) is a receptor for E-selectin, an important adhesin in cancer biology.<sup>117</sup> Epithelial tumors with high sLe<sup>a</sup> (or sLe<sup>c</sup>; CEA) expression have increased metastatic potential and a poorer clinical prognosis. Upregulation of *FUT3*, coupled with downregulation of *FUT2*, is an early step in the epithelial–mesenchymal transition during malignant transformation.<sup>103</sup> In cancer cell lines, *FUT3* silencing by siRNA will inhibit E-selectin binding and adhesion to endothelial cells, as well as reduces cellular proliferation.<sup>117</sup>

Conversely, the upregulation of *FUT2* is observed in breast, lung, and hepatocellular carcinoma.<sup>114,118–120</sup> In hepatocellular carcinoma, the downregulation of miRNA-15b, which normally suppresses *FUT2* expression, is attributed to increased *FUT2* and globo-H synthesis (see P blood group).<sup>114</sup> Finally, the synthesis of cancer markers CA19.9 and CEA is affected by genetic mutations in *FUT3* and *FUT2* genes, and should be considered when interpreting and setting normal ranges for these cancer markers.<sup>120</sup>

### Atherosclerosis

A Le(a–b–) phenotype has been linked to a twofold increased risk of atherosclerotic disease and coronary death.<sup>121</sup> Although the basis for the observation is unknown, Le(a–b–) individuals did demonstrate lower triglyceride levels, which could potentially alter plasma Lewis-GSL concentrations. Molecular typing of 1735 individuals in the Framingham offspring study subsequently showed a 57% increased risk of atherothrombotic disease in confirmed *le/le* individuals.<sup>122</sup> Of three common *FUT3* mutations studied, the *le*<sup>59</sup> mutation had the strongest association with atherosclerotic disease. A Danish study also linked the Le(a–b–) phenotype with an increased risk for stroke.<sup>123</sup>

### Necrotizing enterocolitis and other inflammatory bowel disorders

Necrotizing enterocolitis occurs in 7–10% of premature infants and carries a high mortality rate (20–30%).<sup>124</sup> It is characterized by bowel inflammation and necrosis with evidence of a disturbed intestinal microbiota. Recently, a correlation between NEC, salivary H antigen, and *FUT2* genotype was identified.<sup>125</sup> Infants with low salivary H had a significantly higher risk of death from NEC and sepsis ( $p < 0.001$ ). When examined by genotype, survival was highest among *Se/Se* homozygotes (98%) and *Se/se* heterozygotes (95%) when compared to *se/se* nonsecretors (87%).

From animal and human studies, there is evidence that fucosylation protects against infectious and inflammatory insults to the gastrointestinal tract. In adults, there is a direct spatial relationship between bacterial density and fucosylation, with highest density of bacteria and fucosylation in the colon and rectum.<sup>126,127</sup> As noted earlier, commensal bacteria that utilize fucose as a nutrient can specifically induce *FUT2* in intestinal tissue—a demonstration of a mutually beneficial symbiotic relationship.<sup>110</sup> In mice, inflammatory insults rapidly upregulate *FUT2*, leading to the shedding of fucosylated glycoproteins that promote commensal bacterial growth, while suppressing the expression of bacterial virulence genes.<sup>128</sup> In addition, fucosylation protects against tissue injury with more rapid tissue recovery.<sup>127</sup> In contrast, nonsecretor animals are susceptible to chronic colitis, diarrhea, and weight loss.<sup>128,129</sup> Not surprisingly, the nonsecretor phenotype has also been linked with Crohn's disease and is implicated in intestinal graft-versus-host disease, inflammatory bowel disorder, and altered microflora.<sup>130,131</sup> The nonsecretor phenotype, however, does not appear to alter the composition of the normal gut microbiome.<sup>132</sup>

### *Helicobacter pylori* and other infections

*H. pylori* is a flagellated, Gram-negative pathogen of the stomach associated with chronic gastritis, gastroduodenal ulcers, and gastric cancer.<sup>74</sup> A major colonization and virulence factor is BabA, a 78 kD lectin that recognizes type 1 H and Le<sup>b</sup> structures. Surveys of BabA-positive strains from around the world show that most are “generalists,” capable of binding Le<sup>b</sup>, ALe<sup>b</sup>, BLe<sup>b</sup>, and type 1 H antigen. Le<sup>b</sup>, however, is the preferred ligand in binding assays.<sup>133</sup> The ability to

recognize ABH-modified-Le<sup>b</sup> structures may explain the lack of clear correlation between ABO type and *H. pylori* infection despite older studies showing a linkage between group O and duodenal ulcers.<sup>74</sup> The correlation between *H. pylori* and secretor status is equally unclear, with some studies showing higher colonization rates and worse inflammation among nonsecretors.<sup>134,135</sup>

There is some evidence to suggest that a nonsecretor phenotype may increase the susceptibility to cholera toxin and the related enterotoxigenic *E. coli*, which secretes a cholera-like toxin. Two studies have found an increased incidence of nonsecretors among cholera patients.<sup>136,137</sup> In the largest study of 522 subjects, infected symptomatic individuals were twice as likely to be Le(a+b–) nonsecretors.<sup>137</sup> Likewise, a nonsecretor phenotype may increase the risk of *E. coli* infection in young children. Le(a+b–) children were more likely to have symptomatic infections (71% vs. 29%), especially by strains expressing the CFA I adhesin.<sup>138</sup> Both Lewis and secretor affect susceptibility to *Shigella flexneri*, where Le(a+b–) infants had the highest rates and Le(a+b+) had the lowest rates of infection, respectively.<sup>139</sup> Using the HT-29 colon cell line, the authors showed that fucosylation decreases *S. flexneri* invasion but had no effect on cell-to-cell spread.

Secretor status and fucosylation also contribute to genitourinary and respiratory tract infections.<sup>74</sup> Secretor status is protective against recurrent urinary tract infections by P-fimbriated *E. coli* (see P blood group, below). Secretor may also protect against recurrent vaginitis by *C. albicans*. Three small studies have shown an increased risk for Candida vaginitis among nonsecretors.<sup>74</sup> In animal studies, *FUT2*-null mice had significantly worse *C. albicans* infection than the wild-type *FUT2*+ controls. *C. albicans* strains can bind H-active antigens on cervical mucins, preventing the colonization of vaginal epithelial cells.<sup>140,141</sup> In the respiratory tract, several large pediatric GWAS studies have identified links between secretor and *S. pneumoniae* infection, otitis media, severe asthma, and *P. aeruginosa* bronchiectasis.<sup>142–144</sup>

Finally, secretor status is considered a host susceptibility factor in several viral infections. As noted earlier, norovirus and rotaviruses recognize type 1 ABH structures. In most outbreaks, nonsecretors are relatively resistant to infection.<sup>82,83</sup> Nonsecretor may also provide mild protection against heterosexual HIV transmission, with HIV infection rates 14–30% lower than *Se+* individuals.<sup>145,146</sup> One older study also showed a higher rate of influenza infection among *Se+*.<sup>147</sup>

### I blood group

The I blood group (ISBT 027) was initially described in 1956 in a patient with a potent cold agglutinin and episodes of profound hemolysis characteristic of cold agglutinin disease.<sup>148</sup> Serologic studies showed a panagglutinin reactive with more than 22,000 donors, family members, and several animal species. After extensive testing, five compatible donors were identified, leading investigators to designate her antibody as an anti-I in order to “emphasize the high degree of individuality” of rare I-negative (i+) donors.<sup>148</sup> Dr. Lawrence Marsh later confirmed the inverse serologic relationship between I and i antigens after identification of an anti-i. This antibody was reactive with *i<sub>adult</sub>* and cord red cells but not adult, I+ red cells.<sup>149</sup>

### I/i expression

The I antigen is a widely distributed, developmentally regulated antigen. At birth, cord red cells are I–, presumably as protection

against HDFN due to ABO incompatibility (see later). After three months of age, I antigen progressively increases, accompanied by decreased i antigen, with a normal adult-type I+I- phenotype by 18–24 months.<sup>149–151</sup> Quantitative estimates of I antigen on adult red cells can vary from 32,000 to 130,000/cell due to differences in the fine specificity of anti-I antibodies used for these studies.<sup>150</sup> Estimates of i antigen on untreated cord and adult red cells are 25,000–75,000/cord and 1000–30,000/adult cell, respectively.<sup>150</sup> The i antigen is elevated on reticulocytes and can be increased on mature red cells as a sign of stressed erythropoiesis, dyserythropoiesis, and disordered Golgi trafficking.<sup>150</sup> Conditions associated with elevated i antigen include erythroleukemia, megaloblastic anemia, chronic hemolytic disorders, and hereditary erythroblastic multinuclearity with a positive acidified serum lysis test (HEMPAS).

### I-null ( $i_{adult}$ )

An I-i+ phenotype is a characteristic of  $i_{adult}$  red cells, a rare autosomal-recessive phenotype due to mutations in the I gene (*GCNT2*, *IGnT*) with an estimated incidence of 1:4400 to 1:17,000.<sup>151,152</sup> Heterozygous family members can have an intermediate I+i+ phenotype consistent with gene dosage. Individuals with  $i_{adult}$  can make an allo-anti-I reactive with normal adult red cells.

There are two clinical  $i_{adult}$  phenotypes based on the presence or absence of congenital cataracts.<sup>152,153</sup> In non-Asians, there is an isolated deficiency of I antigen on red cells only. Conversely, many Asian  $i_{adult}$  kindreds show a global loss of I antigen on all tissues, including human lens, accompanied by congenital cataracts. In China, *GCNT2* mutations account for 4–6% of all childhood cataract cases.<sup>154</sup>

### Biochemistry

I and i antigens are biosynthetically and structurally related oligosaccharides, composed of repeating units of *n*-acetyllactosamine (LacNAc,  $[Gal\beta \rightarrow 4GlcNAc]_n$ ). The minimum i antigen epitope is defined as a linear, unbranched type 2 chain oligosaccharide bearing at least two successive LacNAc units (Figure 9.3B).<sup>155</sup> The i antigen is sensitive to the enzyme  $\beta$  endo-galactosidase.

The I antigen is a branched, polygalactosamine derivative of i antigen. The I gene (*GCNT2*, *IGnT*) encodes a  $\beta 1 \rightarrow 6$  *n*-acetylgalactosaminyltransferase that transfers a  $\beta 1 \rightarrow 6$  GlcNAc to a subterminal  $\beta 1 \rightarrow 3$  Gal.<sup>152,153</sup> Extensive studies with purified oligosaccharides indicate that the enzyme recognizes a four-sugar donor acceptor composed of two successive LacNAc units.<sup>156</sup> This is consistent with isolated erythroid glycans, which show at least two LacNAc motifs between branch points.<sup>8</sup> The enzyme can form branches on both distal and centrally placed  $\beta 1 \rightarrow 3$  Gal residues, but will not recognize LacNAc residues modified by fucose or neuraminic acid.<sup>156</sup> As a result, sialylation and fucosylation (ABH,  $Le^X$ , and  $Le^Y$ ) are regulators of I and i antigens, blocking both polygalactosamine elongation and branching. Anti-I antibodies can recognize a variety of glycans but require a  $[-GlcNAc\beta 1 \rightarrow 6 (GlcNAc\beta 1 \rightarrow 3) Gal\beta 1 -]$  as part of the immune epitope (Figure 9.3B).<sup>150,155</sup>

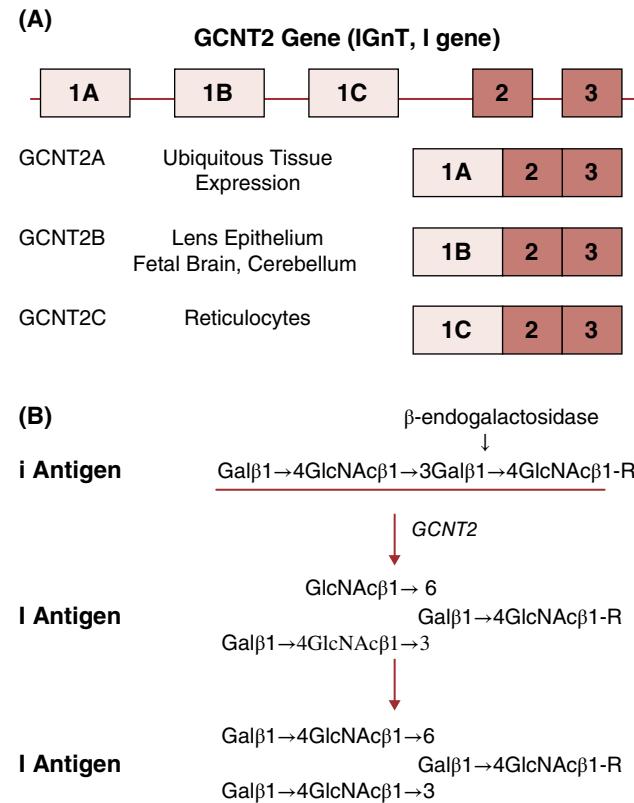

### Molecular biology and genetics

The I gene, *GCNT2* (*IGnT*), is located in an *Alu*-rich region on chromosome 6p24.2.<sup>157</sup> The gene consists of seven exons: five coding exons responsible for the active enzyme (E1-E3) and two upstream noncoding exons. *GCNT2* possesses three tissue-specific variants of exon 1 (E1A, E1B, and E1C; Figure 9.3A), resulting in three different isoforms of the enzyme depending on which exon 1 is utilized.<sup>152,153</sup> *GCNT2A* (*IGnTA* and *IGnT2*) is expressed by most

humans tissues and is derived from exon E1A. *GCNT2B* uses exon E1B and is the only mRNA transcript identified in human lens. *GCNT2C* (*IGnTC*) is an erythroid-specific enzyme that is responsible for I antigen expression on red cells. *GCNT2* is highly homologous to *C2GnT*, a  $\beta 1 \rightarrow 6$  *n*-acetylglucosaminyltransferase responsible for I-type structures on core 2 and core 3 O-glycans.<sup>158</sup>

The enzyme is 400–402 amino acids long and, unlike most glycosyltransferases, does not require a metal ion for enzyme activity.<sup>153</sup> The enzyme retains nine highly conserved cysteines necessary for enzyme folding and five N-glycans but lacks the classic DXD motif found in metal-dependent transferases. Exon 1 encodes 77% of the translated protein, including the transmembrane domain, stem region, and UDP-nucleotide binding domain (UDP-GlcNAc).<sup>150,153</sup> The acceptor domain is primarily encoded by exons E2 and E3. Due to sequence differences in exon 1, the three *GCNT2* isoforms share only 66–73% homology and subtly differ in enzyme activity. In enzyme assays, the erythroid-specific *GCNT2C* isoform shows nearly twofold higher enzyme activity.<sup>153</sup>

*GCNT2C* is transcriptionally regulated in red cells.<sup>159–161</sup> Studies have identified a promoter sequence approximately 250 base pairs (−318 to −251) upstream of the E1C translation initiation site that contains transcription factor binding sites for Oct-2, Sp1, and C/EBP $\alpha$ . All three transcription factors bind the *GCNT2C* promoter region; however, only C/EBP $\alpha$  is absolutely critical for *GCNT2C* transcription. Interestingly, C/EBP $\alpha$  binding and transcriptional activation require dephosphorylation of a specific serine (Ser-21) on C/EBP $\alpha$ , via ERK and SHP2 pathways.<sup>159,161</sup> Phosphoserine

**Figure 9.3** (A) Structure of the I gene (*GCNT2*) and three mRNA isoforms. (B) Synthesis of I antigen from i-active polygalactosamine precursor.

residues are known to regulate C/EBP $\alpha$  function in early hematopoiesis and myeloid differentiation.<sup>159</sup>

*GCNT2C* is also regulated via methylation and microRNA (miRNA) interactions.<sup>161</sup> In early erythroblasts, *GCNT2* is hypermethylated with transcriptional silencing. Upon differentiation, there is demethylation of a critical CpG within the proximal promoter that permits *GCNT2* transcription. In colon, CpG residues within exon E1B are key to *GCNT2* transcription and enzyme expression.<sup>162</sup> Finally, the miRNAs Let-7 and 199 are implicated in downregulating *GCNT2* transcription in red cells and colon, respectively.<sup>161</sup> Two miRNA-199 binding sites were identified in the 3' UTR, although only the site proximal to the poly-A tail appears to play a role in suppressing *GCNT2* expression.<sup>163</sup>

### The molecular basis for *i<sub>adult</sub>*

Mutations in *GCNT2* are responsible for the *i<sub>adult</sub>* phenotype.<sup>20,150,161</sup> Individuals with mutations in E1C, which is responsible for the erythroid-specific *GCNT2C*, show an isolated loss of I antigen expression in red cells only; I expression is retained in other tissues via *GCNT2A* and *GCNT2B*.<sup>152</sup> These individuals are not at an increased risk for congenital cataracts (Table 9.5). Three previously identified *i<sub>adult</sub>* alleles have been reclassified as causing very weak I expression.<sup>161</sup>

The *i<sub>adult</sub>* with congenital cataracts is the result of mutations affecting all three *GCNT2* isoforms, leading to a tissue-wide loss of all enzyme activity.<sup>153</sup> To date, seven-point mutations have been identified in E2 and E3, which are shared by all three enzyme isoforms. In four unrelated kindreds, large deletions (70–93 kb) encompassing most of *GCNT2* (exons E1B, E1C, E2, and E3) were identified. Because *GCNT2* resides in an *Alu*-rich region, it may be particularly susceptible to *Alu*-mediated deletion and genomic rearrangements.<sup>157</sup>

It is presumed that the absence of branched N-glycans in human lens underlies the development of congenital cataracts. This has not been substantiated in a *GCNT2*-null mouse model.<sup>164</sup> *GCNT2*-null mice had no apparent increase in either the incidence or onset of cataracts. This conundrum may reflect species-specific differences in glycan expression. Indirect evidence for the latter is the early development of cataracts in *A3GALT*-null mice, which are unable to synthesize oligosaccharides containing Gal $\alpha$ 1 → 3Gal (linear B) epitopes.<sup>165</sup>

### Transfusion

Anti-I is a common, low-titer, IgM cold agglutinin in normal human sera.<sup>150</sup> Anti-I can demonstrate significant crossreactivity with i epitopes and can show a preference for polylactosamines bearing sialic acid or ABH epitopes. Anti-i, by contrast, is less frequent. Anti-i is commonly associated with infectious mononucleosis, Burkitt's lymphoma, and cirrhosis.<sup>11,150</sup> Many examples of anti-i are sialoagglutinins with a preference for linear structures bearing a terminal sialic acid.<sup>150</sup>

An increase in anti-I/i titers and/or thermal amplitude is not uncommon following infection and in certain lymphoproliferative disorders. B cell malignancies, in particular, can secrete high-titer, monoclonal autoantibodies capable of inducing hemolysis and cold agglutinin disease. In cold agglutinin disease, monoclonal antibodies classically bear the V<sub>H</sub>4–34 IgM heavy gene, which inherently recognizes lactosamine due to the terminal FR1 domain of the molecule.<sup>166</sup> Cold agglutinin disease also displays light chain preferences with clonal rearrangements of the IGKV3-20 gene and CDR3 regions, which may contribute to fine differences in antigen specificity (anti-I vs anti-i).<sup>167,168</sup> In contrast, anti-I/i coincident with infection are polyclonal and reflect a global increase in IgM antibody.<sup>150</sup>

In general, antibodies against anti-I/i are clinically insignificant.<sup>11</sup> However, blood typing difficulties and hemolysis can be observed in patients with high-titer antibodies, particularly if there is strong reactivity above 30–32 °C. These patients may require the use of a blood warmer for transfusion. There are rare cases of hemolytic transfusion reactions with warm-acting anti-IH following transfusion of group O or A<sub>2</sub> red cells.<sup>169</sup>

### Biological roles

#### Hemolytic disease of the fetus and newborn

There is a theory that the absence of I antigen on cord red cells is protective against HDFN due to ABO incompatibility. There is a parallel increase in both I and A/B antigens in the first few months of life, consistent with increasing erythroid *GCNT2C* activity.<sup>150</sup> Supporting evidence for the key role of branching in ABH expression can be found on the bi-antennary N-glycan of Band 3/Diego. On cord cells, the N-glycan is relatively simple and unbranched, with few ABH epitopes on the long, linear α1,6 mannose arm.<sup>150,170</sup> In contrast, adult red cells display a massive N-glycan with extensive β1–6 branching along both α1,6 and α1,3 arms, allowing display of multiple ABH epitopes per N-glycan.<sup>7,150</sup>

**Table 9.5** *GCNT2* Mutations Associated with *i<sub>adult</sub>* Phenotype

Exon	Mutation		Phenotype

Deletion	D189 kb	E1A- > E3	+	+	–

Nucleotide and amino acids are based on *GCNT2C*, which is 402 amino acids long. Note that many publications have listed mutations based on *GCNT2A*, which is 400 amino acids long. (+) is a presumed red cell phenotype based on genetic sequence.

## Galectins

Galectins are a family of highly conserved galactose binding proteins that recognize lactosamine via a 130 amino-acid-long carbohydrate binding domain.<sup>171</sup> Galectin families differ in the size and location of the lactosamine epitope (disaccharide or repeating lactosamine tetrasaccharide; terminal or internal), and their ability to tolerate branching, sialylation, and fucosylation. In general, glycoproteins bearing several large, complex, branched N-glycans with long extended polylactosamines are the preferred receptors for galectins.<sup>161,171</sup>

Galectin binding to N-glycans is believed to create an extracellular lattice structure several angstroms above the lipid membrane.<sup>171</sup> As such, galectins are integral for protein–protein interactions and the composition and function of membrane microdomains. In B-cells, Gal-9 binding to i-active glycans on CD45 have been shown to modulate CD45–CD22 interaction and B cell signaling.<sup>172</sup> Gal-3 binding to i-active glycans on melanoma contribute to tumor growth and metastasis.<sup>173</sup>

## Embryonic and hematopoietic development

I/i antigens are differentially expressed during embryonic development and are considered oncofetal antigens.<sup>150,161</sup> GCNT2 is one of the 90 proteins identified as markers of human embryonic stem cells.<sup>161</sup> In human hematopoiesis, GCNT2 mRNA is weakly expressed by the earliest pluripotent progenitors but is lost with leukocyte differentiation.<sup>161</sup> Aberrant GCNT2 expression is found in mycosis fungoides and adult T-cell leukemia/lymphoma.<sup>174,175</sup> Interestingly, lymphoid and myeloid leukemia cells that express I antigen appear more susceptible to killing by NK cells, possibly through altered interaction with death ligands.<sup>176</sup>

The i antigen was identified as a marker of human mesenchymal stem cells and might serve as a ligand for galactin-3.<sup>177</sup> Galectin-3 is abundantly expressed and secreted by macrophages and is implicated in giant cell formation, dendritic cells, fibrosis, and chronic inflammation.<sup>178</sup> Galactin-3 is hypothesized to play a role in the immunosuppressive properties of mesenchymal stem cells. Galactin-3 also binds and directly activates human neutrophils, promoting neutrophil recruitment, adhesion, and respiratory burst.<sup>177</sup>

## Breast, prostate, and colon cancer

GCNT2 is overexpressed in highly metastatic and basal-like breast cancer cells and was recently identified as a possible disease modifier in BRCA2 breast cancer.<sup>179</sup> A GWA study identified a polymorphism (rs9348512) located on chromosome 6p24, within 1 MB of GCNT2. Homozygosity for the minor “A” allele was associated with a 15% decreased risk of developing breast cancer and correlated with GCNT2 mRNA levels. Furthermore, GCNT2 overexpression promoted breast cancer cell migration, adhesion, and invasion.<sup>173,180</sup> Similar findings have been found in prostate cancer, where high GCNT2 mRNA is linked to cell invasion and extracapsular disease.<sup>173,181</sup> In breast cancer, GCNT2 upregulation is dependent on tumor growth factor  $\beta$ /Smad signaling and may facilitate the mesenchymal–epithelial transition (MET)—an early critical step in epithelial cancers.<sup>163</sup> GCNT2 upregulation has also been linked to MET, tumor depth, and lymphatic spread in colon cancer.<sup>161,162</sup>

## Melanoma

Unlike epithelial cancers, GCNT2 is downregulated in melanoma and is a biomarker for metastatic disease.<sup>173,182</sup> A study of N-glycans on melanoma shows predominantly simple, i-active polylactosamines. Transfection of melanoma cell lines with GCNT2 led to a

decrease in cell signaling, cell activation, and tumor growth.<sup>182</sup> The mechanism behind GCNT2 downregulation is unknown. Rare cases of familial melanoma have been linked to large chromosomal deletions and GCNT2 loss.<sup>161</sup>

## P blood group system

The system historically known as the *P blood group* was initially discovered in 1927 by Landsteiner and Levine after immunizing rabbits with human red cells.<sup>183</sup> The resulting antibody recognized the P<sub>1</sub> antigen, which is variably expressed on most, but not all, human red cells. The P<sup>k</sup> and P antigens were added to the system after the discovery of rare null phenotypes. The historical P system has now expanded into three blood group systems and six serologic antigens, which are assigned based on the last glycosyltransferase necessary for their synthesis.<sup>184</sup> The P1PK system (ISBT 003) encompasses P<sup>k</sup>, P<sub>1</sub>, and NOR antigens, which all share a terminal  $\alpha 1 \rightarrow 4$ Gal epitope. GLOB (ISBT 028) contains the P and PX2 antigens, which terminate in a  $\beta 1 \rightarrow 3$ GALNAc. FORS (ISBT 031) contains a single antigen, Forssman—a xenoantigen expressed by many animals and rare A<sub>par</sub> red cells. *Luke antigen on erythrocytes* (LKE) is a high-incidence antigen that is still classified under the GLOB collection 209. Other related antigens include galactosygloboside, globo-H, and globo-A antigens. Globo-A is a target for anti-A<sub>1</sub>, whereas globo-H, galactosygloboside, and LKE are oncofetal antigens found on stem cells and many epithelial cells.<sup>185</sup>

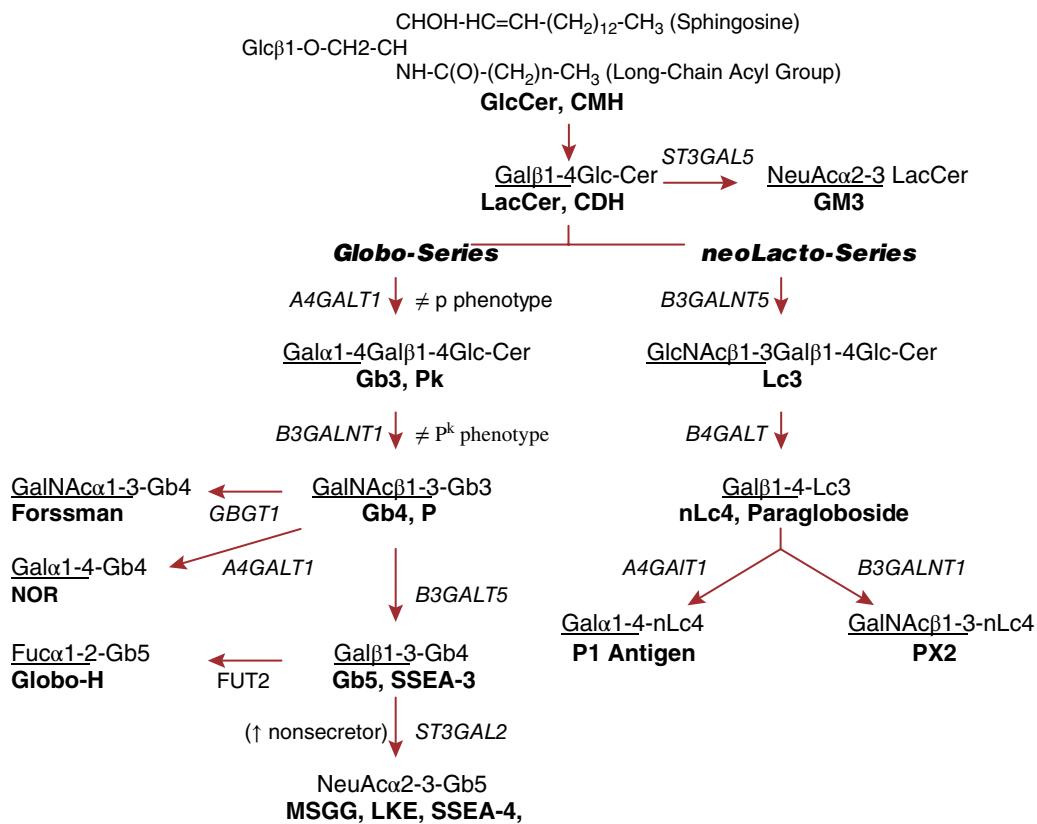

## Biochemistry and synthesis

Unlike ABH, Ii, and Lewis antigens, the antigens of the P system are almost exclusively expressed on glycosphingolipids (GSLs). Chemically, GSLs consist of a carbohydrate head covalently linked to a ceramide lipid tail (*N*-acylsphingosine), which anchors the molecule in the membrane. Most members of the P-system belong to the globoseries of GSLs and share a Gal $\alpha 1 \rightarrow 4$ Gal $\beta 1 \rightarrow 4$ Glc-Ceramide or Gb3 core (Table 9.6). Exceptions are P<sub>1</sub> and PX2, which are type 2 chain, neolacto GSLs derived from paragloboside. A trace amount of P<sub>1</sub> can also be found on red cell N-glycans.<sup>186</sup>

**Table 9.6** GSL Structures Related to Globo, P1, and PX2 Synthesis

GSL	Alias	Structure

**Figure 9.4** Synthesis of P blood group and related glycosphingolipid antigens.

Lactosylceramide (LacCer) is the precursor of both globo- and type 2 chain GSLs (Figure 9.4). Globo-family GSLs proceed from the addition of an  $\alpha 1 \rightarrow 4$ Gal to LacCer by A4GALT1 to form globotriaosylceramide (Gb3, P<sup>k</sup>), the first globo-family GSL. Gb3/P<sup>k</sup> may then serve as a substrate for B3GALNT1, which adds a terminal  $\beta 1 \rightarrow 3$ GalNAc to form globoside (Gb4, P antigen). In animals and rare A<sub>Pae</sub> cells, globoside/P antigen is further modified by the addition of an  $\alpha 1 \rightarrow 3$ GalNAc to form Forssman antigen.<sup>184</sup> The rare NOR antigen shares features of both P<sup>k</sup> and P antigens, with an  $\alpha 1 \rightarrow 4$ Gal terminus on a Gb4/P antigen core.<sup>187</sup>

Synthesis of LKE and extended globo-family antigens requires B3GALT5, which adds a terminal  $\beta 1 \rightarrow 3$ Gal to form galactosylgloboside or Gb5.<sup>185</sup> B3GALT5 is a rate-limiting enzyme for both Gb5 and type 1 chain synthesis and shows developmental and tissue-specific expression.<sup>188</sup> Once formed, Gb5 can serve as a substrate for H-active fucosyltransferases to form globo-H.<sup>9,10</sup> In A<sub>1</sub> individuals, globo-H is converted to globo-A: expression of globo-A is believed responsible for antigenic differences between A<sub>1</sub> and A<sub>2</sub> red cells.<sup>16</sup>

Gb5 can also be sialylated by the  $\alpha 2,3$ sialyltransferase ST3GAL2 to form LKE antigen (MSGG and SSEA-4).<sup>185</sup> In genitourinary tissue, there is competition between FUT2 and ST3GAL2 for Gb5, leading to decreased LKE/MSGG synthesis on epithelial cells of secretors (Se<sup>+</sup>).<sup>189</sup> In some tissues, including red cells, LKE is further sialylated to form disialogalactosylgloboside (DSGG).<sup>190</sup> In human platelets, a minor GSL with a Gb5 core and terminal  $\alpha 1 \rightarrow 4$ Gal was identified in 10–20% of donors.<sup>191</sup>

A4GALT1, the enzyme responsible for P<sup>k</sup> synthesis, is also capable of recognizing paragloboside to form P<sub>1</sub> antigen. Unlike P<sup>k</sup>, P<sub>1</sub> is a minor red cell GSL with variable expression. Paragloboside can also serve as an alternate substrate for B3GALNT1 to form PX2, a

P-active GSL recognized by some allo-anti-P.<sup>184</sup> Synthesis of PX2 is limited to rare p null phenotypes, which lack Gb3/P<sup>k</sup> (see the “Serology” section).

### Serology

**P<sub>1</sub>/P<sub>2</sub>:** The classic P system contains two main phenotypes, P<sub>1</sub> and P<sub>2</sub>. P<sub>1</sub> and P<sub>2</sub> have normal expression of globo-series antigens and only differ in the expression of P<sub>1</sub> antigen (Table 9.7). P<sub>1</sub> is the predominant phenotype in most populations and can vary in strength between individuals. The P<sub>2</sub> (P<sub>1</sub>-negative) phenotype ranges from 6% in Blacks to 75–80% in some Asian populations (China and Vietnam).<sup>20,74</sup> The P<sub>1</sub> antigen is absent on p cells (see below). P<sub>2</sub> individuals can make a naturally occurring anti-P<sub>1</sub>.

**P<sup>k</sup>:** P<sup>k</sup> is a rare autosomal-recessive phenotype due to homozygous inheritance of null B3GALNT1 alleles. P<sup>k</sup> can occur on either a P<sub>1</sub> or P<sub>2</sub> background, giving rise to P<sub>1</sub><sup>k</sup> or P<sub>2</sub><sup>k</sup> phenotype, respectively (Table 9.7). P<sup>k</sup> red cells lack Gb4/P and all subsequent globo-series GSLs (LKE, globo-H), accompanied by increased expression of P<sup>k</sup>/Gb3, LacCer, and type 2 chain GSLs (paragloboside and sialylparagloboside).<sup>184,192</sup> P<sup>k</sup> variants, with increased P<sup>k</sup>/Gb3 and decreased Gb4/P, have been described and may reflect decreased B3GALNT1 activity.<sup>192</sup> P<sup>k</sup> individuals make a potent, clinically significant allo-anti-P that is reactive with all red cells except rare P<sup>k</sup> and p cells. Anti-P can contain reactivity against PX2 as well as other globo-GSLs (Gb5 and LKE).<sup>184,192</sup>

**p null:** The p phenotype is a true globo-null phenotype due to homozygosity for amorph A4GALT1 alleles.<sup>184</sup> Red cells and other tissues lack P<sub>1</sub> and all globo-GSL (Figure 9.4). Red cells show a compensatory increase in type 2 chain GSLs, including paragloboside and PX2. Heterozygous individuals (A4GALT1+/-) show normal

globo-GSL expression with no evidence of gene dosage. Sera from p individuals contain a mix of naturally occurring IgM agglutinins crossreactive with P<sub>1</sub>, P, and P<sup>k</sup> cells (allo-anti-PP<sub>1</sub>P<sup>k</sup>). In solid phase testing, anti-P<sup>k</sup> and anti-P are the predominant specificities.<sup>192</sup>

**LKE:** LKE, also known as Luke, is a minor, high-incidence ganglioside on red cells. There are three recognized LKE phenotypes: LKE-strong positive (LKE<sup>S</sup>), LKE-weak positive (LKE<sup>W</sup>), and LKE-negative (LKE<sup>N</sup>). LKE<sup>N</sup> red cells often show a P<sup>k</sup> variant-like phenotype, with increased P<sup>k</sup>/Gb3 and decreased Gb4 expression.<sup>193</sup> LKE<sup>N</sup> can also occur in weak P red cells, which have marked decrease in Gb3 and Gb4 expression.<sup>192</sup> In P<sub>1</sub> and P<sub>2</sub> individuals, LKE<sup>N</sup> is associated with trace LKE/MSGG (10% normal) on red cells: true LKE-null is only observed in p and P<sup>k</sup> phenotypes.<sup>192</sup> LKE/MSGG is also known as stage-specific embryonic antigen-4 (SSEA4) and is a marker of embryonic, mesenchymal, and cancer stem cells.<sup>9,185,194</sup>

**NOR:** NOR is a rare polyagglutinable phenotype that appears to have arisen in a Polish kindred.<sup>184,187</sup> NOR red cells express unusual penta- and hepatoglycosylglobo-GSLs that bear a Galα1 → 4GalNAc terminus (Table 9.6). Normal human sera contain two classes of naturally occurring antibodies reactive with NOR, with slightly different specificities: type 1, anti-P<sup>k</sup>+NOR and type 2, anti-NOR. NOR is not recognized by anti-P<sub>1</sub>.

**Forssman:** Forssman is a very rare polyagglutinable human phenotype with weak antigen expression, even in Fors+ individuals.<sup>195</sup> Nearly all human sera contain low levels of naturally occurring anti-Forssman. Because the Forssman antigen is commonly expressed by many animal species, Forssman antibodies are major barriers to xenotransplantation.<sup>196</sup> Anti-Forssman can interfere with the monospot test, which reacts sera against sheep or horse red cells, and was used as a rapid screen for patients with suspected infectious mononucleosis. Since both Forssman and A antigen share a common terminal GalNAc, human anti-A can crossreact with Forssman antigen.<sup>197</sup>

## Genetics and molecular biology

### P1PK synthase (A4GALT1)

A4GALT1 encodes an α1,4 galactosyltransferase responsible for P<sup>k</sup>, P<sub>1</sub>, and NOR antigen synthesis.<sup>184</sup> A4GALT1 resides on chromosome 22q13 and is organized into three exons, with the active enzyme localized within exon 3. A4GALT1 belongs to the GT32 family of glycosyltransferases and shares 43% homology with A4GNT, an α1,4 galactosyltransferase involved in gastric mucin

synthesis.<sup>198</sup> A4GALT1 mRNA is ubiquitously expressed in most human tissues.<sup>42</sup>

The predominant enzyme in P<sub>1</sub> and P<sub>2</sub> individuals is a 353-amino-acid type II glycoprotein containing two N-glycosylation sites, five cysteine residues, and a classic DXD motif.<sup>198</sup> There is evidence that A4GALT1 resides in the *trans*-Golgi network, possibly in a heterodimeric complex with LacCer synthase.<sup>199</sup> Synthesis of Gb3 and other globo-GSLs can be suppressed by competing glycosylation pathways, altered Golgi trafficking, and lysosomal degradation.<sup>199–202</sup>

The basis of the P<sub>1</sub>/P<sub>2</sub> phenotype took considerable effort to uncover. Originally, the P<sub>2</sub> phenotype was linked to polymorphisms in the promoter region (−551insC and −160A).<sup>203</sup> Subsequently, Thursson *et al.* identified a minor A4GALT1 mRNA transcript utilizing an alternate exon (exon 2a) that contained a SNP (42C > T) in European P<sub>2</sub> individuals.<sup>204</sup> A later, large systematic study identified one SNP (3084G > T; rs4741348) with P<sub>2</sub> and decreased A4GALT1 transcription.<sup>205</sup> The site was subsequently shown to bind the RUNX1 transcription factor.<sup>206</sup> A4GALT1 does show evidence of gene dosage, where A4GALT1 levels are highest in P<sup>1</sup>/P<sup>1</sup> > P<sup>1</sup>/P<sup>2</sup> > P<sup>2</sup>/P<sup>2</sup>.<sup>204,205</sup>

The NOR phenotype is the result of a missense mutation (Gln211>Glu) in the catalytic domain of the enzyme.<sup>207</sup> A comparison of A4GALT1 sequences from humans, gorilla, pig, cattle, rat, and mouse indicates that Q211 is a conserved amino acid. It is hypothesized that the mutation broadens acceptor substrate specificity, allowing the enzyme to recognize either a β-Gal or β-GalNAc acceptor.<sup>207</sup> The p phenotype can arise from a variety of missense, frameshift, nonsense, and deletion mutations. Over 30 amorph A4GALT1 alleles are described to date.<sup>20,184</sup>

### P synthase (B3GALNT1)

B3GALNT1 is located on chromosome 3q26 and encodes a β1 → 3 n-acetylgalactosaminyltransferase responsible for P and PX2 antigen synthesis.<sup>20,184</sup> Originally named B3GALT3, B3GALNT1 is a member of the GT31 family of glycosyltransferases and is ubiquitously expressed in most human tissues.<sup>42,208</sup> The gene contains five exons with the open reading frame located in exon 5. The translated enzyme is 331 amino acids with three β1,3 galactosyltransferase motifs, five potential N-glycans, and six cysteines, including four cysteines conserved among other β1,3 galactosyltransferases.<sup>208</sup> Fourteen null alleles associated with the P<sup>k</sup> phenotype are reported to date.<sup>20</sup>

### Forssman synthase (GBGT1)

*GBGT1* encodes an  $\alpha 1 \rightarrow 3$ galactosaminyltransferase belonging to the GT6 family of  $\alpha 1,3$ -Gal/GalNAc transferases and is responsible for Forssman synthesis.<sup>195,209</sup> Members of the GT6 family arose from a common ancestral gene and includes the *ABO* gene, isogloboside synthase (*A3GALT2*), and the enzyme necessary for linear B synthesis (*GGTA1*).

*GBGT1* is located on chromosome 9q34 as a pseudogene.<sup>209</sup> Like the *ABO* gene, the open reading frame is spread over several exons. Surprisingly, *GBGT1* mRNA can be detected in a wide host of human tissues despite the absence of Forssman expression. The absence of Forssman antigen in humans and apes is the consequence of two inactivating mutations (Gly230Ser; Gln296Arg) that arose late in primate evolution. Using recombinant enzyme constructs, Yamamoto and colleagues were able to restore enzyme activity in human *GBGT1*, where Gly230+Gln296 > Gly230 > Gln296.<sup>209</sup> Gly230 is homologous to Gly235 in the human *ABO* gene, which is crucial for UDP-GalNAc and H-antigen acceptor recognition. Forssman expression on rare A<sub>pa</sub>e red cells is due to an Arg296 > Gln mutation that restores partial enzyme activity. It is hypothesized that de novo Forssman expression reported in some cancers could reflect a similar process.<sup>209</sup>

### Transfusion medicine

P<sub>2</sub> individuals can make a naturally occurring anti-P<sub>1</sub>, a low-titered, IgM agglutinin.<sup>11</sup> Anti-P<sub>1</sub> is generally clinically insignificant, although rare acute hemolytic transfusion reactions have been reported. High-titer anti-P<sub>1</sub> can be observed in bird fanciers and certain Helminth infections due to the presence of P<sup>k</sup>- and P<sub>1</sub>-like substances in bird droppings and parasites.<sup>11,74</sup> Although there is no evidence that anti-P<sub>1</sub> is advantageous against Helminth infections, it is interesting that the highest incidence of P<sub>2</sub> occurs in regions with a high incidence of *Echinococcus* infection.<sup>74</sup>

Unlike anti-P<sub>1</sub>, the allo-anti-PP<sub>1</sub>P<sup>k</sup> and allo-anti-P present in p and P<sup>k</sup> individuals are always clinically significant antibodies, capable of causing acute hemolytic transfusion reactions.<sup>11</sup> Patients require rare antigen-negative units for transfusion. Females are also at risk for recurrent miscarriages, even at relatively low antibody titers.<sup>210,211</sup> Miscarriage tends to occur in the first trimester due to P and P<sup>k</sup> antigen expression on the fetal placenta. Early intervention has been used with variable success including plasma exchange, IVIG, steroids, and aspirin.<sup>210</sup>

A hemolytic auto-anti-P is the most common antibody specificity observed in paroxysmal cold hemoglobinuria (PCH). Patients typically present with acute hemolysis, a positive DAT (IgG-negative, C3-positive) and a negative antibody screen. The antibody is a biphasic, low affinity IgG hemolysin that binds red cells and fixes complement at cool temperatures but dissociates at 37°C. The Donath-Landsteiner test is required to confirm PCH. PCH patients can be safely transfused with P+ units through a blood warmer.<sup>212</sup>

Anti-LKE is rare, with only six known cases.<sup>192</sup> Most examples of anti-LKE were low-titer, IgM antibodies and clinically insignificant. There is one report of a hemolytic transfusion reaction associated with a high-titer anti-LKE in a patient with newly diagnosed lymphoma.<sup>192</sup>

### Biological role

#### Development and cancer

Globo-GSLs are expressed on embryonic stem cells, where they may play a role in development. Two extended globo-GSLs, Gb5 (SSEA-3) and LKE/MSGG (SSEA-4), are markers of embryonic

stem cells, embryonic carcinoma, and teratocarcinomas.<sup>213</sup> In vitro studies with human embryonal carcinoma cell lines have shown homotypic cell-cell adhesion and signaling mediated by Gb4-Gb5 interactions.<sup>214</sup> In murine embryos, LKE/MSGG-enriched lipid rafts participate in cytokinesis, localizing along the cleavage furrows in cooperation with actin and E-cadherin.<sup>215</sup> In mice, the deletion of *B3GALNT1*, with loss of Gb4, Gb5, and MSGG, is embryonic lethal.<sup>216</sup>

Several globo-GSLs are increased in malignancy and serve as cancer markers. Gb3 is elevated in Burkitt's lymphoma and is a marker of apoptotic germinal center B cells.<sup>184</sup> Globo-H, Gb5, and MSGG are expressed by breast cancer and cancer stem cells.<sup>9,217</sup> In breast cancer, Gb5- and MSGG-enriched lipid rafts contribute to tumor invasion and resistance to apoptosis through their interaction with integrins, cSrc, FAK, AKT, and RIP.<sup>217,219</sup> A MSGG-binding protein FKBP4 was recently identified in breast cancer cells.<sup>218</sup> In vitro studies have shown that de novo MSGG synthesis is associated with a decreased adhesion and epithelia phenotype consistent with a mesenchymal–epithelial transition (MET, see I blood group).<sup>220</sup> Finally, MSGG and/or disialosylgalactosylgloboside (DSGG) are elevated on renal cell carcinoma.<sup>190,221</sup> DSGG binds siglec-7 and is associated with pulmonary metastasis and inhibition of NK cells.<sup>221,222</sup>

#### Immune response

Gb3 is expressed on B-cells and may serve as a stimulatory glycolipid antigen for iNKT cells.<sup>223</sup> In addition, Gb4 was identified as an endogenous ligand for toll-like receptors (TLRs), a member of the innate immune system expressed on monocytes, spleen, and phagocytic cells.<sup>224</sup> In Gram-negative sepsis, the TLR4-MD2 complex binds bacterial LPS via the lipid A tail, triggering an intense inflammatory response. In *A4GALT1*-knockout mice, exogenous Gb4 administration can reduce LPS-induced inflammation and mortality by binding TLR4-MD2 and blocking LPS binding. In wild-type mice, LPS upregulates *A4GALT1* transcription with upregulation of Gb4 synthesis, coupled with the recruitment of TLR4-MD2 into Gb4-enriched lipid rafts.

### Parvovirus B19 and HIV

P antigen is a cofactor for parvovirus B19 on red cells, the causative agent of erythema infectiosum or fifth disease.<sup>74</sup> B19 is an erythrovirus, preferentially infecting marrow erythroblasts, resulting in reticulocytopenia, anemia, and, on occasion, aplastic crisis and pure red cell aplasia. Erythroblasts may be particularly susceptible to B19 due to their high concentration of Gb4.<sup>74</sup> P<sup>k</sup> and p individuals, who lack P antigen, are resistant to B19 infection. Current research suggests that infection requires a two-step process, in which B19 initially binds Gb4 or related glycolipid, leading to a conformational change in the viral capsid.<sup>225,226</sup> The modified B19 can then bind a secondary receptor that is likely localized within a lipid raft and undergoes clathrin-mediated endocytosis.<sup>225</sup> Although P antigen is not mandatory for viral binding, P antigen appears to be required for productive viral infection.<sup>226</sup>

GSL-enriched lipid rafts play an important role in HIV fusion, endocytosis, and HIV budding.<sup>227</sup> In human lymphoid cells, there is an inverse relationship between Gb3 and HIV infection. Lymphocytes from p individuals are hypersusceptible to HIV in vitro, whereas lymphocytes from P<sup>k</sup> donors, or patients with Fabry disease, are HIV resistant.<sup>228,229</sup> Other investigators, on the other hand, have identified Gb3 as a coreceptor, facilitating the interaction between HIV, CD4, and CXCR4.<sup>230</sup>

### **Shigella, E. coli, and Streptococcus suis**

*Shigella dysenteriae* and enterohemorrhagic *E. coli* express shiga toxins (Stx) that recognize GSLs bearing a terminal Gal $\alpha$ 1 → 4Gal epitope, including P<sub>1</sub>, Gb<sub>3</sub>, and “band 0.03.”<sup>74</sup> Gb3, however, is the physiologic receptor in infection and development of hemolytic uremic syndrome (HUS). Gb3-enriched lipid rafts are necessary for toxin binding, Stx-mediated cell signaling, and endocytosis. Six studies have examined the correlation between P<sub>1</sub>/P<sub>2</sub> phenotype, HUS, and clinical outcomes, with mixed results.<sup>74</sup> A study from the *E. coli* O157:H7 network, however, found a fourfold increased risk of HUS in P<sub>1</sub><sup>strong</sup> individuals.<sup>231</sup> Gb3 is also a receptor for *S. suis*, a pathogen of pigs that can cause life-threatening infections in humans.<sup>74</sup>

Globo-GSLs are also receptors for P-fimbriated, uropathogenic *E. coli* strains. P-fimbriae recognize all globo-GSLs, although LKE/MSGG is the preferred receptor in solid phase testing. The ability of FUT2 to decrease MSGG synthesis is likely responsible for the 3.4–26-fold higher incidence of UTI in nonsecretors.<sup>232,233</sup> The impact of the P<sub>1</sub>/P<sub>2</sub> phenotype on *E. coli* UTI is less clear. Early pediatric studies showed a slight increase in UTI and recurrent pyelonephritis in P<sub>1</sub> children.<sup>74</sup> In contrast, studies in adults have found little or no association between UTI and P<sub>1</sub> phenotype.<sup>232</sup>

### **Sd<sup>a</sup> (SID)**

The Sd<sup>a</sup> antigen or SID was named after a longtime volunteer blood donor (Sidney) at the London Lister Institute.<sup>234</sup> First described in 1967, it was officially designated as a blood group by ISBT in 2019. Sd<sup>a</sup> is widely expressed on human tissues including red cells, stomach, colon, and kidney, where Sd<sup>a</sup> is most commonly associated with the Tamm–Horsfall (uromodulin) protein along the distal convoluted tubules and collecting ducts.<sup>235</sup> In the intestine, there is an inverse expression of Sd<sup>a</sup> and ABH, with Sd<sup>a</sup> predominant in the descending colon.<sup>236</sup> Sd<sup>a</sup> is also found in fluids such as saliva, serum, milk, meconium, and urine.<sup>237</sup> Sd<sup>a</sup> is also expressed on many animal tissues and fluids. Although Sd<sup>a</sup> is not considered a clinically significant antigen for transfusion, Sd<sup>a</sup> is currently recognized as an important carbohydrate antigen in cancer and xenotransplantation.

### **Serology and transfusion**

Sd<sup>a</sup> is a high incidence red cell antigen with variable expression and autosomal dominant inheritance.<sup>32</sup> Accurate Sd<sup>a</sup> typing requires both RBC and urine since nearly half of individuals with Sd(a–) red cells still express Sd<sup>a</sup> on other tissues and fluids, like urine.<sup>235</sup> In many ways, Sd<sup>a</sup> phenotyping is similar to determining “secretor status,” in which individuals can type as Le(a–b–) but still secrete ABO antigens in urine (see the Lewis blood group, earlier).

The majority (90%) of donors express weak Sd<sup>a</sup> (+ to 1+; Sda+), with <1% of donors typing as Sd<sup>a</sup> strong (2+, Sda++).<sup>235</sup> CAD, a very rare polyagglutinable phenotype, is also strongly Sd<sup>a</sup>-positive (sometimes referred to as “super Sd<sup>a</sup>”).<sup>32</sup> Approximately 9% of donors are negative for Sd<sup>a</sup> on red cells; however, nearly half of these donors are found to secrete Sd<sup>a</sup> in urine. As a result, only 4% of donors are considered true Sd(a–).<sup>235</sup> Sd<sup>a</sup> is absent on cord cells but is present by 10 weeks of age. Sd<sup>a</sup> is reported on i<sub>adult</sub> cells.<sup>32</sup>

Anti-Sd<sup>a</sup> is a naturally occurring IgM antibody, reactive at room temperature.<sup>32</sup> The reaction gives a characteristic mixed field appearance, with small red cell agglutinates in a field of unagglutinated cells. This mixed field agglutination can give a “shimmering appearance” similar to that described for some Lutheran antibodies

(e.g., anti-Lu<sup>a</sup>). Antibody inhibition is used to confirm Sd<sup>a</sup> specificity by incubating samples with guinea pig urine, which is a particularly rich source of Sd<sup>a</sup> substance. Pooled, concentrated human urine can also be used but is less inhibitory than guinea pig urine.<sup>235</sup> Sd<sup>a</sup> inhibitory substance is not available commercially and requires local collection and processing of urine.

Anti-Sd<sup>a</sup> is identified in ~1% normal donors when tested against common Sd(a+) red cells.<sup>32</sup> A higher frequency is observed when testing donors against Sd(a++) strong red cells, and nearly all donors will react to rare polyagglutinable CAD cells.<sup>32</sup> Anti-Sd<sup>a</sup> is not clinically significant and is not associated with HDFN, transfusion reactions, or shortened red cell survival.

### **Biochemistry and synthesis**

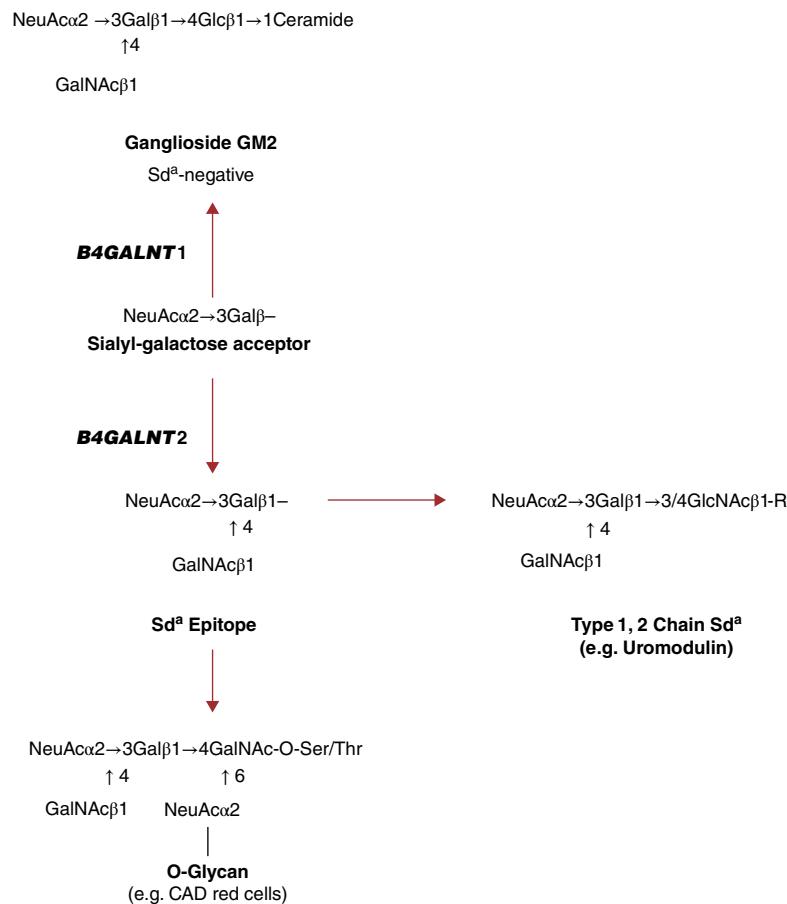

Sd<sup>a</sup> is a terminal, sialylated trisaccharide epitope characterized by an immunodominant β1-4GalNAc. Sd<sup>a</sup> synthesis is dependent on the N-acetyl-galactosaminyltransferase B4GALNT2, which recognizes the sialylated disaccharide NeuAcα2 → 3Gal-R.<sup>235</sup> The enzyme adds a GalNAc, in a β1 → 4 linkage, to the subterminal Gal, resulting in the trisaccharide GalNAcβ1 → 4(NeuAcα2 → 3)Gal-R. Studies have shown a strict requirement for the terminal sialic acid (NeuAcα2 → 3Gal) for enzyme activity.

As shown in Figure 9.5, the Sd<sup>a</sup> trisaccharide can be expressed by an array of different glycan scaffolds (glycolipids, N- and O-glycans) and chain types (type 1, type 2, branched; O-glycan cores 1–4). The nature of the Sd<sup>a</sup>-active antigen on red cells is still not clear. In the rare polyagglutinable phenotype CAD, Sd<sup>a</sup>-type structures were identified on glycophorin A and trace type 2 chain gangliosides; however, these same antigens were not identified in Sd<sup>a+</sup>, CAD-red cells.<sup>32,235</sup> Like Lewis antigens, Sd<sup>a</sup> may represent an adsorbed glycolipid antigen based on some serologic findings including (1) resistance to enzymes; (2) absence on cord cells; (3) presence in plasma, saliva, and urine; (4) decrease/loss during pregnancy; and (5) rich expression in gastrointestinal tissue, which are also the source for Lewis glycolipids. Unfortunately, attempts to convert Sd(a–) red cells to Sd(a+) by incubating cells in Sd(a+) plasma were unsuccessful.<sup>32</sup> Ganglioside GM2 (figure 1), which shares an Sd<sup>a</sup>-type terminus, is not expressed by red cells and is not recognized by human anti-Sd<sup>a</sup>.<sup>234</sup>

### **Molecular biology**

The gene for B4GALNT2 is on chromosome 17q21.33 and shows 39% homology to B4GALNT1, the glycosyltransferase responsible for ganglioside GM2 synthesis.<sup>235</sup> The B4GALNT2 gene is large with 11 exons, including two forms of exon 1 (E1S and E1L), leading to two major enzyme isoforms that differ only in the length of the cytoplasmic N-terminal domain.<sup>235</sup> Exon E1S encodes a 506 amino acid enzyme whereas E1L is responsible for a minor 566 amino acid enzyme with an unusually long 66 amino acid cytoplasmic tail. The E1S short enzyme has higher activity than the less common longer isoform. Both isoforms are located in the trans-Golgi; however, the long isoform is also found in cytoplasmic vesicles and plasma membrane.<sup>238</sup>

Transcriptional regulation of B4GALNT2 is complex and still under investigation. B4GALNT2 possesses several CpG islands and can be upregulated by demethylating agents like 5-azacytidine.<sup>235,239</sup> Methylation immediately 5' of exon E1s has been linked to decreased synthesis of the major short form of the enzyme.<sup>237</sup> Paradoxically, hypermethylation of a CpG located between exons 6 and 7 is associated with high B4GALNT2 mRNA in human colon cancer.<sup>238</sup> There is indirect evidence for the miRNA-204-5p in

**Figure 9.5** Synthesis of Sda-active glycans by B4GALNT2. Ganglioside GM2, which is synthesized by B4GALNT1 and shares a similar epitope, is not recognized by anti-Sda.

downregulating colon *B4GALNT2* expression.<sup>239</sup> It is believed that specific transcription factors also play a role in *B4GALNT2* expression.<sup>239</sup>

Although the role of B4GALNT4 in Sd<sup>a</sup> synthesis has been known for over 20 years, it was only recently that mutations in *B4GALNT4* were identified as the etiology of the Sd(a-) phenotype.<sup>240</sup> Both missense (Arg523Trp; Gln436Arg) and splice site mutations were identified in four Sd(a-) individuals, with most being compound heterozygotes. No mutations were identified in a fifth Sd(a-) person and may represent mutations in regulatory regions. Weak *B4GALNT2* mRNA expression is reported in bone marrow preparations but not in erythroid cells. The latter adds to evidence that Sd<sup>a</sup>, like Lewis antigens, may not be of erythroid origin.

### Biological role

#### Sd<sup>a</sup> and cancer

Sd<sup>a</sup>/B4GALNT2 have been identified as good prognostic markers in gastric and colon cancers.<sup>239,241,242</sup> In these cancers, *B4GALNT2* expression is depressed relative to normal tissue.<sup>241,242</sup> Colon cancer patients with the highest residual *B4GALNT2* expression had better long-term survival than patients with little or no *B4GALNT2* expression.<sup>239</sup> In transfected cancer cell lines, *B4GALNT2* expression led to a loss of “stemness” as measured by aldehyde dehydrogenase activity and distinct changes in the cell transcriptome.<sup>239,241</sup> Likewise, *B4GALNT2* expression led to decreased clonogenic and metastatic potential in vivo and in vitro, respectively.<sup>241,242</sup> *B4GALNT2*

suppresses expression of sLe<sup>X</sup>, a selectin receptor and adhesion factor that is known to play a role in many malignancies.<sup>242</sup> *B4GALNT2* utilizes and competes for the same NeuAc $\alpha$ 2 → 3Gal-R acceptor used for the synthesis of sLe<sup>X</sup> (and sLe<sup>a</sup>, type 1 chain).<sup>242</sup>

#### Sd<sup>a</sup> and xenotransplantation

Sd<sup>a</sup> is also expressed by other species including pigs, cows, ferrets, sheep, and mice.<sup>234,243</sup> The most extensive work exploring Sd<sup>a</sup> and xenotransplantation has been in transgenic pigs, where Sd<sup>a</sup> has been identified as a major, non- $\alpha$ Gal xenoantigen on endothelium and other tissues. Despite the fact that most people are Sd(a+) and only 1% possess a weak anti-Sd<sup>a</sup>, essentially all people will react with porcine Sd<sup>a</sup> antigen.<sup>242</sup> Furthermore, the transfection and expression of porcine *B4GALNT2* into human HEK93 kidney cell lines are associated with increased human antibody binding and a 20-fold increase in antibody-mediated cytotoxicity.<sup>243</sup> Conversely, knocking out *B4GALNT2* in transgenic pigs leads to a marked decrease in human antibody recognition.

The pig *B4GALT4* gene is 76% homologous with human *B4GALNT4*, but the chemical nature of the Sd<sup>a</sup> antigen expressed on porcine cells is not known.<sup>234</sup> It is assumed that porcine Sd<sup>a</sup> antigen is presented on alternate carbohydrate structures that affects antibody recognition, analogous to anti-A1 and type 4 globo-A (see ABO). At least one investigator has suggested that the porcine Sd<sup>a</sup> antigen may resemble the CAD antigen on human RBC, a rare polyagglutinable red cell phenotype that is reactive with all human serum.<sup>234</sup>

## Sd<sup>a</sup> and infection

Influenza infection initially requires colonization of nonciliated cells of the tracheobronchial tree via a sialic-acid-specific viral hemagglutinin.<sup>74</sup> Neuraminic acid in  $\alpha$ 2,6 linkage (NeuAc $\alpha$ 2 → 6) is rich in the upper respiratory tract whereas sialic acid in  $\alpha$ 2,3 linkage (NeuAc $\alpha$ 2 → 3) is enriched in the lower respiratory tract. Although most human influenza strains prefer NeuAc $\alpha$ 2 → 6 epitopes, viral strains recognizing NeuAc $\alpha$ 2 → 3 do arise from epizootic transmission and are often associated with pneumonia and severe infections (e.g., H5N1). Parainfluenza virus, a cause of croup, also recognizes NeuAc $\alpha$ 2 → 3 epitopes.<sup>74</sup> B4GALNT2, which modifies NeuAc $\alpha$ 2 → 3 epitopes, was found to significantly decrease viral binding and infection by  $\alpha$ 2,3NeuAc-specific influenza strains.<sup>244,245</sup> Although B4GALNT2 may act as a host resistance factor in animal species, B4GALNT2 is not expressed by normal lung epithelium.

B4GALNT2 appears to moderate bacterial colonization in mice. The absence of B4GALNT2 activity leads to altered murine microbiota.<sup>246</sup> As a result, B4GALNT2 may increase susceptibility to *Helicobacter* species and *Salmonella*.<sup>246,247</sup>

## Summary

Although the Rh and LW antigens are carried on entirely different proteins, they are incorporated together in this chapter based on a historic serologic connection and evidence that they are physically associated within the red cell membrane.

## Rh blood group system

### History and nomenclature

The Rh system is second only to the ABO system in importance in transfusion medicine because Rh antigens, especially D, are highly immunogenic, and antibodies to these antigens cause hemolytic disease of the fetus and newborn (HDFN) and hemolytic transfusion reactions (HTRs). HDFN was first described by a French midwife in 1609 in a set of twins, one of whom was hydropic and stillborn, whereas the other was jaundiced and died of kernicterus.<sup>1</sup> That a wide range of observed clinical scenarios involving red cell hemolysis were related—from severely hydropic stillborn fetuses to infants with mild or significant levels of jaundice and kernicterus—was not realized until 1932.<sup>2</sup> The cause of red cell hemolysis remained elusive until 1939, when Levine and Stetson described a woman who delivered a stillborn fetus and also suffered a severe hemolytic reaction when transfused with blood from her husband. Levine and Stetson correctly surmised that the mother had been immunized by a fetal red cell antigen inherited from the father and suggested that the cause of what was termed “erythroblastosis fetalis” was maternal antibody in the fetal circulation.<sup>3</sup> They did not give the target blood group antigen a name. Meanwhile Landsteiner and Wiener, to discover new blood groups, injected rabbits and guinea pigs with rhesus monkey red cells. The antiserum they obtained agglutinated not only rhesus monkey red cells but also the red cells of 85% of subjects, whom they called “Rh positive”; the remaining 15% of individuals tested were termed “Rh negative.”<sup>4</sup> The “anti-Rhesus” serum seemed to be reacting similarly to the maternal antibody in serologic testing; hence, the blood group system responsible for HDFN came to be known as “Rh.” The anti-Rhesus serum, in fact, was detecting the LW antigen (subsequently named for Landsteiner and Wiener), which is present in greater amounts on Rh-positive than on Rh-negative red cells.<sup>5</sup> Years of

debate followed concerning whether the human antibodies and the Rhesus antibodies were detecting the same antigen. Interestingly, this debate extended long after serologic reactivity largely confirmed they were reacting with different structures. Landsteiner and Wiener never accepted the LW terminology because doing so would have implied that they had not discovered the cause of HDFN.<sup>6</sup>

It was soon obvious that Rh was not a simple, single-antigen system. In 1941, Fisher named the C and c antigens (A and B had been used for ABO) and used the next letters of the alphabet, D and E, to define antigens recognized by additional antibodies. In 1945, the e antigen was identified.<sup>5</sup>

It is helpful to appreciate that the often-confusing nomenclature used to describe Rh antigens results from the difference in opinion that existed concerning the number of genes that were involved in the expression of the antigens. The Fisher–Race nomenclature reflect their opinion that three closely linked genes (C/c, E/e, and D) were responsible, whereas the Wiener nomenclature (Rh–Hr) was based on his belief that a single gene encoded one “agglutinogen” that carried several blood group factors. Even though neither theory was correct (there are two genes—RHD and RHCE—correctly proposed in 1986 by Tippett<sup>7</sup>), both nomenclatures are still in use. For written communication, the Fisher–Race designation (DCE) for haplotypes is preferred; when speaking about the Rh system, a modified version of Wiener’s nomenclature is generally used (Table 10.1). “R” indicates that D is present while use of a lowercase “r” (or “little r”) indicates that it is not. The C or c and E or e Rh antigens carried *in cis* with D are represented by subscripts: 1 for Ce ( $R_1$ , DCe), 2 for cE ( $R_2$ , DcE), 0 for ce ( $R_0$ , Dce), and Z for CE ( $R_z$ , DCE). The antigens present in the absence of D are represented by superscript symbols: “prime” for Ce (r’), “double-prime” for cE (r’’), and “y” for CE (r’’). The “R” versus “r” terminology allows one to convey the Rh antigens present on one chromosomal haplotype in a single term, e.g., a “ $R_0$ ” haplotype encodes D, c, and e, but not C or E.

The major Rh antigens are D, C, c, E, and e, but the Rh system is more complex because of the number of additional antigens that have been reported (Table 10.2). These include compound antigens *in cis* (e.g., f [ce], Ce, and CE), low-incidence antigens arising from hybrid proteins (e.g., D<sup>w</sup>, Go<sup>a</sup>, and Evans), and antigens arising from various point mutations in the RHCE protein (e.g., C<sup>w</sup>, C<sup>x</sup>, and VS).

**Table 10.1** Nomenclature and Prevalence of Rh Haplotypes

Haplotype (Fisher-Race)	Haplotype (Modified Wiener)	Occurrence (%) <sup>a</sup>		
		Whites	Blacks	Asians
DCe	R <sub>1</sub>	42	17	70
DcE	R <sub>2</sub>	14	11	21
Dce	R <sub>0</sub>	4	44	3
DCE	R <sub>z</sub>	<0.01	<0.01	1
ce	r	37	26	3
Ce	r'	2	2	2
CE	r''	1	<0.01	<0.01
CE	r'	<0.01	<0.01	<0.01

Note: Rh13 through 16, 24, and 25 are obsolete.

\* High-prevalence antigen. The antibody is made by D-/D-- (lacking RHCE) antigens) and similar phenotypes.

<sup>b</sup> Low-prevalence antigens, except in Blacks: 30% of Blacks are V positive and up to 40% are VS positive.

<sup>a</sup> High-frequency antigen. The antibody is made by rare individuals lacking all RH antigens.

<sup>s</sup> High-frequency antigen. The antibody is made by rare D+ Black individuals.

Table 10.2 also includes the numeric designations for Rh antigens.<sup>8</sup> With a few exceptions (RH17 and RH29), the numeric designations are not widely used in the clinical laboratory in the US but are more often used in other countries.

### Genes and their expressed proteins

Two genes designated *RHD* and *RHCE* encode the Rh proteins.<sup>10</sup> Each has 10 coding exons. The sequence of the exons are 97% identical and result from a gene duplication on chromosome 1p34–36.<sup>11</sup> Rh-positive individuals have both genes, whereas most Rh-negative individuals have only the *RHCE* gene (below). RH genes are noted in italics.

RhD and RhCE are 417-amino-acid transmembrane spanning proteins that atypically lack glycosylation. One protein carries the D antigen, and the other carries various combinations of the CE antigens (ce, cE, Ce, or CE). RhD differs from RhCE by 32–35 amino acids depending on which form of RhCE is present (Figure 10.1).<sup>12–15</sup> The Rh proteins migrate in sodium dodecyl sulfate polyacrylamide gels with an approximate  $M_r$  of 30–32 kD and hence were

sometimes referred to as the *Rh30* proteins. They are predicted to span the membrane 12 times and are covalently linked to fatty acids (palmitate) in the lipid bilayer (Figure 10.1).<sup>16</sup>

### Association with RhAG

RhAG is a 409-amino-acid glycosylated protein encoded by the *RHAG* gene on chromosome 6. The protein's name (Rh-associated glycoprotein) derives from its properties. It shares 37% amino acid identity with RhD and RhCE proteins, has the same predicted membrane topology, but has one N-glycan chain that carries ABO and Ii specificities.<sup>17</sup> RhAG is not as polymorphic as RhCE and RhD, and only four antigens, forming a separate blood group system, RHAG, have been identified.<sup>18</sup> RhAG, which is important for targeting the Rh proteins to the membrane during erythroid maturation, co-immunoprecipitates with RhD and RhCE.<sup>19</sup> Based on the conformation of their protein homologs (see Rh protein family and function), RhD and RhCE are predicted to form a trimer with RhAG. The exact composition of the trimer is unknown, but most likely 2 RhAG monomers associate with 1 RhD or RhCE monomer.<sup>20</sup>

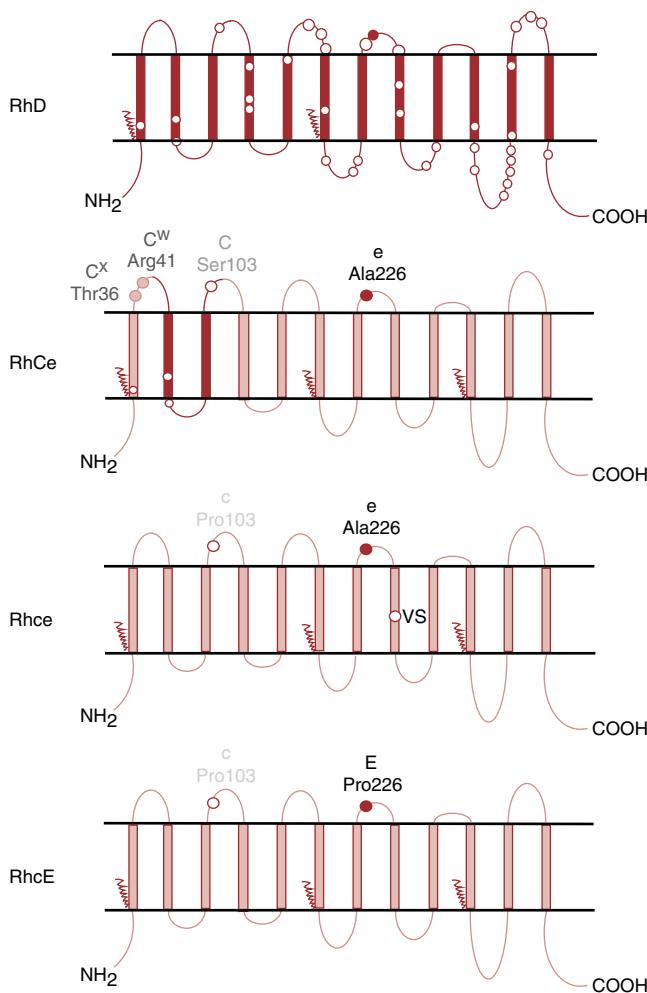

### Basis for antigen expression

#### D antigen

"Rh-positive" and "Rh-negative" refer to the presence or absence of RhD, respectively. The Rh-negative phenotype occurs in 15–17% of Whites but is not as common in other ethnic populations and is very rare in Asians.<sup>5,21</sup> The absence of D on the red cells of people of European ancestry was caused by a complete deletion of the *RHD* gene<sup>22</sup> which occurred on a Dce (R<sub>0</sub>) haplotype because the allele most often carried with the deletion is *RHCE'ce*. Deletion of the *RHD* gene is associated with being "Rh-negative" in all populations, but inactive or silenced *RHD* is also a cause of D-negative phenotypes in Asians or Africans. D-negative phenotypes in Asians occur with a frequency of <1%,<sup>5</sup> and most carry mutations in *RHD* genes associated with *RHCE'Ce*, indicating that they probably originated on a DCe (R<sub>1</sub>) haplotype. Only 3–7% of South African Blacks are D-negative, but 66% have *RHD* genes that contain a 37-bp internal duplication, which results in a premature stop codon,<sup>23</sup> and 15% result from a hybrid *RHD\*DIIIa-CE-D* gene that does not encode D epitopes.<sup>24</sup> This is important when designing polymerase chain reaction (PCR)-based methods to predict the D status of a fetus and the possibility of HDFN. The population being tested, and the different molecular events responsible for D-negative phenotypes (i.e., gene deletion or gene mutation) must be considered. Even among D-negative Whites, cases of an *RHD* gene that is not expressed because of mutation or nucleotide insertion or deletion (indels) have been reported.<sup>25</sup>

#### Weak D

An estimated 1–2% of individuals have reduced expression of the D antigen, which is characterized by weaker than expected reactivity with anti-D typing reagents or, alternatively, as failure of such red cells to agglutinate directly with anti-D requiring the use of an indirect antiglobulin test for detection. The genetic basis of weak expression of D is heterogeneous but is primarily associated with the presence of point mutations often predicted to be intracellular or in the transmembrane regions of RhD rather than on the outer surface of the red cell (Figure 10.2).<sup>26</sup> These mutations appear to affect the efficiency of insertion and the quantity of protein in the membrane without altering the expression of D epitopes. This explains why most individuals with a weak D phenotype can safely

**Figure 10.1** Predicted membrane topology of RhD and the major RhCE proteins. The amino and carboxy termini are cytoplasmic, and the proteins are predicted to transverse the membrane 12 times. The locations of the amino acid residues that differ between D and CE are represented by open circles on RhD, only five of which are predicted to be strictly extracellular, by the most recent estimations.<sup>20</sup> The C/c (Ser103Pro) polymorphism located on the second extracellular loop and the e/E (Ala226Pro) polymorphism on the fourth extracellular loop are shown. The shared region of RhD and RhCe responsible for expression of the G antigen is shown in dark gray. Amino acid changes responsible for C<sup>x</sup> and C<sup>w</sup> are located on the first extracellular loop; and the amino acid change responsible for the VS antigen, common in Blacks, is in the eighth transmembrane domain of Rhce. The zigzag lines represent covalent linkage to fatty acid in the lipid bilayer.

receive D-positive blood and do not make anti-D. There are over 200 different mutations known to cause weak D antigen expression, many of which have been named to reflect this (weak D type 1, weak D type 2, etc.).

For transfusion recipients, testing for weak expression of D antigen is not required. If they mistakenly test as D-negative, they can receive Rh negative units without untoward effects. However, this approach will increase the use of D-negative blood products, which are always in short supply. There is benefit to confirming that patients have the weak D phenotype. Observational studies indicate that individuals with weak D types 1, 2, and 3, which are the most

common weak D types in Whites, are unlikely to make anti-D and are not at risk for clinically significant anti-D. These patients can safely receive D-positive blood, and females are not candidates for Rh immune globulin.<sup>27</sup> When weaker than expected reactivity with anti-D is seen when typing females of childbearing potential, *RHD* genotyping should be considered to guide transfusion therapy, conserve D-negative donor units, and determine candidates for Rh immune globulin. A very weak form of D expression (D<sub>e</sub>), which cannot be detected by routine serology methods but can be demonstrated by adsorbing and eluting anti-D, is relatively common in Asians (10–30% of apparent D-negative).

In contrast, from the blood donation perspective, it is important that donor center procedures detect and label weak D RBC units as D-positive because they can stimulate the formation of anti-D in D-negative recipients.<sup>28,29</sup>

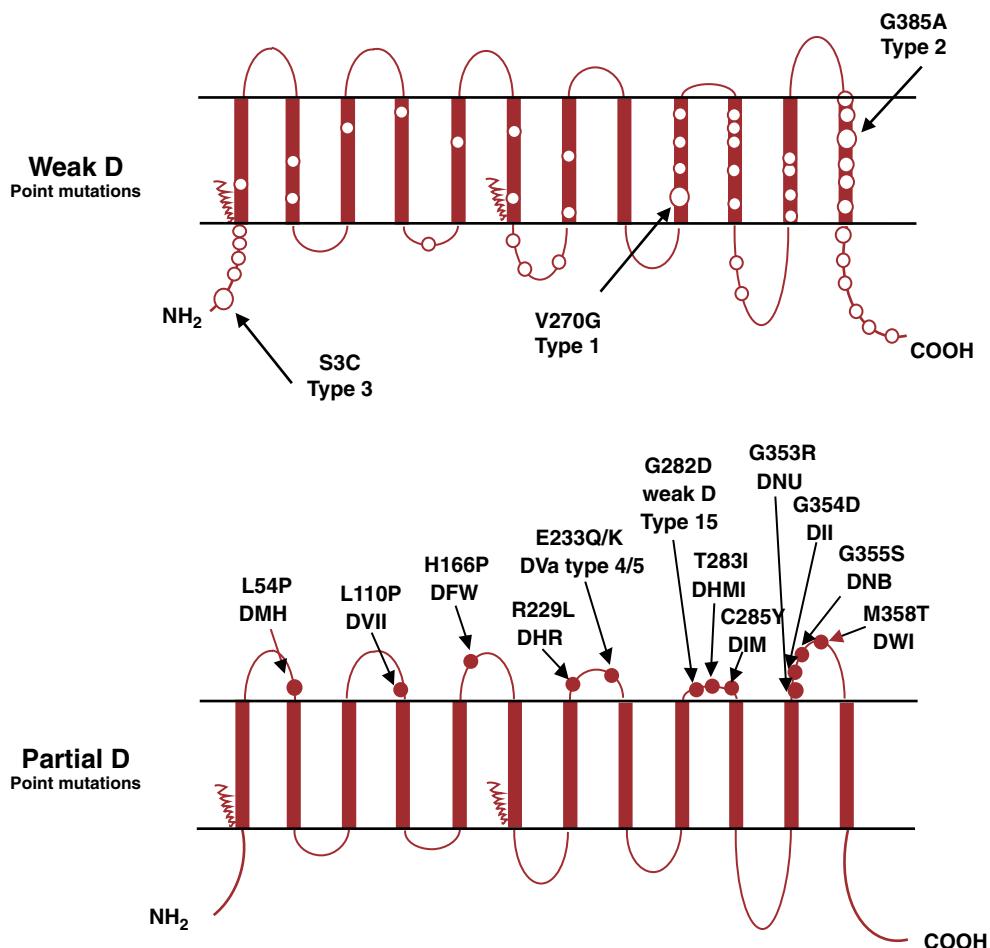

#### Partial D

“Partial D” refers to RBCs that type as Rh-positive with anti-D reagents but lack some D epitopes. This is why some apparently Rh-positive individuals produce anti-D when exposed to D antigen. At the genetic level, portions of *RHD* are replaced by corresponding portions of *RHCE* in many cases (Figure 10.3).<sup>25,30</sup> In addition to lacking D epitopes, the novel sequences of amino acids and the conformational changes that result from segments of RhD joined to segments of RhCE can generate new antigens (e.g., BARC, D<sup>w</sup>, FPTT, DAK, Go<sup>a</sup>, Evans, and Rh32) (Figure 10.3 and Table 10.2). The replacements are the result of gene conversion, the hallmark being that the donor gene is unchanged. Gene conversions can involve single or multiple exons, whereas others involve short stretches of amino acids (Figure 10.3). Loss or alteration of D epitopes resulting in “partial D” phenotypes can also result from single-amino-acid changes (e.g., DII, DVII, and DNB), most often predicted to be located on the extracellular loops of the protein, whereas those which are predicted to be cytoplasmic or transmembrane are more likely to cause weak D phenotypes (above). Lastly, any changes that modify interprotein interactions in the Rh complex can alter D epitopes causing a partial D phenotype.<sup>20</sup>

From a clinical standpoint, individuals with partial D antigens are at risk for anti-D. Ideally, females of childbearing potential with partial D should receive D-negative blood and, if they become pregnant, are candidates for Rh immune globulin. Some RBCs with partial D react weaker than expected with anti-D reagents, but they cannot be distinguished by serologic methods from weak D RBCs. *RHD* genotyping can guide clinical decision making for Rh immune globulin prophylaxis and transfusion.<sup>27</sup> In practice, many individuals with partial D phenotypes will type strongly D-positive and will be recognized only after they have made anti-D following a transfusion with D-positive cells or pregnancy with a D-positive fetus. Routine *RHD* genotyping is now recommended to overcome the limitations of serologic D typing for these individuals.<sup>27,31</sup>

#### C/c and E/e antigens

*RHCE* gene(s) encode four different proteins: Rhce, -Ce, -cE, and -CE (Figure 10.1).<sup>14</sup> The corresponding alleles are noted *RHCE\**c<sub>e</sub>, *RHCE\**C<sub>e</sub>, *RHCE\**c<sub>E</sub>, and *RHCE\**C<sub>E</sub>, respectively. C and c antigens differ by four amino acids: p.Cys16Trp encoded by exon 1, and p.Ile60Leu, p.Ser68Asn, and p.Ser103Pro encoded by exon 2 (Figure 10.1, open circles on RhCe). Of those four amino acids, only the residue at p.103 is predicted to be extracellular and is located on the second loop. All the amino acids encoded by exon 2 of *RHCE\**C<sub>e</sub> are identical to those encoded by exon 2 of *RHD*

**Figure 10.2** Predicted location of point mutations that cause the most common weak D phenotypes. Weak D types 1, 2, and 3 reflect amino acid changes predicted to be intracellular or in the transmembrane regions of RhD. Many other mutations have been shown to cause a weak D phenotype.

(Figure 10.1, dark color on RhCe). *RHCE*<sup>cE</sup> arose from the transfer of exon 2 from *RHD* into *RHCE*<sup>ce</sup>.

The sharing of exon 2 encoded amino acids by RhD, RhCe, and RhCE accounts for the expression of the G antigen on red cells that are D or C positive. Individuals who lack D and C can make anti-G, which can be distinguished from a combination of anti-D and anti-C by absorption and elution studies.<sup>6</sup> The presence of anti-G can explain why a D-negative person who was transfused with D-negative, but C-positive RBCs (or exposed to such cells through pregnancy), can appear to have made anti-D. The identification of anti-G is generally of academic interest only because transfusion requirements for such an individual would be the same (i.e., RBCs that are both D and C negative). However, in the case of a pregnancy, it is important to identify individuals with anti-G only, as Rh immune globulin prophylaxis would be indicated.

E and e differ by one amino acid, Pro226Ala, predicted to reside on the fourth extracellular loop of the protein (Figure 10.1, solid circle). The E antigen arose from a single point mutation that occurred in exon 5 of *RHCE*<sup>ce</sup> giving rise to *RHCE*<sup>cE</sup>.

#### Silenced CE

In several rare RBC phenotypes, designated D--, Dc-, and DC<sup>w-</sup>, some or all CE antigens are silenced. Genetic rearrangements analogous to the partial D rearrangements described in the "Partial D"

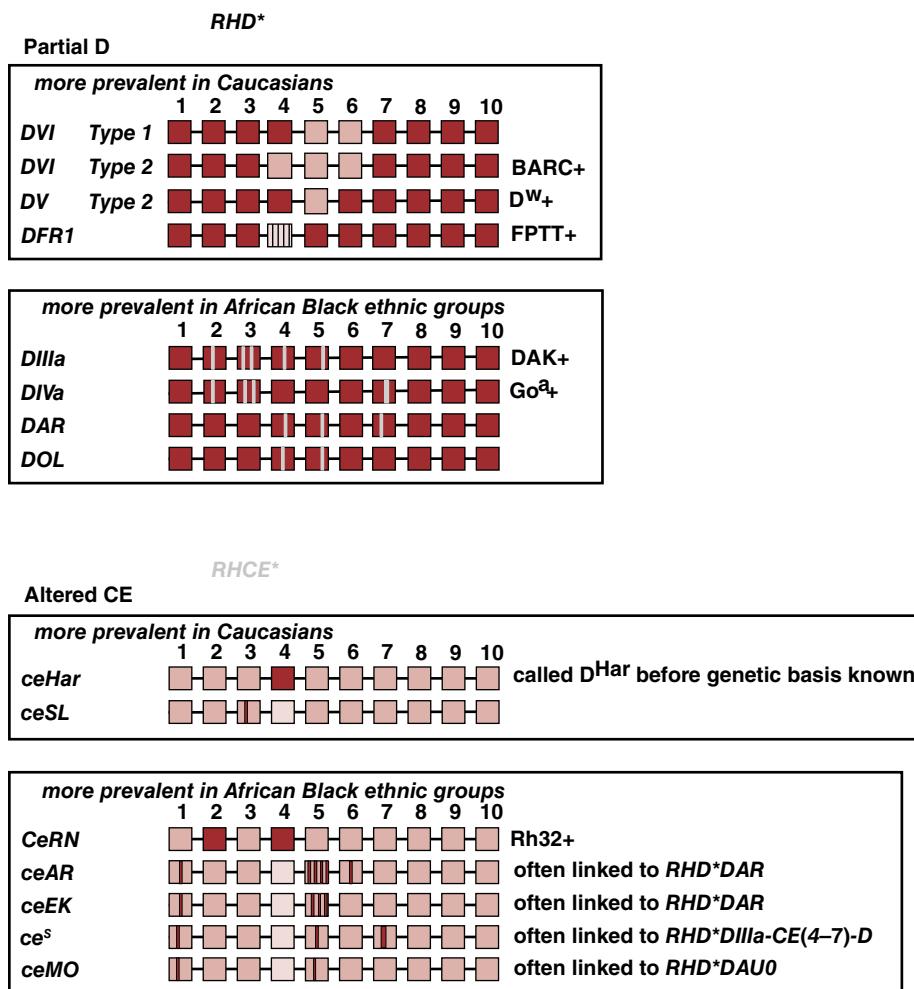

section above are sometimes responsible, but in this case they represent the replacement of portions of *RHCE* by *RHD*. The additional *RHD* sequences in *RHCE* along with a normal *RHD* lead to enhanced D antigen expression and account for the reduced or missing CE antigens. Point mutations, insertions, and deletions can also cause a premature stop codon or frameshift and silence CE antigens. Individuals with such altered CE phenotypes can make anti-Rh17 when immunized. Clinically, significant anti-Rh17 reacts with all cells that have RhCE proteins, and the only compatible RBCs are those with the D-- phenotype (or those expressing the same Rhce variant).

#### Altered CE

Over 150 *RHCE* alleles have been described to date, many of which encode weak or partial Cc or Ee antigens not immediately apparent by serology, as described above for *RHD*.

C<sup>w</sup> and C<sup>x</sup> are low-incidence antigens that result from single amino-acid changes (p.Gln41Arg and p.Ala36Thr, respectively) located on the first extracellular loop of RhCE (Figure 10.1, light colored circles).<sup>32</sup> These antigens are more common in Finns (4%) and are most often present on RhCe.<sup>33</sup>

V and VS antigens, which are expressed on RBCs of more than 30% of Blacks, result from a p.Leu245Val substitution in the predicted eighth transmembrane segment of Rhce (Figure 10.1).<sup>34</sup>

**Figure 10.3** Gene conversion events between *RHCE* and *RHD* produce chimeric Rh proteins and new low prevalence antigens or loss of high prevalence antigens (shown on right side). Dark gray (*RHD*) and light gray (*RHCE*) boxes represent the 10 exons that encode Rh proteins. Gene conversion events involve amino acid changes (vertical bars) or whole exons (filled boxes). Replacement of portions of *RHD* by *RHCE* (upper set of panels), with or without additional point mutations, causes many of the partial D phenotypes with the highest risk of anti-D formation and hemolytic complications, some of which are shown here. Two alleles with altered CE antigen expression (third panel) which may interfere with D antigen typing in the absence of normal D are shown here. Replacement of portions of *RHCE* by *RHD* (last panel) causes altered RhCE expression. Some of the *RHCE* alleles with the highest risk of antibody formation and hemolytic complications are shown here. Many more conversion events or point mutations not shown here can alter antigen expression with a risk of antibody formation.

The V-VS+ phenotype results from a p.Gly336Cys change on the 245Val background.<sup>35</sup> V+ and VS+ are associated with weak and altered expression of e antigen, indicating that p.Leu245Val causes a local conformation change on the fourth extracellular loop where the e-specific amino acid resides.

Most individuals have e-positive RBCs, but the e antigen is second in complexity to D antigen because variant or altered expression has frequently been observed.<sup>36</sup> The e antigen is altered most often on RBCs from African Blacks, and some of the more common alleles encoding altered expression are shown (Figure 10.3). Extensive discussion is beyond the scope of this chapter, but these alleles are prevalent in patients with sickle cell disease (SCD),<sup>37,38</sup> who not infrequently produce anti-e following transfusion despite having an e-positive red cell phenotype. RH genotyping of these patients can help to determine if the anti-e is an allo- or auto-antibody and to inform selection of blood for transfusion.<sup>39</sup>

E antigen variants are not common and include categories EI, EII, and EIII, which result from a point mutation (EI) or gene conversion and replacement of RhCE amino acids with RhD residues (EII and EIII) with concurrent loss of some E epitope expression. Category EIV red cells, which have an amino acid substitution in an intracellular domain, do not appear to lack E epitopes but have reduced E expression.<sup>39</sup>

Variants of c antigen are infrequent. The very rare RH:-26 results from a p.Gly96Ser transmembrane amino acid change that abolishes Rh26 and weakens c expression.<sup>40</sup> The lack of anti-c associated with c antigen variants in humans compared to the other Rh antigens, and the preservation of expression of c on the RBCs of non-human primates, suggests that the two proline residues involved (p.P102 and p.P103) form a stable structure that is resistant to perturbations and changes in Rhce.<sup>41</sup>

In summary, point mutations and genetic exchange, mainly involving gene conversion events between *RHD* and *RHCE*, are primarily responsible for the large number of Rh antigens. Additional complexity results because many of the Rh epitopes are highly conformational, and single-amino-acid changes in one part of the protein, including changes within the transmembrane regions, can affect the expression of cell-surface-exposed antigen epitopes on other parts of these proteins.

### Rh membrane complex and Rh<sub>null</sub> phenotype

The Rh proteins exist in the red cell membrane as complexes with several other proteins, with Rh and RhAG serving as the core of the complex.<sup>42</sup> That several other proteins interact with the Rh core complex is based on observations of Rh<sub>null</sub> RBCs, which lack expression of all Rh antigens. Individuals suffer from a compensated hemolytic anemia, with variable degrees of spherocytosis,

stomatocytosis, and increased red cell osmotic fragility.<sup>43</sup> The Rh<sub>null</sub> phenotype is rare and occurs on two different genetic backgrounds that disrupt the RhAG/Rh trimer association in the membrane. In the more common “regulator” type of Rh<sub>null</sub>, the absence of Rh antigens is caused by the mutation of *RHAG* with absence or defective RhAG protein.<sup>44</sup> The “amorph” type of Rh<sub>null</sub> is due to absence of *RHD* along with mutation/silencing of *RHCE*. RBCs with no RhD or RhCE proteins have reduced amounts (~20%) of RhAG.

Rh<sub>null</sub> cells also have reduced glycophorin B (GPB), a sialoglycoprotein that carries S, s, and U antigens. GPB appears to aid RhAG trafficking to the membrane because the RhAG protein in GPB-deficient cells has increased glycosylation reflecting longer dwell time in the endoplasmic reticulum. Rh<sub>null</sub> cells also lack LW (discussed in more detail below), a glycoprotein of unknown function that belongs to the family of intercellular adhesion molecules (ICAM-4). Band 3 (the anion exchanger) enhances the expression of the Rh antigens in transfected cells, suggesting that band 3 may also be associated with the Rh core complex.<sup>45</sup> The Rh core complex is linked to the membrane skeleton through interactions between CD47 and protein 4.2<sup>46</sup> and through an Rh/RhAG–ankyrin cytoskeleton connection.<sup>47</sup> Rh<sub>null</sub> RBCs also have reduced expression of CD47, an integrin-associated protein (IAP) that has wide tissue distribution, binds β<sub>3</sub> integrins, and is required for integrin-regulated Ca<sup>2+</sup> entry into endothelial cells. Its function on the red cells is unknown; however, it has been suggested that CD47 acts as a “do not eat me” signal and has become an experimental target for the treatment of hematologic malignancies and solid tumors.<sup>48</sup> Anti-CD47 therapies can interfere with pretransfusion testing.<sup>49</sup>

## Rh family and function

### MEP/Amt/Rh superfamily and ammonia transport

The Rh proteins reveal the power of comparative genomics and proteomics, in which sequence analysis and homology modeling can give important insight into mammalian protein function.<sup>20,50,51</sup> The Rh blood group proteins are well-known to blood bank professionals because of their importance in blood transfusion. However, the mammalian family of Rh proteins also includes RhAG in erythrocytes and the related proteins, RhBG and RhCG, in other tissues (kidney, liver, etc.). Homologous proteins can also be found in many other organisms, including bacteria, yeast (MEP), and plants (AMT),<sup>52</sup> where they function as ammonia transporters. For example, in the bacterial transporters, charged H<sup>+</sup> and neutral NH<sub>3</sub> are carried separately across the membrane after NH<sub>4</sub><sup>+</sup> deprotonation.<sup>53</sup> RhAG, RhBG, and RhCG have also been shown to transport ammonia across the plasma membrane in an electroneutral process that is driven by the NH<sub>4</sub><sup>+</sup> concentration and the transmembrane H<sup>+</sup> gradient.<sup>54,55</sup>

### Clinical relevance of Rh protein expression in RBCs

On the other hand, RhCE and RhD, when expressed in heterologous systems, do not transport ammonia<sup>56</sup> as these Rh proteins lack the highly conserved histidine residues located in the membrane pores that are critical for ammonia transport. Phylogenetic analysis indicates that RhCE and RhD proteins diverge the most from their homologs.<sup>57</sup> One hypothesis is that their main function is structural with the formation of the Rh trimer with RhAG. RhD and RhCE are subject to a low selection pressure as protein folding will be conserved for all alterations described except Rh<sub>null</sub> cells. Through the formation of Rh trimers, RhD/CE proteins maintain the RBC biconcave shape by interacting with the cytoskeleton.<sup>47</sup> In addition

to ammonia transport mentioned above,<sup>54</sup> RhAG is important for ion balance in RBCs.<sup>58,59</sup> Hereditary overhydrated stomatocytosis (OHSt), an autosomal dominant macrocytic hemolytic anemia, is caused by a p.Phe65Ser mutation in RhAG. OHSt red cells exhibit cation leak with elevated Na<sup>+</sup> and reduced K<sup>+</sup> content, and loss of ammonia conductance.<sup>58</sup>

## RH genotyping

### RHD zygosity

Serologic testing for red cell expression of D, C/c, and E/e can predict the likelihood that a sample is homozygous (D/D) or hemizygous (D/-) for *RHD*, but genotyping enables zygosity to be determined by assaying for the presence of a recessive D-negative allele. In prenatal practice, paternal *RHD* zygosity testing is important to predict the fetal D status when the mother has anti-D. Several different genetic events cause a D-negative phenotype, and multiple assays must be performed to accurately determine zygosity.<sup>60</sup> If the father is *RHD* homozygous, the fetus will be D-positive, and monitoring of the pregnancy will be required. If the father is hemizygous or heterozygous with one inactive or silenced *RHD*, there is a 50% possibility the fetus will be D-positive, and the D type of the fetus can be determined by fetal genotyping.

### Fetal typing

Genotyping is important in the prenatal setting to determine whether the fetus has inherited the paternal antigen to which the mother has a clinically significant antibody.<sup>61</sup> Fetal DNA can be isolated from cells obtained by amniocentesis; however, the discovery that cell-free, fetal-derived DNA is present in maternal plasma or serum by approximately five weeks gestation allows maternal plasma to be used as a source for fetal DNA testing.<sup>62</sup> Fetal DNA in maternal plasma is derived from apoptotic syncytiotrophoblasts, increases in concentration with gestational age, and is rapidly cleared following delivery.<sup>63</sup> There are technical challenges in that the small quantity of cell-free fetal DNA present relative to maternal DNA requires positive controls for the isolation of sufficient fetal DNA to validate negative results.

Isolation of fetal DNA from maternal plasma for *RHD* testing has become routine in several European countries to determine the fetal RhD phenotype and assess which patients are candidates for administration of Rh immune globulin.<sup>64</sup> This has been most successful for D typing because the D-negative phenotype in most samples is caused by the lack of *RHD*. Testing for the presence or absence of a gene is less demanding than testing for a single gene polymorphism or SNP. For the same reasons as *RHD* zygosity testing, diverse populations pose technical challenges.<sup>65</sup> Testing the maternal plasma for the presence of a fetal *RHD* gene eliminates the unnecessary administration of antepartum Rh immune globulin (RhIG) to the approximately 40% of D-negative women who are carrying a D-negative fetus. This approach is cost effective for some healthcare systems and reduces exposure to RhIG that is not entirely risk free as it is a human blood product.<sup>66</sup> Noninvasive testing for other fetal RBC antigens, including K and c, and platelet antigens (HPA), has also been reported.<sup>67,68</sup> Fetal typing from maternal plasma is not readily available in the United States as the cost of testing and liability concerns require widespread adoption nationally as a standard of practice to be feasible.

### Distinction between weak D and partial D

As indicated above, altered expression of D antigen is not uncommon. Weak D phenotypes have amino acid changes that primarily

affect the quantity of RhD in the membrane. Partial D phenotypes have amino acid changes that alter D epitopes or are hybrid proteins with portions of RhD joined to portions of RhCE. The distinction between weak D and partial D phenotypes is of clinical importance because the latter are at risk for anti-D. Routine serologic typing reagents cannot distinguish between these red cells; however, *RHD* genotyping strategies can discriminate between weak D and partial D and should be performed whenever the D type is in question.<sup>27</sup>

#### **Detecting patients at risk for production of Rh antibodies to high incidence antigens**

Alloimmunization is a serious complication of chronic transfusion, particularly in patients with SCD requiring long-term transfusion support. Many transfusion programs attempt to prevent or reduce the risk and incidence of alloantibody production in patients with SCD by transfusing RBC units that are antigens matched for D, C, E, and K. Although this approach reduces the incidence of alloimmunization, its effectiveness can be reduced because variant *RHD* and *RHCE* genes are common in African Blacks and individuals of mixed ethnic backgrounds. The prevalence of *RH* alleles that encode altered D, C, and e antigens in this patient group explains why some SCD patients become immunized to Rh despite Rh antigen matching for D, C, and E.<sup>38,69</sup> These antibodies often have complex Rh specificities, and it can be difficult or impossible to find compatible units after alloimmunization.

RH genotyping provides an effective approach to identify those patients who are homozygous for variant *RH* alleles and at risk for production of alloantibodies to high-incidence Rh antigens, as well as to identify compatible donors for transfusion. In some countries where the transfusion system is organized at the national level and in some US programs, all SCD patients are genotyped once for the RH variants to identify which of the patient's antigen(s) present a risk for alloantibody formation.<sup>70</sup> A challenging future approach will be to match SCD recipients and donor units according to RH alleles. This is expected to further reduce alloimmunization and is currently used to transfuse some patients with complex clinically significant RH antibodies.<sup>71</sup>

### **Immune response to Rh**

#### **Medical aspects**

Human red cells can express combinations of more than 400 different blood group antigens. Typing patient and donor cells for every known antigen with the intention of providing perfectly matched blood would not be practical or feasible. Fortunately, such extensive testing is not required for several reasons, the most important of which is that exposure to most foreign red cell antigens through transfusion does not lead to the production of clinically significant antibodies. RhD is one notable exception. As many as 50% of D-negative patients on deliberate immunization with D-positive red cells may develop high-titer, polyreactive, IgG antibodies that may persist for the rest of their lives even if they are never exposed to the antigen again.<sup>72</sup>

These antibodies can cause HTRs and can cross the placenta, causing HDFN when present in a D-negative female carrying a D-positive fetus. Although other Rh antibodies to C, c, E, and e can cause HTRs and HDFN, these antigens are much less immunogenic than D (~1% rate of sensitization).

In practice, D-positive patients can be transfused with either D-positive or D-negative RBCs—the absence of D on transfused cells will cause no harm—but it is deemed prudent to reserve units of D-negative blood (~15% of donor units) for D-negative

individuals. In cases of trauma and/or massive transfusion in which the patient's D status is unknown, efforts are made to provide D-negative blood for females of childbearing potential until the appropriate testing can be completed. When D-negative blood is in short supply, it may be necessary to transfuse D-negative patients with D-positive units.

Unlike ABO blood group antigens, which are expressed by all transfused blood cells including platelets, the D antigen is present only on red cells. Theoretically, the selection of platelet units for transfusion should be independent of the D status of the donor. However, a platelet transfusion may introduce as much as 5 mL of donor red cells, which if they are D-positive may be sufficient to immunize a D-negative patient. Therefore, the standard of care is to avoid transfusing D-negative females of childbearing potential with platelet units derived from D-positive donors. If such units are unavoidable, the administration of RhIG can be considered. A standard 300-µg dose of RhIG, which may inhibit the immunizing potential of up to 15 mL of D-positive red cells, would neutralize the effects of D-positive red cells from several mismatched platelet transfusions. If mismatched platelet transfusions are repeatedly given over time and their content of D-positive red cells is not expected to exceed the volume of red cells for which a standard dose of RhIG is indicated, then a single dose of the drug should be sufficient for at least 2–4 weeks of prophylaxis given the three-week half-life of IgG.<sup>73</sup> With respect to the transfusion of plasma products, the D status of the donor is not an issue because plasma products do not contain cellular or soluble material capable of inducing anti-D.

#### **Serologic aspects**

The immune response to Rh, like that to other peptide antigens, is typically thymus-dependent, requiring T-cell help. Upon exposure to a foreign Rh antigen, an IgM response may develop, but this is quickly followed by the production of IgG antibodies. Consequently, nearly all examples of Rh antibodies are IgG (primarily IgG1 and IgG3), which bind optimally to red cells at 37 °C and require the addition of an antoglobulin reagent to produce hemagglutination during in vitro testing. Although IgG1 and IgG3 classically initiate complement activation, most anti-Rh-containing sera do not do so. The usual explanation for this cites the relatively low copy number of Rh antigens per red cell, which results in Rh molecules situated too far apart on the cell surface to permit the simultaneous binding of C1q by multiple Rh IgG antibodies, as well as the cytoskeletal linkage and absence of capping of the Rh complex. Therefore, hemolysis from the transfusion of Rh-incompatible RBCs is generally extravascular resulting from the phagocytosis of IgG-coated erythrocytes by cells of the reticuloendothelial system.

Thanks to the use of RhIg in pregnancy, anti-D antibodies have become less common in patients. The Rh antibodies most found in the sera of alloimmunized individuals are now anti-E > anti-c > anti-e > anti-C.<sup>74</sup>

In approximately 50% of cases of warm-type autoimmune hemolytic anemia (WAIHA), autoantibodies are believed to be directed to Rh antigens by virtue of their “pan-reactivity” with all red cell phenotypes except  $Rh_{null}$  cells. However, direct binding of autoantibodies to putative epitopes common to D and CE polypeptides or to other components of the Rh membrane complex (RhAG, CD47, etc.) has yet to be demonstrated in WAIHA. The difficulties in approaching this problem are largely technical in nature and relate to both the inability to produce workable quantities of pure patient autoantibody in vitro (i.e., clone the autoantibody-producing B

lymphocytes) and the inability to purify Rh proteins in a way that retains their native, conformationally dependent epitopes.

### Molecular aspects of antibodies

The characterization of Rh antibodies on a molecular level, particularly that of anti-D, has been the focus of much study not only because of their clinical significance, but also because of the need to develop suitable *in vitro* methods for their production.<sup>75</sup> Ironically, because of better transfusion practice and the use of RhIG, alloimmunization of D-negative individuals is significantly less common (as are sera donors willing to be purposely hyperimmunized) so that supplies of Rh antibodies for use as typing reagents and for the preparation of RhIG are dwindling. To better understand the molecular makeup of Rh antibodies, investigations have focused on analyzing their variable regions to determine whether there are commonly shared genetic and/or structural features among Rh antibodies made by different individuals.

The repertoire of heavy chain variable regions in IgG anti-D was shown to be restricted to  $V_H$ 3–33 and highly related genes.<sup>76–79</sup> The use of molecular approaches such as site-directed mutagenesis,<sup>80</sup> complementarity-determining region (CDR) sequence randomization,<sup>81</sup> and heavy-chain/light-chain “shuffling”<sup>82</sup> has demonstrated the genetic relatedness among anti-D molecules directed against different D epitopes as well as among antibodies with D and E specificity. These studies and others<sup>83,84</sup> have supported the hypothesis that a restricted “Rh footprint” for D alloantibodies and a process termed “epitope migration”<sup>85</sup> play a role in the molding of the anti-Rh immune repertoire.<sup>86</sup>

Although the precise significance of immunoglobulin germline gene restriction by Rh antibodies is not fully understood, it may have practical significance for the preparation of anti-D for both therapeutic and diagnostic use. Although IgM anti-D monoclonal antibodies are well suited for antigen typing because they may serve as direct agglutinins, the fact that they are most often encoded by  $V_H$ 4–34 (the germline gene to which cold agglutinins are also restricted)<sup>87,88</sup> may explain why many IgM monoclonal anti-D typing reagents falsely agglutinate D-negative cells when used at cooler than recommended temperatures. This phenomenon may also explain the body of literature claiming that the D antigen was present on numerous nonerythroid cells. Using IgM anti-D, these investigators may have been detecting antigens of the I/i blood group system.

There have been many unsuccessful attempts to develop recombinant formulations of RhIG that would function as effectively as naturally derived anti-D, which have highlighted the role that Fc glycosylation may play in inducing anti-D immune prophylaxis.<sup>63,75,85,86,89</sup> Small, recent clinical trials with one recombinant monoclonal anti-D have shown promising results that need to be confirmed.<sup>90</sup>

## LW blood group system

### History and nomenclature

The LW antigens are the original so-called “Rhesus” antigens shared by humans and the rhesus monkey. As discussed earlier, the confusion occurred because LW antigens are more abundant on D-positive than on D-negative red cells. When the situation was clarified, the term *Rh* remained associated with the human antigen, so the antigen shared by humans and the rhesus monkey was renamed *LW* in honor of Landsteiner and Wiener (an unwelcome honor, as mentioned above).<sup>6</sup>

The confusion can be understood today in the transfusion service when weak examples of anti-LW<sup>a</sup> often appear initially to be anti-D. The LW system has undergone additional terminology revisions. The historical terminology of LW<sub>1</sub>, LW<sub>2</sub>, LW<sub>3</sub>, LW<sub>4</sub>, and LW<sub>0</sub> used to describe phenotypes was based on both the LW and the D status of the red cells but is now obsolete.<sup>6</sup> The phenotypes are now designated as LW(a+b−), LW(a−b+), LW(a+b+), and the rare LW(a−b−); the antigens are designated LW<sup>a</sup>, LW<sup>b</sup>, and LW<sup>ab</sup>.

### Genes and their expressed proteins

LW is encoded by a single gene located on chromosome 19. The 42-kD LW glycoprotein is a member of the family of Intracellular Adhesion Molecules (ICAMs) and has been renamed ICAM-4 (CD242). LW passes through the red cell membrane once, and the N-terminal extracellular region is organized into two immunoglobulin superfamily (IgSF) domains.<sup>91</sup>

### Basis for antigen expression

LW<sup>a</sup> is the common antigen, whereas LW<sup>b</sup> has an incidence of less than 1% in most Europeans.<sup>5</sup> The LW<sup>a</sup>/LW<sup>b</sup> polymorphism is caused by a single amino acid substitution, p.Gln70Arg, on the LW glycoprotein.<sup>92</sup> An increased frequency of the uncommon LW<sup>b</sup> antigen in Latvians and Lithuanians (6%), Estonians (4%), Finns (3%), and Poles (2%) suggests that the LW<sup>b</sup> mutation originated in the people of the Baltic region.<sup>93</sup> The LW<sup>ab</sup> antigen was originally defined by an alloantibody made by the only known (genetically verified) LW(a−b−) person, who lacks expression of all LW antigens.<sup>6</sup>

Rh antigen expression was not altered, and there was no clinical evidence of an associated pathology. The *LW* gene in this rare LW(a−b−) individual has a 10-bp deletion and a premature stop codon in the first exon.<sup>94</sup> Rh<sub>null</sub> red cells also lack LW antigens but do not have defective *LW* genes. Rh proteins appear to be required for LW to traffic to the membrane, and association with RhD is preferred.

LW antigens require divalent cations (e.g., Mg<sup>2+</sup>) for expression<sup>95</sup> and have intramolecular disulfide bonds that are sensitive to dithiothreitol (DTT) treatment.<sup>96</sup> This is helpful to differentiate anti-LW from anti-D because the D antigen is resistant to DTT. DTT-treated and untreated D-positive red cells can be prepared and tested for reaction with patient serum.<sup>97</sup> Also helpful in identifying anti-LW is the fact that LW antigens are expressed equally well on group O, D-positive and D-negative cord blood red cells.<sup>5</sup>

Transient loss of LW antigens has been described in pregnancy and patients with diseases, particularly Hodgkin’s disease, lymphoma, leukemia, sarcoma, and other forms of malignancy, in the absence of any overt associated RBC abnormality. Transient loss of LW antigens is associated with the production of autoanti-LW that can appear to be alloantibody.<sup>5</sup>

### LW function

The LW glycoprotein, ICAM-4, is a ligand with broad specificity for a number of  $\beta 1$ ,  $\beta 2$ ,  $\beta 3$ , and  $\beta 5$  integrins, including  $\alpha_L\beta_2$  (LFA-1),  $\alpha_M\beta_2$  (Mac-1),  $\alpha_4\beta_1$  (VLA-4),  $\alpha_v\beta_1$ ,  $\alpha_v\beta_5$ , as well as platelet integrin  $\alpha_{2b}\beta_3$ .<sup>91,98–101</sup> In addition, LW binds to the I domains of CD11a/CD18 and CD11b/CD18 on leukocytes.<sup>99,102</sup> The function of LW glycoprotein on mature red cells is not known, but LW may have a role in erythroblastic island formation through interaction with macrophage integrins.<sup>103,104</sup> LW appears to play a pathophysiologic role in the development of vaso-occlusion in SCD patients where it is mediated by endothelial cell integrins<sup>105,106</sup> and in the development of thrombosis mediated by activated integrins on platelets.<sup>101</sup>

## Summary

The genetic basis for the Rh antigens has been known for over 25 years. A gene deletion or silent *RHD* gene explains the absence of the D antigen in Rh-negative individuals. The large number of amino acid differences between the RhD and RhCE proteins explains why exposure in an individual lacking D often results in a vigorous immune response characterized by a very heterogeneous population of antibodies. The proximity of *RHD* and *RHCE*, duplicated genes on the same chromosome, has resulted in numerous exchanges by gene conversion between them. This has generated new polymorphisms and explains the many antigens observed in this blood group system. Rh antigen expression is affected not only by changes in extracellular amino acids but also by intracellular changes, highlighting the conformational nature of these blood group antigens and complicating attempts to map the epitopes to specific amino acid residues.

Serology cannot identify samples with altered RhD associated with risk for clinically significant anti-D, and *RHD* genotyping should be used to inform clinical decisions. *RH* genotyping can be used to determine paternal *RHD* zygosity to predict HDFN, and the fetus can be typed from amniocytes or from the maternal plasma. *RH* genotyping can also be used in patients facing long-term transfusion therapy to identify those who are homozygous for variant *RH* alleles and at risk to produce alloantibodies to high-incidence Rh antigens. When partnered with *RH* genotyping of donors, this approach promises to have a positive impact on transfusion therapy outcomes by reducing alloimmunization, especially in patients with SCD.

Questions remain concerning the function of the Rh proteins in erythrocytes. The discovery that Rh protein homologs also exist in the liver and kidney indicates that the Rh blood group antigens belong to a conserved family of proteins that function in ammonia

transport. Similarly, the function of LW on the mature red cell is not entirely clear, but its ability to interact as an adhesion molecule with a broad range of integrin-binding specificity suggests an important role in both normal red cell development as well as disease-associated processes such as vaso-occlusion and thrombosis.

## CHAPTER 11

# Other protein blood groups

Jennifer Ricci Hagman & Jill R. Storry

Department of Clinical Immunology and Transfusion Medicine, Division of Laboratory Medicine, Office for Medical Services; and Division of Hematology and Transfusion Medicine, Department of Laboratory Medicine, Lund University, Lund, Sweden

Of the 43 currently known blood group systems, 8 are carbohydrate in nature and are discussed in Chapter 9. Antigens of the remaining 35 blood group systems are carried by (glyco)proteins. Three of these 35 systems—Rh (ISBT 004), RhAG (ISBT 030), and the closely associated LW (ISBT 016)—are discussed in detail in Chapter 10. The remaining blood group systems are summarized in Table 11.1 and are discussed here.

Many of the proteins carrying blood group antigens are functionally important, yet not all antibodies directed against these antigens represent an immunological barrier in transfusion medicine. Antibodies against the clinically important antigens can, however, result in a variety of complications ranging from mild to severe, delayed or acute. These adverse antigen–antibody interactions, deemed hemolytic transfusion reactions (HTRs), result in decreased survival/hemolysis of transfused antigen-positive red blood cells (RBCs). During pregnancy they can give rise to hemolytic disease of the fetus and newborn (HDFN) in a mother with antibodies directed at paternally inherited antigens on the fetal erythrocytes. Some antibodies are even implicated in difficulty to carry a fetus full term. Furthermore, the presence of antibodies may delay the availability of compatible units of RBCs for transfusion and, occasionally, make the transfusion of incompatible RBCs unavoidable, particularly in urgent settings or with antibodies to high-incidence antigens. This chapter addresses only those antigens that elicit formation of clinically significant antibodies while briefly commenting on the other blood group systems. Further details may be found in review articles<sup>1,2</sup> and specialized textbooks.<sup>3–5</sup>

### MNS blood group system (ISBT 002)

Antigens of the MNS blood group system are carried by glycoporphin A (GPA) and glycoporphin B (GPB). Both molecules are highly expressed in the erythrocyte membrane, with an estimated  $0.5\text{--}1.0 \times 10^6$  copies of GPA and  $0.1\text{--}0.3 \times 10^6$  copies of GPB per red cell.<sup>6</sup> GPA and GPB are encoded by homologous genes, GYPA and GYPB, at chromosome 4q28–q31. A third gene, GYPE, is also a member of this gene family but does not normally produce any protein. Both GPA and GPB are integral membrane proteins with a

single transmembrane  $\alpha$ -helical segment and with the N-termini located extracellularly (Figure 11.1). GPA was the first blood group-bearing protein whose primary structure was determined by amino acid sequencing.<sup>7</sup>

The M and N antigens are located on the N-terminus of GPA. Although two amino acid substitutions underlie M/N antigen identity (Ser20Leu and Gly24Glu), an important requirement for the recognition of these antigens by human antibodies is the presence of sialylated O-glycans attached to terminal serine and threonine residues. These glycans also provide the RBC with a net negative charge.

Although the genes share greater than 95% identity, GYPB encodes a shorter protein due to a single nucleotide variation (SNV) in intron 3 that otherwise mirrors the GYPA exon 3/intron 3 boundary. Since GYPB arose by gene duplication of GYPA, the first 26 amino acids of GPB are identical to those of GPA<sup>N</sup>, and GPB expresses an N-like antigen designated as 'N' (Figure 11.1).

The S, s, and U antigens are carried on GPB. S and s differ by one amino acid at position 48, with the S allele (*GYPB*\*03) encoding methionine and the s allele (*GYPB*\*04) encoding threonine. The U antigen is a high-prevalence antigen whose epitope is adjacent to the point where GPB enters the lipid bilayer (Figure 11.1).<sup>8</sup>

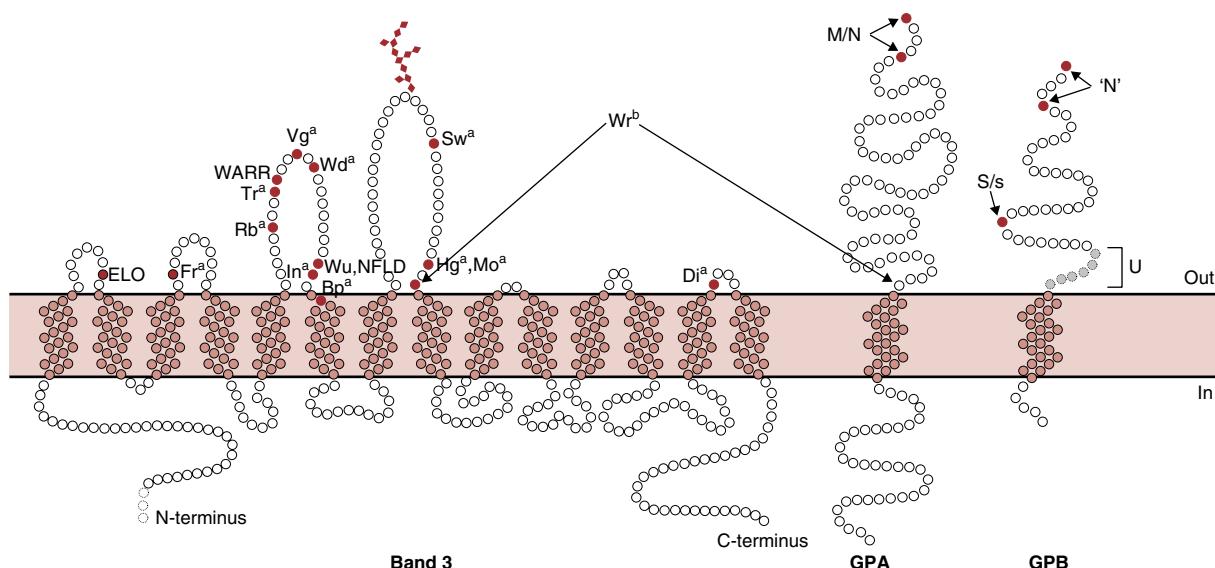

Homologous genes in close proximity to each other are often targets for unequal crossing over or gene conversion events. GYPA and GYPB are no exception and numerous recombination events have been described, resulting in hybrids of the two proteins.<sup>9</sup> This phenomenon is responsible for many low-prevalence MNS antigens carried by different hybrid proteins such as Mi<sup>a</sup>, V<sup>w</sup>, Hil, MUT, MINY, St<sup>a</sup>, and DANE. In addition to creating low-prevalence antigens, the expression of S and s antigens may also be altered on some hybrid proteins that can result in false-negative phenotype results.<sup>3,10</sup> Of note, while hybrids carrying the Mi<sup>a</sup> and Mur antigens are seldom encountered in European and African individuals, they are common in people from Southeast Asia. Targeted screening of Asian American blood donors at one large US blood center showed that 4.5% of donations were Mi(a+).<sup>11</sup>

**Figure 11.1** Antigens of the Diego and MNS blood group systems in a schematic of band 3 and glycophorins A and B. The membrane domain of band 3 with 14 transmembrane segments is shown. Mutations underlying the Diego blood group antigens are located in the putative first, second, third, fourth, and seventh extracellular loops. Positions of the M and N antigens in GPA and the 'N', S, s, and U antigens in GPB are indicated. Arrows point to the sites in band 3 and GPA that are involved in the formation of the Wr<sup>b</sup> epitope and, therefore, have to come into close contact in the membrane.

Diego blood group system (see below) is formed by the association of GPA with Band 3. This further demonstrates the intimate association of GPA and Band 3 in the plasma membrane.<sup>12</sup>

### MNS in transfusion medicine

The most commonly encountered antibodies are directed against the M, N, S, and s antigens. Anti-M is a common antibody that may be found in the sera of persons who have not been exposed to human erythrocytes, which is sometimes termed “naturally occurring.” They are predominantly IgM with a thermal optimum below 30 °C; however, anti-M frequently contain an IgG component and occasionally are exclusively IgG. Nevertheless, anti-M is rarely clinically significant, and cases of hemolytic anti-M are usually IgG and react at 37 °C. Selection of blood for transfusion can be made based on a negative crossmatch irrespective of M antigen status. Similarly, anti-M is not considered to be an important antibody with regard to HDFN, although occasional cases have been described.<sup>13,14</sup> Anti-N is rare, most likely because of the immune tolerance induced by the ‘N’ antigen on GPB, and is usually a weak, cold-reactive antibody of no clinical significance. These should be distinguished from the strong and potentially clinically significant antibodies observed in persons of the rare phenotype M+N–S–s–U– who do not express GPB and for whom phenotypically similar, crossmatch-compatible blood should be provided.

In contrast to anti-M and anti-N, antibodies to S, s, and U usually occur after exposure to allogeneic erythrocytes and should be considered clinically significant because all are capable of causing HTRs and HDFN. The appropriate antigen-negative, crossmatch-compatible blood should be selected for transfusion for patients expressing these antibodies.

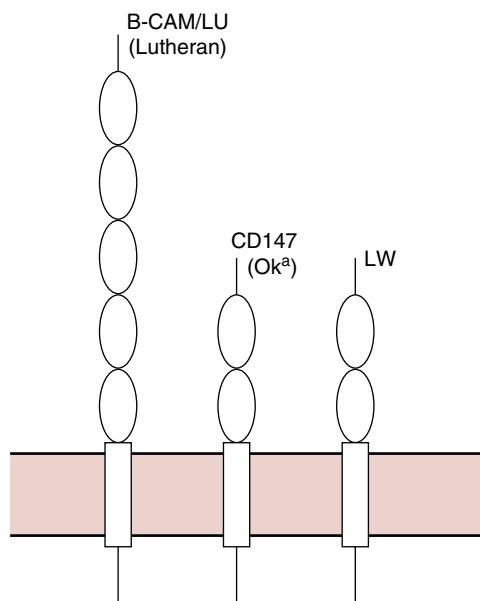

Lastly, severe HDFN due to rare antibodies to low-prevalence MNS antigens has also been reported and should be suspected in a strongly DAT-positive or symptomatic newborn where alloantibodies cannot be detected by routine screening.

### Lutheran blood group system (ISBT 005)

Lutheran antigens reside on B-CAM/LU (Figure 11.2), a pair of spliceosomes (protein products arising from the same gene because of alternative splicing of hnRNA) that belong to the immunoglobulin superfamily (IgSF).<sup>15,16</sup> Basal cell adhesion molecule (B-CAM) is involved in the adhesion of the basal surface of epithelial cells to the basement membrane. B-CAM/LU is a receptor for laminin.<sup>17,18</sup> Expression of B-CAM/LU is increased on erythrocytes from patients with sickle cell disease<sup>17</sup> and also on a number of malignant epithelial tumors,<sup>19</sup> which lose the polarity of B-CAM/LU expression found in normal tissues.

The Lutheran blood group system contains multiple antigens; however, clinically significant antibodies are rarely encountered. The most important antigens are Lu<sup>a</sup> and Lu<sup>b</sup>. The prevalence of Lu<sup>a</sup> is less than 10% in most populations, whereas Lu<sup>b</sup> is a high-prevalence antigen with an average occurrence of 99.8% in all populations. Lutheran antigens are poorly developed at birth and, not surprisingly, anti-Lu<sup>a</sup> has been associated only rarely with mild cases of HDFN. It does not cause transfusion reactions. Lu<sup>b</sup> is somewhat more immunogenic, and anti-Lu<sup>b</sup> has caused mild or moderate HTRs and mild HDFN. Of historical note, Lu and Se (Chapter 9) were the first two loci for which an autosomal linkage in humans was demonstrated.

The null phenotype, Lu(a–b–), is rare but quite interesting. It may result from three different patterns of inheritance. A recessive

**Figure 11.2** Members of the immunoglobulin superfamily carrying blood group antigens. B-CAM/LU contains five immunoglobulin domains and carries antigens of the Lutheran blood group system. CD147, or basigin, contains two Ig domains and carries the Ok<sup>a</sup> antigen. CD147 is similar to the LW protein, which is discussed in Chapter 8.

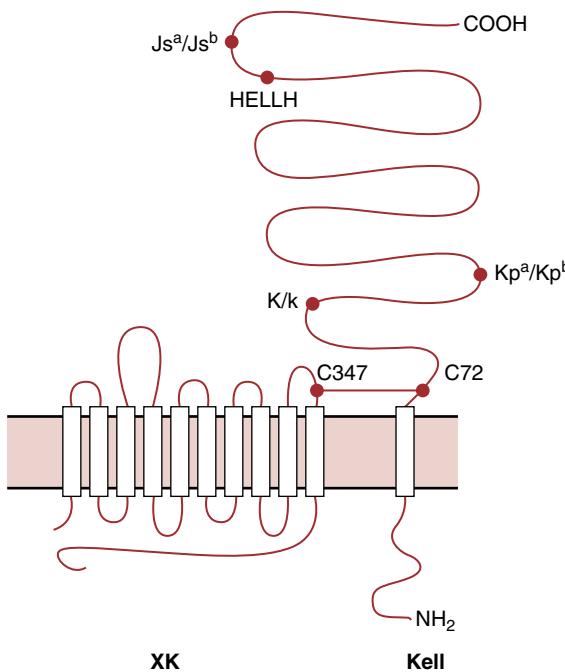

pattern of inheritance is associated with exceedingly rare null alleles of the LU gene. In the most common dominant type (so-called In(Lu)), heterozygous inheritance of mutations in the gene encoding KLF1, a common erythroid transcription factor, results in marked suppression of not only the Lutheran glycoprotein but also P1, i, In<sup>a</sup> and In<sup>b</sup>, and AnWj (see the Indian Blood Group System section).<sup>20,21</sup> The third cause of the Lu(a–b–) phenotype was first hypothesized to be the consequence of an X-linked recessive suppressor gene XS2.<sup>22</sup> Similar to In(Lu), the molecular basis has been identified as heterozygosity for a mutation in the GATA1 gene.<sup>23</sup> GATA1 is an important transcription factor in the differentiation of erythrocytes and megakaryocytes, and mutations in GATA1 account for cases of dyserythropoiesis, thrombocytopenia, and anemia.<sup>24</sup>

### Kell and Kx blood group systems (ISBT 006 and 019)

#### Structure, function, and interaction of the Kell and XK proteins

Antigens of the Kell blood group system are carried by a 93-kD red cell membrane glycoprotein, which consists of a short cytoplasmic N-terminal portion, a single membrane-spanning  $\alpha$ -helical segment, and a large, 665-amino-acid extracellular C-terminal portion held in a globular conformation by multiple disulfide bonds (Figure 11.3).<sup>25</sup> Kell antigens are disrupted by reducing agents such as dithiothreitol, suggesting that disulfide bonds are important in maintaining its antigenic conformation.

The Kell glycoprotein is a member of the neprilysin (M13) family of zinc metalloproteases. This family consists of Kell, neutral endopeptidase 24.11, two different endothelin-converting enzymes, the product of the PEX gene, and XCE.<sup>26</sup> Members of the M13 subfamily of membrane zinc endopeptidases have widely different roles, including processing of opioid peptides, Met- and Leu-enkephalin,

**Figure 11.3** Schematic representation of the Kell/XK complex in the red cell membrane. The XK protein is a multipass membrane protein, while Kell has only one transmembrane domain, most of which is exposed on the extracellular side. Due to multiple disulfide bonds, the extracellular portion of Kell is a globular structure; however, it is represented here schematically so that the positions of the main antigens can be shown. A disulfide bond between Cys72 of Kell and Cys347 of XK connects the two proteins. The position of the pentameric sequence HELLH is shown which is important for zinc binding and catalytic activity of zinc endopeptidases. The K/k polymorphism at amino acid 193 changes the consensus sequence for N-glycosylation at Asn191, which is not glycosylated in K. This difference in glycosylation may be important for the marked antigenicity of K. Positions of two additional sets of antithetical antigens Kp<sup>a</sup>/Kp<sup>b</sup> and Js<sup>a</sup>/Js<sup>b</sup> at amino acids 281 and 597 are indicated.

oxytocin, bradykinin, angiotensin, endothelins, and parathyroid hormone. Kell protein has been shown to preferentially activate endothelin-3,<sup>27</sup> however, the *in vivo* physiologic role of Kell protein is probably complex because K<sub>0</sub> (null) persons are apparently healthy.

Kell glycoprotein interacts in the erythrocyte membrane with the 37-kD protein XK, which plays an important role in the expression of Kell system antigens. In contrast to the Kell protein, XK is a multiple membrane-spanning protein with both of its N- and C termini located intracellularly (Figure 11.3). Absence of XK results in McLeod neuroacanthocytosis syndrome, an X-linked, late-onset neuromuscular disorder.<sup>28,29</sup> Structurally, XK resembles the glutamate transporters, but it has very little amino acid sequence homology with this group of transport proteins and a role in divalent cation homeostasis has been suggested since perturbation of the Kell/XK complex disturbs cell volume regulation. The Kell and XK proteins are covalently associated in the membrane by a disulfide link between cysteine 72 of Kell and cysteine 347 of XK (Figure 11.3).<sup>30,31</sup> The gene encoding the Kx antigen is located on the short arm of the X chromosome near the loci for X-linked chronic granulomatous disease (CGD) and Duchenne muscular dystrophy (DMD).<sup>32</sup>

### Kell in transfusion medicine

The Kell blood group system is the second most important protein blood group system in transfusion medicine after Rh because the antibodies can cause HTRs and HDFN. The most important antigens in this system are K (KEL1) and the antithetical k (KEL2). K and k are codominant autosomal alleles. While approximately 9% of whites and 2% of blacks are K-positive (i.e., K+k- or K+k+), the majority are K-negative (i.e., K-k+). Antigens of the Kell blood group system are highly immunogenic and, excluding ABO, K is second only to RhD in its potential to elicit production of alloantibodies.

Anti-K is a commonly encountered red cell alloantibody. Fortunately, it is easy to obtain blood for transfusion purposes since more than 90% of donor units are K-negative. In contrast, although anti-k is relatively rare, it is also of clinical significance and only 1 in 500 random donor units is antigen-negative. The other two sets of antithetical antigens to which antibodies are often found are Kp<sup>a</sup>/Kp<sup>b</sup> and Js<sup>a</sup>/Js<sup>b</sup> (Figure 11.3), although there are many other rare polymorphisms.

Mothers with anti-K are relatively rare, but since the introduction of Rh prophylaxis, anti-K accounts for nearly 10% of cases of severe HDFN. In contrast to RhD, anti-K titers are poor predictors of fetal anemia. In addition, affected Kell-alloimmunized infants have lower reticulocyte counts and amniotic fluid bilirubin concentrations than RhD-sensitized infants. Because Kell glycoprotein is synthesized early in erythropoiesis, anti-K has been hypothesized to suppress erythropoiesis at the progenitor cell level.<sup>33,34</sup> Administration of recombinant erythropoietin (rHuEPO) to the newborn has been tried with some success in rare cases where the mother has a Kell blood group system antibody causing prolonged anemia in a newborn whose RBCs and their progenitors express the cognate antigen in question.<sup>35,36</sup>

It is important to determine if a fetus is at risk when the mother has anti-K. The putative father should be typed; if he carries the K antigen, genotyping from amniocentesis or cell-free fetal DNA (cffDNA) in the mother's plasma can be performed using molecular techniques.

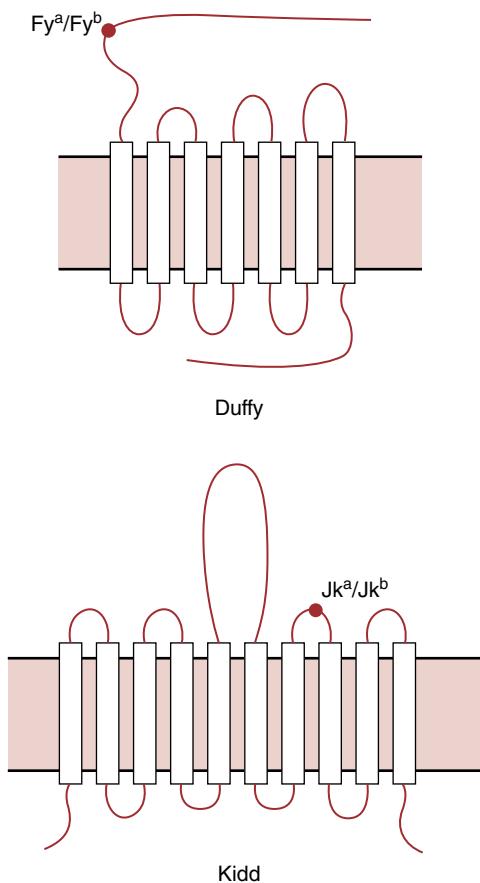

### Null phenotypes

There are two rare but clinically interesting null phenotypes. Rare individuals have erythrocytes that completely lack the Kell glycoprotein. Although these cells exhibit the null phenotype (K<sub>0</sub>), they are morphologically normal and survive normally *in vivo*. Yet, individuals lacking the XK protein, and thus Kx antigen, exhibit depressed levels of the Kell glycoprotein.<sup>25</sup> This phenotype, known as the McLeod neuroacanthocytosis syndrome, is associated with acanthocytic erythrocytes and a mild chronic hemolytic anemia.<sup>28</sup> It is coupled with late onset of neuromuscular symptoms that include muscle weakness or atrophy, cognitive alterations, as well as psychiatric symptoms. The phenotype is caused by large gene deletions encompassing XK.<sup>37</sup>

### Duffy blood group system (ISBT 008)

#### Structure and function of the Duffy protein

The Duffy gene (ACKR1) encodes a glycoprotein of 336 amino acids with a molecular weight of 36 kD. The Duffy glycoprotein has seven transmembrane  $\alpha$ -helical domains and is homologous with proteins of the G-coupled protein receptor family.<sup>38</sup> The Fy<sup>a</sup> and Fy<sup>b</sup> antigens are carried on the extracellular N-terminus; the C-terminus is intracellular (see Figure 11.4). Duffy protein func-

**Figure 11.4** Schematic depiction of proteins carrying the Duffy and Kidd blood group antigens. The Duffy antigen receptor for chemokines (DARC) consists of seven transmembrane segments. The N-terminus is located extracellularly, functions as both the chemokine and *P. vivax* attachment site, and carries the Fy<sup>a</sup>/Fy<sup>b</sup> polymorphism. The Kidd protein has 10 transmembrane segments, both N- and C-termini are intracellular, and the amino acid determining the Jk<sup>a</sup>/Jk<sup>b</sup> polymorphism is located in the fourth extracellular loop.

tions as a chemokine receptor and is also known as the Duffy atypical chemokine receptor 1 (ACKR1).<sup>39</sup> Duffy binds CXC chemokines, such as IL8 (interleukin-8) and MGSA (melanoma growth stimulatory activity), as well as CC chemokines, for instance RANTES (Regulated upon Activation, Normal T Cell Expressed and Presumably Secreted) and MCP1 (macrophage chemoattractant protein-1).<sup>40</sup> It is currently not known why a red cell, with its limited metabolism and response to chemokine binding, would carry a significant number of chemokine receptors at its surface. One possible explanation is that the chemokine receptor acts as a scavenger for locally released chemokines. However, individuals who do not express the Duffy protein either on erythrocytes or in all tissues are phenotypically normal, suggesting that the Duffy protein is dispensable.

Duffy is the primary receptor for the human malarial parasite *Plasmodium vivax*, which infects the erythrocytes of Duffy-positive individuals.<sup>41</sup> Evolutionary pressure exerted by *P. vivax* has led to the selective inactivation of erythroid ACKR1 in West and Central Africa (the Fy(a–b–) phenotype). Recently, Duchene *et al.* identified a role for ACKR1 in normal hematopoiesis and showed that in Fy(a–b–) individuals, phenotypically distinct polymorphonuclear

(PMN) leucocytes were produced that readily left the bloodstream, resulting in an apparent neutropenia (benign ethnic neutropenia, BEN).<sup>42</sup> Genome wide association studies confirmed that rs2814778, the SNV that inactivates the GATA1 binding site responsible for the Fy(a–b–) phenotype in these individuals, was also responsible for the BEN phenomenon and showed for the first time that ACKR1 was normally expressed on neutrophils.<sup>43</sup> In ACKR1-null individuals, erythroid progenitors preferentially differentiated to myeloid cells, and that the absence of ACKR1 on neutrophils resulted in premature egression to the spleen.

### Duffy in transfusion medicine

The two main alleles of the Duffy blood group system are the anti-thetical codominant antigens Fy<sup>a</sup> and Fy<sup>b</sup> whose genetic determinant is a Gly/Asp polymorphism in position 44 (Figure 11.4).<sup>44</sup> These two alleles occur with similar frequencies in persons of European ancestry, with Fy<sup>a</sup> being somewhat more common. The Fy(a–b–) phenotype is extremely rare among whites, but approximately two-thirds of African Americans and more than 90% of native West Africans are Fy(a–b–). This is most likely caused by the genetic adaptation for resistance to *P. vivax* malaria, although this hypothesis is contradicted by some data. For instance, in contrast to the other malarial parasites, *P. vivax* causes a relatively mild form of malaria.<sup>38</sup> Furthermore, despite the high prevalence of Duffy-negative individuals in West Africa, the Duffy protein has recently been shown to be a cofactor in platelet factor 4 (PF4)-dependent killing of *P. falciparum* parasites, suggesting that it has a protective role in this disease.<sup>45</sup>

Fy<sup>a</sup> antibodies are found relatively frequently, constituting 6–10% of the clinically significant antibodies identified by immunohematology laboratories. Both immediate and delayed HTRs caused by Fy<sup>a</sup> incompatibility have been described, ranging from mild to severe hemolysis. HDFN due to anti-Fy<sup>a</sup> is usually mild; only a few cases of severe HDFN have been reported. Fy<sup>b</sup> is a relatively poor immunogen and, consequently, anti-Fy<sup>b</sup> is considerably less common. Although, anti-Fy<sup>b</sup> is usually found in delayed HTRs, it has caused severe acute hemolysis on rare occasions. Only a few cases of mild HDFN have been attributed to the presence of anti-Fy<sup>b</sup>.

The underlying molecular mechanism for the Fy(a–b–) phenotype in individuals of African descent is a single nucleotide substitution c.–67T>C upstream of ACKR1 exon 1. This change interrupts a GATA1 site and abolishes transcription of the gene in the erythroid cells, while leaving the transcription in other tissues unaffected.<sup>46</sup> Consequently transfused Fy(a–b–) people of African ancestry do not develop anti-Fy<sup>b</sup>, and matching is not required for this antigen. In Africans, the change is carried exclusively on the FY\*B allele; however, it has been found on the FY\*A allele in individuals from Papua New Guinea.<sup>47</sup>

### Kidd blood group system (ISBT 009)

Kidd (SLC14A1) is an integral protein with 10 transmembrane domains and both N- and C-termini located intracellularly (Figure 11.4). Of the five extracellular loops, the longest third loop is N-glycosylated, and the relatively short fourth loop carries an Asp280Asn polymorphism corresponding to the Jk<sup>a</sup>/Jk<sup>b</sup> antigens.<sup>48</sup> Kidd protein is expressed not only on the red cell surface but also on neutrophils and in the kidney.

The two main antigens of the Kidd blood group system, Jk<sup>a</sup> and Jk<sup>b</sup>, are found with almost identical frequencies in white populations, while Jk<sup>a</sup> has a higher prevalence in people of African origin.

$\text{Jk}^a$  is a better immunogen, and anti- $\text{Jk}^a$  is found more frequently than anti- $\text{Jk}^b$ . Anti- $\text{Jk}^a$  may cause severe immediate or delayed HTRs and, occasionally, HDFN. It is one of the most dangerous immune antibodies because of its tendency to decrease to undetectable levels in between transfusions, its relatively weak reactivity in standard antibody identification tests, and its ability to bind complement. For these reasons, it accounts for a large proportion of delayed HTRs. Anti- $\text{Jk}^b$  may also cause immediate or delayed HTRs, albeit less severe than those caused by anti- $\text{Jk}^a$  (see <https://www.shotuk.org/shot-reports/> for more information). Several cases of mild HDFN caused by anti- $\text{Jk}^b$  have been reported. Weakly expressed forms of the protein have been described, in which the  $\text{Jk}^a$  and/or  $\text{Jk}^b$  antigens may be barely detectable.<sup>49–51</sup>

The early discovery that cells of the  $\text{Jk}(\text{a}-\text{b}-)$  phenotype are resistant to lysis by 2M urea alluded to the function of the glycoprotein carrying the Kidd antigens. Based on this finding and in vitro expression of the cloned Kidd cDNA,<sup>52–54</sup> it is now known that the protein is the primary erythrocyte urea transporter (SLC14A1). While the importance of urea transport for RBCs is not completely understood, its presence or absence may not be critical for red cell structure and function because carriers of the  $\text{Jk}(\text{a}-\text{b}-)$  phenotype have erythrocytes indistinguishable from those of controls.

## Diego blood group system (ISBT 010)

### Structure and function of the Diego protein

Antigens of the Diego blood group system are carried by band 3 (SLC4A1, anion exchanger 1), the most abundant integral protein of the red cell membrane together with GPA (see above). Band 3 is also one of the most important proteins for the structure and function of the membrane because it maintains red cell integrity by linking the red cell membrane to the underlying spectrin-based membrane skeleton. It also mediates exchange of chloride and bicarbonate anions across the plasma membrane, thereby significantly increasing the carbon dioxide carrying capacity of blood. Several disorders of red cell structure and function have been associated with mutations in the band 3 gene, including Southeast Asian ovalocytosis,<sup>55</sup> autosomal dominant spherocytosis, and distal renal tubular acidosis.<sup>56</sup>

Band 3 consists of an N-terminal cytosolic domain that interacts with the cytoskeleton and a membrane domain, responsible for gas transport. The membrane domain contains 14 transmembrane helices connected by ecto- and endoplasmic loops (Figure 11.1).<sup>57,58</sup> The fourth loop of band 3 is N-glycosylated, and the attached carbohydrate chain carries over half of the red cell ABO blood group epitopes.<sup>59</sup>

### Diego in transfusion medicine

$\text{Di}^a$  was originally described in South American Indians by Layrisse *et al.* in 1955<sup>60</sup> and was reported later to be carried on the Memphis II variant of erythroid band 3.<sup>61</sup> The antithetical antigen  $\text{Di}^b$  was reported in 1967.<sup>62</sup>  $\text{Di}^a$  and  $\text{Di}^b$  represent codominantly expressed gene products.  $\text{Di}^a$  is a low-prevalence blood group antigen in persons of European ancestry who carry the antithetical high-prevalence antigen  $\text{Di}^b$ . However,  $\text{Di}^a$  was used as one of the original markers for studying migration of people from Southeast Asia across the Bering Strait and southward through the American continents.<sup>63</sup> Prevalence of  $\text{Di}^a$  is as high as 8% in certain areas of Southeast Asia and reaches up to 40% in some groups of South American Indians. The  $\text{Di}^a/\text{Di}^b$  antigens are defined by the amino acids p.Pro854Leu in the last extracellular loop of band 3.<sup>64</sup>

Another antithetical pair of antigens,  $\text{Wr}^a/\text{Wr}^b$ , were mapped to the fourth extracellular loop (p.Glu658Lys).<sup>12</sup> The  $\text{Wr}^b$  antigen is only expressed when both GPA and band 3 protein are expressed in the erythrocyte membrane; thus, erythrocytes that lack GPA (so-called En(a–) phenotype) but have normal band 3 are also  $\text{Wr}(\text{b}-)$  (Figure 11.1).

A further 17 low-prevalence antigens are associated with single-point mutations on band 3 and included in the Diego system.<sup>65–67</sup> Positions of the amino acid polymorphisms in the band 3 molecule are shown in Figure 11.1, which also depicts the regions of band 3 and GPA that interact in the membrane and are involved in the formation of the  $\text{Wr}^b$  antigen.

Some antigens of the Diego blood group system have been localized to regions of band 3 protein implicated in the adhesion of abnormal erythrocytes, such as sickle cells or malaria-infected erythrocytes, to vascular endothelium.<sup>68,69</sup> Erythrocytes from carriers of low-prevalence blood group antigens in band 3 may serve as a model for the evaluation of the sequence requirements for adhesion. The so-called *senescent* or *aging red cell antigen* may also be located in the extracellular loops of band 3.<sup>70</sup>

In general, antibodies to Diego system antigens have been implicated in HTRs and HDFN and should be considered clinically significant; however, it has been estimated that 30% of autoimmune sera contain anti- $\text{Wr}^a$  and these are not generally considered to be clinically important.

## Xg blood group system (ISBT 012)

The Xg system contains two antigens carried on glycoproteins,  $\text{Xg}^a$  and CD99.<sup>71</sup> The role of  $\text{Xg}^a$  on erythrocytes has not yet been determined; however, it is 48% homologous to CD99, an adhesion molecule. A single nucleotide variation (SNV) at rs311103 upstream of the *XG* gene, which disrupts binding to the GATA1 box in erythropoietic cells, differentiates between the  $\text{Xg}(\text{a}+)$  and the  $\text{Xg}(\text{a}-)$  phenotype, as well as controlling expression levels of CD99.<sup>72,73</sup>

$\text{Xg}^a$  was the first blood group antigen to be assigned to a chromosome due to its differential distribution between men and women.<sup>74</sup> The *CD99* gene and the rs311103 locus lie within pseudoautosomal region 1 (PAR1) on the X and Y chromosomes, while *XG* on the X chromosome straddles the pseudoautosomal boundary (PAB) and consequently escapes lyonization (X-inactivation).<sup>71</sup> As such, men carry two copies of *CD99* but only a single copy of *XG*. On the Y chromosome, a pseudogene *XGY2* consisting of the first three exons of *XG* is present in PAR1 and does not express a protein product.  $\text{Xg}^a$  antibodies are clinically insignificant.

## Scianna blood group system (ISBT 013)

The seven antigens of the Scianna blood group system are carried by the erythroblast membrane-associated protein (ERMAP), potentially a receptor/signal transduction molecule specific for erythroid cells.<sup>75</sup> Mild delayed HTRs and mild HDFN caused by anti-Sc-2 and anti-Sc-3 antibodies have been reported.

## Colton and GIL blood group systems (ISBT 015 and 029)

Antigens of these two blood group systems are carried by members of the large aquaporin family. Antibodies against the two antigens of the Colton blood group system, the high-prevalence  $\text{Co}^a$  and the less common antithetical  $\text{Co}^b$ , are rare and have only occasionally been

associated with mild HTRs and mild HDFN. These two antigens, together with the high-prevalence Co3 and Co4, are present on all erythrocytes except those of the very rare null phenotype Co (a–b–). They are carried by aquaporin-1 (AQP1),<sup>76</sup> a member of a large family of water channels.<sup>77</sup> The absence of AQP1 in the rare Co(a–b–) phenotype is associated with only slightly abnormal erythrocytes and with normal kidney function,<sup>78</sup> suggesting an alternative water regulating mechanism. The GIL antigen is carried by aquaporin-3 (AQP3), which differs from AQP1 in that it transports not only water, but also glycerol and urea.<sup>79</sup> Anti-Gil is rare, but transfusion reactions have been reported. No HDFN has been described.

### Chido/Rodgers blood group system (ISBT 017)

Antigens of the Chido/Rodgers blood group system are the only protein antigens that are not produced by erythrocytes but instead adhere to the red cell surface (Lewis antigens are glycolipids, see Chapter 9). They are carried by the complement component C4 and adsorbed onto RBCs. Although antibodies against the nine known antigens of the system are generally benign, a severe anaphylactic reaction following a transfusion of platelets to a patient with anti-Ch3 has been described.<sup>80</sup> In the laboratory, anti-Ch/-Rg are readily inhibited by pooled plasma.

### Gerbich blood group system (ISBT 020)

There are 13 antigens in the Gerbich blood group system, and similarly to the MNS system, the antigens are located on glycophorins, i.e., glycophorin C and D (GPC and GPD). However, the glycophorin terminology is the only common feature of these two classes of glycophorins. GPC and GPD are the products of a single gene, GYPC, and are the products of alternative splicing. GPC is produced by a full-length gene transcript, whereas the less abundant GPD is produced from a second initiation methionine that encodes a protein that is 21 amino acids shorter. Although present in much fewer copy numbers than GPA and GPB, GPC plays an important role in the structural integrity of the red cell membrane.<sup>81</sup> In the Leach phenotype, deletions of exons 3 and 4 or a frameshift mutation leads to complete absence of glycophorins C and D from the plasma membrane.<sup>82</sup> The affected individuals have moderate elliptocytosis and decreased red cell deformability and mechanical stability. Antibodies in the Gerbich system, to both the high- and low-prevalence antigens, are rare although anti-Ge2 is more commonly found in individuals from the Middle East. Anti-Ge2 is generally not clinically significant and has not been implicated in HDFN; however, anti-Ge3 may cause a transfusion reaction and has been implicated in severe HDFN. GPC is expressed early on erythroid progenitors, and corresponding antibodies may result in severe anemia in fetuses similar to HDFN in women with anti-K.

### Knops blood group system (ISBT 022)

Antigens are located on the C3b/C4b complement receptor 1 (CR1, CD35). CR1 protects erythrocytes from autohemolysis by inhibiting the classical and alternative complement pathways through cleavage of C4b and C3b. CR1 is a large 190- to 280-kD molecule. It contains 30 complement control protein domains (CCPDs) of about 60 amino acids and seven CCPDs form a long homologous repeat (LHR) of about 450 amino acids. Various forms of CR1 contain up to six LHRs.<sup>83</sup> Erythrocyte CR1 binds immune complexes and carries them to the liver and spleen for removal.

The majority of blood group antigens in the Knops system are carried primarily in LHR-D, including: the antithetical antigen pairs Kn(a/b), McC(a/b), and KCAM/KDAS; the antigen trio Sl1/Sl2/Sl3; and Yk(a). Antibodies to the high-prevalence antigens Kn<sup>a</sup>, McC<sup>a</sup>, and Yk<sup>a</sup> are relatively common but they are readily inhibited by commercially available soluble recombinant LHR-D peptides. Failure of some Knops antibodies to be inhibited by these peptides led to the recent identification of another antithetical antigen pair DACY/YCAD located on LHR-C.<sup>84</sup> Antibodies to Knops system antigens are not clinically significant but can take time to identify. Expression of CR1 on erythrocytes of one individual to another varies widely from 20 to 1500 molecules and is decreased in hemolytic anemias, AIDS, systemic lupus erythematosus, and other autoimmune disorders. *Plasmodium falciparum*-infected erythrocytes deficient in CR1 have greatly reduced rosetting capacity, indicating an essential role for CR1 in rosette formation. This suggests the possibility that CR1 polymorphisms in Africans that affect the interaction between erythrocytes and parasite-encoded protein PfEMP1 may protect against severe malaria.<sup>85</sup> CR1 could therefore be a potential target for future therapeutic interventions to treat severe malaria.

### Indian blood group system (ISBT 023)

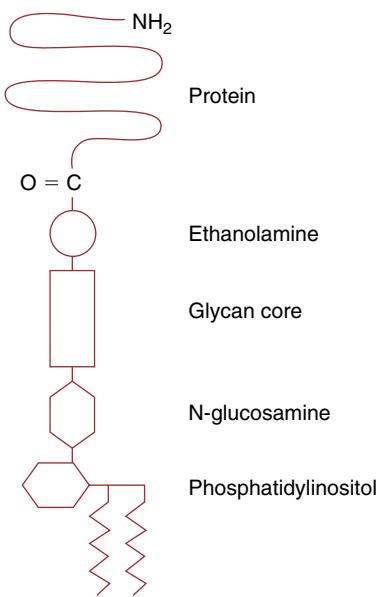

This system consists of the antithetical pair, In<sup>a</sup>/In<sup>b</sup>, and high-prevalence antigens INFI, INJA, INRA, and INSL. These antigens reside on CD44, an adhesion molecule also expressed in leukocytes, fibroblasts, epithelial cells, and other tissues. CD44 is an important lymphocyte marker that functions as a hyaluronan receptor and a lymphocyte homing receptor (Figure 11.2).<sup>86</sup> Transfection of non-adherent cell lines with CD44 cDNA confers an adherent phenotype.<sup>87</sup>

The rare In(a+b–) phenotype is found in individuals from South Asia, stretching east from Iran to India. As with the Lutheran antigens, the expression of Indian blood group system antigens is suppressed in the In(Lu) phenotype (see above). The high-prevalence antigen, AnWj, is also associated with CD44 and is a receptor for *Haemophilus influenzae*.<sup>88</sup> Antibodies to Indian blood group system antigens are rare and of limited clinical significance. Anti-AnWj is extremely rare.

### Blood group antigens on glycosylphosphatidylinositol-linked proteins: Cartwright (ISBT 011), Dombrock (ISBT 014), Cromer (ISBT 021), JMH (ISBT 026), CD59 (ISBT 035), KANNO (ISBT 037), and EMM (ISBT 042)

The common denominator of antigens in these blood group systems is the linkage of the carrier protein to the glycosylphosphatidylinositol (GPI) anchor (Figure 11.5). The Cartwright (Yt) blood group system antigens are located on red cell acetylcholinesterase (AChE) and include the antithetical pair Yt<sup>a</sup>/Yt<sup>b</sup> and three high-prevalence antigens,YTEG, YTLI, and YTOT. In the laboratory, the antibodies are readily inhibited by soluble AChE. Anti-Yt<sup>a</sup> is usually benign; however, continuously transfusing against patient phenotype may result in reduced survival of RBCs.<sup>89</sup> The function of acetylcholinesterase on erythrocytes is not understood, although it appears to play a role in vascular signaling.<sup>90</sup>

The Dombrock blood group system consists of the antigen pair Do<sup>a</sup>/Do<sup>b</sup> and eight other high-prevalence antigens located on

**Figure 11.5** Schematic representation of a GPI-anchored protein. The membrane anchor is provided by phosphatidylinositol. The inositol moiety binds to a glycan core via a molecule of N-glucosamine. The glycan core is attached via ethanolamine to the C-terminus of the protein.

ART-4, a member of the adenosine 5'-diphosphate (ADP)-ribosyltransferase ectoenzyme gene family.<sup>91</sup> Absence of ART4 is defined by the Gy(a–) phenotype. Although rare, antibodies to Dombrock blood group antigens can be of clinical importance. ART4 expression is developmentally regulated during erythroid differentiation and occurs at highest levels in the fetal liver.

The polymorphic Cromer blood group system contains 20 antigens located on decay-accelerating factor (DAF, CD55), a complement regulatory protein. Extraordinarily, many of the polymorphisms appear restricted to one ethnic group or another, making it a very interesting blood group system.<sup>92</sup> Antibodies to Cromer blood group antigens are rare and of limited clinical importance, and due to the expression of DAF on the placenta, antibodies disappear over the course of pregnancy and pose no threat to the fetus.<sup>93</sup> Although DAF was the first complement regulatory protein identified, it plays only a minor role in complement-mediated lysis, the more important being CD59 (MIRL). This was clearly demonstrated in the case of the null phenotype, IFC-negative (Inab), which is associated with lack of DAF expression on all circulating cells but not with increased hemolysis.<sup>94</sup>

The eight high-prevalence antigens of the JMH blood group system reside on a GPI-linked protein, semaphorin 7A (CD108), which is part of a plasma membrane complex associated with intracellular protein kinases.<sup>95</sup> CD108 is expressed in multiple tissues and may play a role in signal transduction. Anti-JMH is generally a weak, clinically benign antibody found in older people, leading to the colloquial terms the “old boys club” or the “over 60 group” for antibody producers.

CD59, also known as MAC-inhibitory protein, was assigned blood group system status following the report of an antibody produced in response to transfusion in a CD59-deficient girl.<sup>96</sup> Although the absence of CD59 in this and other patients has severe clinical consequences, the clinical significance of the antibody is not known.

The high-prevalence antigen KANNO was recently shown to be due to a missense mutation in *PRNP*, the gene encoding the prion protein.<sup>97</sup> Anti-KANNO was first described in 1991 and is most commonly found in Japanese women with a history of pregnancy.<sup>98</sup>

There have been no reports of HTRs or HDFN, and its clinical significance remains unknown.

Another high-prevalence antigen located on a GPI-linked protein belongs to the EMM blood group system. The Emm-negative phenotype is caused by different mutations ranging from single nucleotide changes to partial gene deletions in *PIGG*, a gene in the GPI synthesis pathway.<sup>99,100</sup> Anti-Emm is rare and is most often naturally occurring.<sup>3</sup>

Not surprisingly, the expression of all GPI-linked antigens is decreased in paroxysmal nocturnal hemoglobinuria (PNH), a multi-symptomatic disorder caused by defects in the X-linked phosphatidylinositol glycan class A (*PIG-A*) gene, which participates in an early step of GPI anchor synthesis.<sup>101</sup> The pathophysiology of PNH is due almost exclusively to the absence of CD55 and CD59, which are important regulators of the complement system: CD55 accelerates the rate of destruction of membrane-bound C3 convertase and thus limits C3 activation; and CD59 reduces the amount of the membrane attack complex (MAC) formed by preventing C9 accumulating and thus lytic pore formation. Anemia, due to both hemolysis and bone marrow failure, and thrombosis are also common in PNH patients.<sup>101</sup> See Chapter 29 for a complete discussion of PNH.

### Other minor blood group systems: OK (ISBT 024), RAPH (ISBT 025), JR (ISBT 032), LAN (ISBT 033), VEL (ISBT 034), AUG (ISBT 036), CTL2 (ISBT 039), PEL (ISBT 040), MAM (ISBT 041), and ABCC1 (ISBT 043)

The three high-prevalence antigens of the OK blood group system are carried on basigin (CD147), a widely distributed IgSF molecule.<sup>102</sup> Rare Ok(a–) individuals have so far been reported only in Japan, and the absence of the high-prevalence antigens OK2 and OK3 has been described in single families.<sup>103</sup> As with LW, its extracellular domain contains two immunoglobulin domains. The function of the Ok glycoprotein in erythrocytes is not known, but it has recently been described as a novel receptor of *P. falciparum*.<sup>104</sup>

MER2 is the only antigen of the RAPH system carried on CD151.<sup>105</sup> CD151 is a tetraspannin that is expressed not only on erythrocytes but also on basement membranes, where in the kidney and in skin it is thought to facilitate binding of integrins to the extracellular matrix to maintain integrity.<sup>106</sup>

To date, four proteins in the ABC transporter family have been shown to carry blood group antigens. In 2012, the molecular basis for the Jr(a–) and Lan– phenotypes was identified, and in 2020, the PEL– negative phenotype was resolved.

The Jr<sup>a</sup> antigen was localized to ABCG2, where the Jr(a–) phenotype represented the null phenotype.<sup>107,108</sup> ABCG2 is a well-characterized protein that confers multidrug resistance (e.g., in breast cancer) and is also important in porphyrin homeostasis. It has a high affinity for urate, and Japanese Jr(a–) individuals have a higher incidence of gout. Anti-Jr<sup>a</sup> is not usually considered clinically important; however, it has caused severe HDFN.<sup>109</sup>

The high-prevalence Lan antigen is carried on ABCB6, a mitochondrial porphyrin transporter considered essential for heme synthesis.<sup>110</sup> Like Jr(a–), Lan– individuals represent the null phenotype and lack the protein. ABCB6 is highly expressed during erythropoiesis. Anti-Lan is not generally considered clinically important, and antigen expression is variable.<sup>111</sup>

The PEL antigen is carried by the ABC transporter ABCC4, also called MRP4 for multidrug resistance protein 4. Whole genome sequencing combined with comparative global proteomic

investigations has revealed a large deletion in *ABCC4/MRP4* responsible for the PEL negative phenotype.<sup>112</sup> While this rare phenotype is associated with impaired platelet aggregation, no implications regarding RBC function have been suggested. Even though reduced survival of incompatible RBCs has been observed, anti-PEL is not generally considered clinically important.

The most recent blood group system to be described is named simply ABCC1 after the protein carrier also known as multidrug resistance protein 1. One high-prevalence antigen, WLF, has been described. WLF negative individuals represent the null phenotype, similar to the blood group antigens described above in this section. Even though the ABCC1<sub>null</sub> phenotype seemingly has little effect on the RBCs, possibly due to compensatory mechanisms, it might have an impact on renal function.<sup>113</sup>

Expression of the clinically important Vel antigen has been shown to be dependent on SMIM1, a small transmembrane protein of unknown function.<sup>114–116</sup> The protein is well-conserved across species, suggesting that it is an important protein, and GWA studies suggest that it might play a role in iron metabolism.<sup>117</sup> Anti-Vel is considered clinically significant and has caused severe hemolytic transfusion reactions.

At<sup>a</sup> is a high-prevalence antigen belonging to the Augustine (AUG) blood group system. The At(a–) phenotype has mainly been reported in people of African origin. Lack of the At<sup>a</sup> antigen is due to an SNP in *SLC29A1*, encoding the equilibrative nucleoside transporter 1 (ENT1). Although the SNP does not affect the function of ENT1, anti-At<sup>a</sup> can cause severe HTRs and mild HDTN. While ENT1 is abundant on the membrane of RBCs, the biological function in RBCs remains unclear. Complete loss of ENT1 as in the AUG<sub>null</sub> phenotype, associated with ectopic calcification, does not seem to affect the RBCs.<sup>118</sup>

*SLC44A2* encodes the choline transporter-like 2 protein (CTL2). Two antigens, VER and RIF, make up the CTL2 blood group system. The rare RIF– phenotype is due to a missense mutation in *SLC44A2*, whereas a large deletion underlies the rare SLC44A2<sub>null</sub> (VER–) phenotype, causing complete loss of CTL2 expression.<sup>119</sup> Neither anti-RIF nor anti-VER have been associated with HTRs. However, both antibodies are implicated in TRALI (transfusion related acute lung injury) since they react with CTL2, carrying the human neutrophil antigen 3 (HNA-3), on neutrophils. Despite CTL2 having an evident biological function, as seen by multiple disease associations, the role of CTL2 on RBCs appears to be redundant.

The rare MAM– phenotype was shown recently to be due to different genetic aberrations in *EMP3*, the gene that encodes the tumor suppressor epithelial membrane protein 3 (EMP3), and which had not previously been described on erythroid cells.<sup>120</sup> *EMP3* plays an important role as a regulator of erythropoiesis as shown by increased early progenitor proliferation in cell cultures from MAM– individuals and interacts with CD44 in the RBC membrane. Anti-MAM has been shown to cause severe HDFN and, in some cases, neonatal thrombocytopenia.

## Summary

The century-long history of modern transfusion medicine and immunohematology practice led to the identification of an enormous number of blood group antigens. These have been catalogued into a

framework of blood group systems, collections, and low- and high-prevalence antigen series.<sup>121</sup>

Advances in biochemical and molecular biology techniques over the past decades have led to better understanding regarding gene variation, amino acid polymorphisms, protein structure and function, as well as the immunogenicity of individual antigens. Despite increasingly sophisticated and high throughput applications such as whole genome sequencing and variant filtering strategies, unravelling of a novel blood group antigen still, interestingly, begins with a patient presenting an antibody with an atypical RBC agglutination pattern. Careful sequential serological investigations need to be performed to resolve these antibodies. Although some may have little clinical significance, it is still important to determine their specificity since they may cloud the field, masking clinically relevant antibodies capable of causing HTRs and HDFN. Fortunately, the transfusion medical services have a wide array of techniques at their disposal, and the development of tools such as recombinant soluble proteins is an important contribution to antibody identification (see Chapter 12). The availability of increasingly advanced patient applications coupled with time and cost-efficient methods for phenotyping large volumes of blood donors has undoubtedly contributed to accurate compatibility testing and to safe transfusion of erythrocytes.

## CHAPTER 12

# Immunohematology and compatibility testing

Connie M. Westhoff & Lynsi Rahorst

Laboratory of Immunohematology and Genomics, New York Blood Center Enterprises, New York, NY, USA

### Introduction

Immunohematology is the study of the immune response to blood group antigens following stimulation with foreign blood cells through transfusion or pregnancy and the resulting impact on donor-recipient compatibility. Although numerous differences (polymorphisms) in protein and carbohydrate molecules are present on blood cells of individuals, by definition, the foreign protein epitope or carbohydrate must have stimulated production of a specific antibody to be considered a “blood group antigen.” This is especially relevant today as extensive polymorphisms in molecules on blood cells will be cataloged in genomic databases, but until found to be the target of an immune response in a patient, these differences are not given blood group antigen status.

This chapter reviews the basic concepts of immunity as they apply to the production of antibodies to foreign red blood cell (RBC) antigens called “atypical” alloantibodies to distinguish them from anti-A and anti-B that are found in the plasma depending on ABO blood type (referred to as “natural” antibodies). Antibodies to platelets and neutrophils, as well as autoantibodies and drug-induced antibodies, are discussed elsewhere.

Identification of the specificity of alloantibodies (antibody identification) is performed by testing plasma or serum against commercial red cells of known phenotypes. Modern immunohematology uses knowledge of the extended blood group profile of the patient to aid and inform the process of antibody identification and the selection of red cell units for transfusion. The chapter also includes a discussion of the steps and requirements for pretransfusion compatibility testing and release of blood components for transfusion, as well as efforts to track adverse transfusion events through biovigilance programs and to reduce alloimmunization by extended antigen matching.

### Red cell immunology

#### The basics of the immune response

Immune responses are divided into two categories: humoral immunity and cell-mediated events. Humoral immunity is B-cell mediated and results in the production of antibody. Cell-mediated immunity involves the activation of T cells, which regulate the

immune response through the production of cytokines and direct interactions with other cells of the immune system.<sup>1</sup>

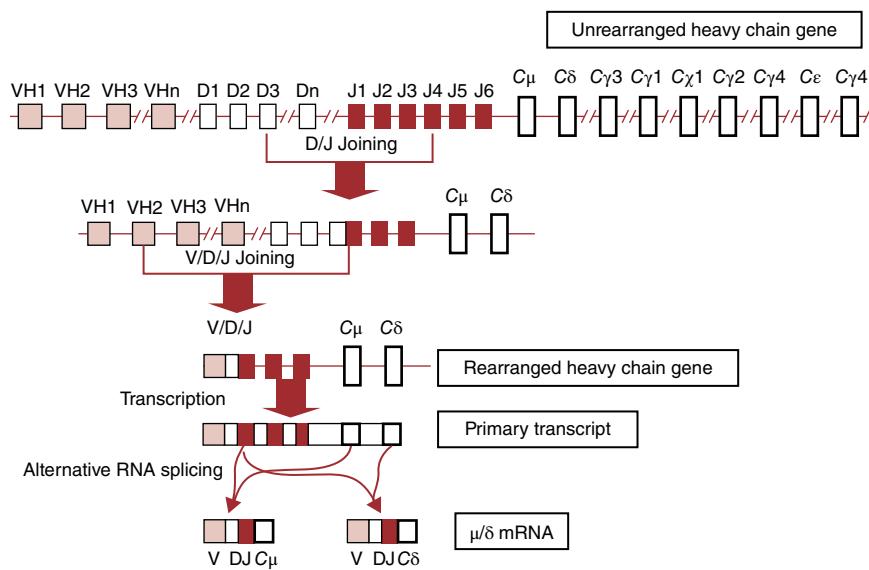

#### Antigen receptors on T cells and B cells

The antigen receptors of both T and B cells consist of two polypeptide chains synthesized under the direction of two different chromosomal loci. In the early stages of lymphocyte development, the genetic material at each of these loci undergoes a process of rearrangement, known as *somatic recombination*, which is unique to each cell.<sup>1</sup> The gene segments, grouped into families based on sequence similarity, and the rearrangement process entail selection and joining of the segments for each portion of the immunoglobulin molecule (Figure 12.1).

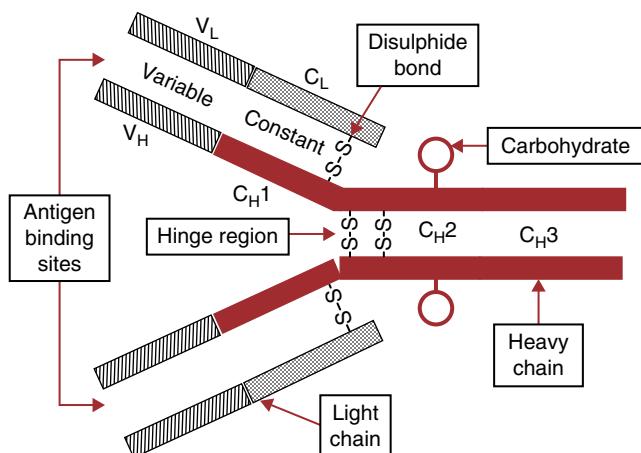

Each B-cell and T-cell receptor chain consists of a variable region, associated with antigen binding, and a constant region. B cell receptors are immunoglobulin molecules; the amino acid sequences of the constant region determine the isotype; and amino acid sequences of the variable region determine the antigenic specificity. The human immunoglobulin heavy chain loci are polymorphic between individuals in the number of genomic V, D, and J segments, but the heavy chain locus has at least 51 V gene segments, 6 J region gene segments, and 27 D region gene segments, and the number of possible rearrangements for different antibody binding regions is over 8000. At the light chain loci, there are at least 71 V gene segments and 9 J gene segments. Further variation is introduced by imprecise splicing of the gene segments and addition of extra nucleotides (called *N nucleotides*), which are not encoded in the genome, to V-D and D-J joints in the heavy chain variable region. Given all these mechanisms and assuming the combination of gene segments is random, the number of different antibody variable regions, and hence antigen binding specificities, is virtually unlimited.<sup>1</sup>

#### Immunoglobulin molecules

Figure 12.2 portrays the basic structure of an antibody molecule, which consists of four polypeptide chains: two identical light chains of 211–217 amino acids and two identical heavy chains of 440 or more amino acids. Antigenic specificity is conferred by the N-terminal amino acids of the heavy and light chains; these are described as *variable regions*. The remaining portions are referred to as *constant regions*.<sup>1</sup>

**Figure 12.1** Diagram of gene rearrangement generating antibody diversity at the immunoglobulin heavy chain locus on chromosome 14. The unrearranged locus (top) shows the V, D, and J gene segments on the left and the constant region segments to the right. Gene rearrangement occurs by selection and joining of one D and one J segment (exon) to form a D/J unit. This is then joined by one V exon. The V/D/J unit, via alternative splicing, is joined to C $\mu$  or C $\delta$  heavy chain gene segments. In later generations, clonal progeny can undergo isotype switching in which the same variable region V/D/J is joined to other sequences from the constant region.

**Figure 12.2** Basic structure of an immunoglobulin molecule.

### Light chains

The constant region of light chains can have one of two different amino acid sequences, designated kappa ( $\kappa$ ) and lambda ( $\lambda$ ). A single B cell will synthesize either  $\kappa$  or  $\lambda$  chains, but not both.

### Heavy chains

The constant region of heavy chains, designated by the Greek letters  $\alpha$  (alpha),  $\delta$  (delta),  $\epsilon$  (epsilon),  $\gamma$  (gamma), and  $\mu$  (mu), gives rise to five types of immunoglobulin classes or isotypes, termed IgA, IgD, IgE, IgG, and IgM, respectively. A single B cell will synthesize only one type of heavy chain.

### Exposure to foreign protein antigens

If foreign protein antigens enter the host, antigen-presenting cells (APCs) process the antigen and display antigen-derived peptides in association with host Class II MHC molecules on the cell surfaces. This peptide–MHC complex is recognized as foreign by the T-cell receptor on T lymphocytes. In contrast, B-cell receptor antibody molecules on B lymphocytes recognize foreign epitopes directly on the protein. Cytokines produced by the activated T cells cause antigen-specific B cells to develop into immunoglobulin-secreting

plasma cells. Plasma cells have a short but active life of antibody production. Some antigen-specific B cells develop into memory cells that persist in the circulation long after their initial activation.<sup>1</sup>

### Primary response

For foreign blood group antigens, as for other immune responses, the first immunoglobulin class to appear is immunoglobulin M (IgM), and the time between antigen exposure and appearance of antibody can vary from days to weeks. Shortly after the appearance of IgM antibody, IgG antibody of the same specificity usually becomes detectable. The IgM component disappears over time, whereas the IgG component persists indefinitely, but in regard to testing for atypical antibodies prior to transfusion the antibody can drop in titer to undetectable levels in laboratory testing. Cytokines from activated T cells are essential for immunoglobulin class switching and for the generation of memory B cells.

### Secondary (anamnestic) response

On re-exposure to a foreign antigen, a memory response is activated within a few hours or days, resulting in a sharp rise in the level of IgG antibody, higher than that was produced in the primary response. In regard to response to foreign blood group antigens and blood transfusion, this can result in a hemolytic transfusion reaction with the destruction of transfused cells.

### T-cell independent response

Antibodies produced in response to foreign carbohydrate antigens are primarily IgM. This is because antigen receptors on B-cells can be activated by direct binding to repeating polysaccharide epitopes, such as the blood group A or B antigens. Structures that have multiple identical repeat carbohydrate chains can initiate B-cell proliferation and antibody secretion without T-cell help. In the absence of T-cell help, isotype switching from IgM to other isotypes does not occur.<sup>1,2</sup>

### Affinity maturation

The affinity of IgG antibody for a specific antigen increases progressively during the immune response. Affinity maturation involves somatic mutation and clonal selection of B cells with

higher affinity antibody receptors for the antigen. This is sometimes seen early in the response to foreign RBC antigens as nonspecific or panagglutinin reactivity in laboratory testing. The following process occurs in the germinal centers of the secondary lymphoid organs:

- 1 **Somatic hypermutation:** Mutations occur in the variable, antigen-binding sequences (complementarity-determining regions [CDRs]) of the immunoglobulin genes. The mutation rate is up to 1,000,000 times higher than normal resulting in 1–2 mutations per CDR per cell generation which alter the binding specificity and affinity of the antibody.<sup>2</sup>
- 2 **Clonal selection:** Only B cells with the highest affinities for antigen will survive. Over several rounds of selection, the resultant secreted antibodies will have increased specificity and affinity for the antigen.<sup>2</sup>

### Clonality

Only antigen-activated B cells proliferate and mature into antibody secreting plasma cells. A polyclonal response occurs when many different B cells are activated simultaneously, best exemplified by anti-D made in D-negative individuals who lack the RhD protein, which carries multiple foreign epitopes. A more restricted oligoclonal response occurs when the antibody-producing cells originate from a few B cells, exemplified by anti-Fy<sup>a</sup> produced by a Fy(b+) individual, which represents a response to a single amino acid difference.

Monoclonal antibodies, which are commonly used as reagents in the laboratory, are specific for a single epitope. Antigen-specific monoclonal antibody responses are rarely found *in vivo* and are usually associated with some leukemias and multiple myeloma. Monoclonal antibodies are isolated *in vitro* from polyclonal responses using hybridoma technology.

### Blood group antibodies

Blood group antibodies bind to antigens on the surface of red cells, platelets, or neutrophils. The focus of this chapter is primarily on antigens expressed on red cells. Most blood group antibodies are either IgG or IgM; only occasionally they are IgA.<sup>3</sup> IgD and IgE immunoglobulins have not been implicated as blood group antibodies.

### Physical properties

The physical properties and serologic characteristics of the three antibody classes with blood group specificity are summarized in Table 12.1. IgM antibodies are pentameric and have 10 antigen binding sites, are direct agglutinating, and often fix complement to the red cells. Antibodies to A and B antigens, which are carbohydrates, are predominantly IgM and are found in persons whose red cells lack the corresponding antigen. They are acquired “naturally,” meaning they are stimulated by plants and bacteria that carry blood group A- and B-like polysaccharides.

Most other blood group antibodies are immune in origin and do not appear in plasma unless the host is exposed to foreign red cell antigens through blood transfusion, pregnancy, or transplantation. The majority are IgG, which have two antigen binding sites (bivalent) (Figure 12.2). Most IgG antibodies do not activate complement, but this depends on both the subclass of IgG and the number and nature of the antigen on the cells.

Antibodies to red cell antigens are considered “unexpected” alloantibodies and are directed to antigens absent on the RBCs of the individual. “Clinically significant” antibodies are those that can

**Table 12.1** Characteristics of Blood Group Antibodies

Immunoglobulin Characteristic	IgM	IgG	IgA
H-chain isotype	μ	γ	α
Subclasses	2	4	1
L-chain types	κλ	κλ	κλ
Sedimentation constant	19 S	7 S	11 S
Molecular weight	900–1000 kD	150 kD	180–500 kD
Electrophoretic mobility	Between β and γ	γ	Γ
Serum concentration (mg/dL)	85–205	1000–1500	200–350
Antigen binding sites	10 (pentameric)	2	4 (dimeric)
Fixes complement	Often	Some	No
Placental transfer	No	Yes	No
Direct agglutinin	Yes	Usually not*	Usually not
Example	Anti-A, anti-B	Anti-D	Anti-Lu

\* Some examples of IgG anti-M are an exception.

cause accelerated destruction or removal of antigen-positive transfused red cells. In pregnancy, IgG antibodies may cross the placenta and cause hemolytic disease of the fetus and newborn (HDFN).<sup>3</sup> There are more than 350 different blood group antigens described.<sup>4</sup> The immunoglobulin class and clinical relevance of some of the antibodies encountered are shown in Table 12.2.

### Red cell antigen–antibody interactions

Red cells normally repel one another due to the zeta potential at the surface which depends on the electronegative surface charge and the ionic cloud that surrounds it (Figure 12.3).<sup>5</sup> In pretransfusion laboratory testing, interaction between red cells and specific blood group antibodies must overcome this repulsion. Interaction between antibody and red cells is observed as agglutination (clumping), or rarely hemolysis, and often requires the use of a secondary antihuman globulin reagent.

### Agglutination reactions

There are two phases of red cell antigen–antibody agglutination interactions that often occur simultaneously. The first is one of association, involving binding of antibody to antigens on the red cell membrane. The second involves the formation of an agglutination lattice of antibody-coated cells. For the latter to occur, antibody molecules must be able to span the distance between adjacent red cells.

IgM antibody molecules can cause direct agglutination of RBCs carrying the corresponding antigen (Figure 12.3C). IgG antibodies often do not cause direct agglutination unless there are many antigens on the RBC (for example, the M antigen located on glycoprotein A). IgG antibodies coating RBCs can be detected with the addition of antihuman IgG (Figure 12.3D). Detection of agglutination routinely requires incubating plasma or serum with red cells at 37°C, followed by centrifugation. For *in vitro* enhancement of the interaction of red cell antigens and antibodies, the surface charge of the red cells can be decreased through a variety of methods: addition of bovine serum albumin; addition of low ionic strength solution (LISS); addition of polyethylene glycol (PEG) solution; or by treating the cells with proteolytic enzymes such as papain or ficin, which cleave the proteins that carry the negatively charged sialic acid residues.

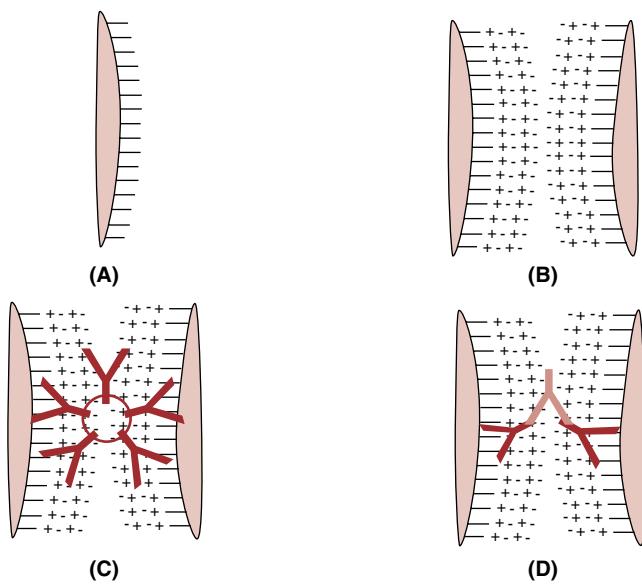

To aid the identification of the antibody specificity, especially when multiple antibodies are present, the strength of the agglutination reactions is graded, and numerical values are assigned based on a scoring system.<sup>6</sup>

**Table 12.2** Blood Group Antibody, Class, Clinical Significance, and % Antigen-Negative (Compatible) Donors<sup>7</sup>

**Figure 12.3** (A) Red cells carry a strong negative electric charge, imparted primarily by the carboxyl ( $\text{COO}^-$ ) group of *N*-acetyl-neuraminic acid. (B) When suspended in saline, red cells are kept apart by virtue of their negative surface charge. The magnitude of this charge is modified by the formation of an ionic cloud of positively charged (+) sodium ions and negatively charged (-) chloride ions at the red cell membrane surface. The force of repulsion that exists between red cells in suspension is referred to as the *zeta potential*. (C) In order for antibody molecules to cause agglutination of adjacent red cells, they must be able to span the intercellular distance. Pentameric IgM antibody molecules can readily bridge the distance between adjacent red cells causing agglutination. (D) IgG molecules cannot readily cause direct agglutination. The bound IgG antibody can be detected by antihuman IgG antibody (e.g., rabbit antihuman IgG), depicted here as lighter color, causing agglutination. Source: Based on Pollack *et al.* (1965).<sup>5</sup>

### Hemolysis

IgM antibodies, in particular anti-A and anti-B, can cause direct lysis of antigen-positive red cells in the presence of complement. Hemolysis results from the action of complement, a series of  $\alpha$  and  $\beta$  globulins that act to form a complex (membrane attack complex) that causes rupture of the red cell membrane. For initiation of the complement cascade, the Fc portions of two immunoglobulin heavy chains must be in proximity on the red cell surface. Initiation of the complement cascade readily occurs when a single pentameric IgM antibody molecule is bound; for it to occur with IgG antibodies, there must be closely adjacent heavy chain regions of two IgG molecules. Not all IgM antibodies bind complement to red cells, and complement binding does not always proceed to complete red cell lysis (intravascular hemolysis). Rather, activated C3b may be cleaved to C3d, which remains bound to red cells and can be detected by the antiglobulin test if anticomplement is included in the reagent.<sup>6</sup> Red cells coated with C3b are also removed by cells of the reticuloendothelial system (extravascular hemolysis).

### Antiglobulin test

IgG antibodies bound to red cells (and complement as well, if the reagent also contains anticomplement) are detected by the antiglobulin test. Once called the Coombs' test after the originator, the test entails the use of (IgM) antibodies raised in animals (rabbit), or prepared from a hybridoma (murine), to detect human IgG and/or

**Table 12.3** Overview of Antiglobulin Tests

Direct Antiglobulin Test (DAT)	Indirect Antiglobulin Test (IAT)
<ol style="list-style-type: none"> <li>Wash red cells to remove plasma/serum.</li> <li>Add antihuman globulin and/or anticomplement reagent.</li> <li>Centrifuge.</li> <li>Examine for agglutination and hemolysis.</li> </ol>	<ol style="list-style-type: none"> <li>Mix serum or plasma and red cells.*</li> <li>Incubate at 37 °C.</li> <li>Centrifuge.</li> <li>Examine for agglutination and hemolysis.</li> <li>Wash, to remove unbound immunoglobulins.</li> <li>Add antihuman globulin reagent.</li> <li>Centrifuge.</li> <li>Examine for agglutination.</li> </ol>

\* An enhancement reagent to promote antibody uptake is often incorporated here.

complement bound to red cells. These antibodies, generally referred to as antihuman globulin (AHG) reagent, will react with human globulins, either bound to red cells or free in plasma or serum. Red cells must be washed free of unbound antibodies before the addition of the AHG to avoid false-negative tests caused by the neutralization of AHG by the unbound globulins.

### Direct antiglobulin test

The direct antiglobulin test (DAT) is used to detect antibodies bound to red cells *in vivo*; such antibodies may be seen in patients with autoimmune hemolytic anemia, infants with hemolytic disease of the fetus and newborn, and patients manifesting an immune response to a recent transfusion.<sup>6</sup>

### Indirect antiglobulin test

An indirect antiglobulin test (IAT) is used to detect and identify unexpected IgG antibodies in the serum or plasma. These antibodies may be seen in individuals who have been previously transfused or pregnant.<sup>6</sup>

For the steps involved in direct and indirect antiglobulin testing refer to Table 12.3.

### Compatibility testing

Pretransfusion compatibility testing involves donor unit testing, patient sample collection and testing, and labeling and clerical checks between the donor unit and intended recipient (Table 12.4). Proper performance and critical attention to each element are needed to ensure that the right unit of blood is transfused to the right patient. A critical part of the process is proper identification of the patient, both at sample collection and at administration of the blood product. An avoidable cause of morbidity and mortality following blood transfusion is ABO incompatibility due to mislabeling of the sample, wrong blood in tube (WBIT), or misidentification and transfusion to the wrong patient.<sup>8</sup>

### Donor testing

#### Collection facility

ABO, RhD, and antibody detection tests on donor blood, tests for infectious diseases, and labeling of donor units are functions performed by a blood donor center; however, some hospital-based transfusion services continue to procure a portion of their blood needs, and thus perform these activities.

The volume of tests performed at donor centers necessitates the use of automated equipment. ABO grouping entails testing both red

**Table 12.4** Pretransfusion Compatibility Testing<sup>a</sup>

	<b>Element</b>	<b>Requirement</b>
Donor unit testing	Collection facility	ABO RBCs tested with anti-A and anti-B Plasma/serum tested with A <sub>1</sub> and B red cells Concordance between red cell and plasma/serum
		RhD Use a method to detect weak D
		Antibody detection Use a method to detect clinically significant antibodies
		Product labeling Process to verify correct information on the label
		Infectious disease testing Per FDA regulations
	Confirmation of ABO	Confirmation of ABO Test integrally attached segment, after label has been affixed
		Red cell testing only
	Confirmation of RhD Patient consent	Confirmation of RhD Confirm only red cells units labeled Rh-negative (weak D testing not required)
		Patient consent Blood bank or transfusion service medical director participates in the development of policies, processes, and procedures
Patient sample collection and testing	Transfusion facility	<b>Patient Sample Collection Identification</b> Positive identification of intended recipient and blood sample at the time of collection Mechanism to identify phlebotomist
		<b>Label</b> Contains two independent identifiers (e.g., first and last names, hospital registration number, and/or date of birth) Mechanism to identify date and time of collection
		<b>Timing</b> Affixed to sample before leaving side of intended recipient Within 3 days of red cell transfusion if patient was transfused or pregnant within previous 3 months or if patient history is uncertain or unavailable
		<b>Patient Sample Testing ABO</b> RBCs tested with anti-A and anti-B Plasma/serum tested against A <sub>1</sub> and B reagent red cells Concordance between red cell result and plasma/serum result
	<i>RhD</i>	RBCs tested with anti-D (weak D testing optional)
		<i>Unexpected antibodies</i> Utilize method that demonstrates clinically significant antibodies using reagent red cells (that are not pooled) Comparison of current ABO, RhD, and antibody screen with historical records. If no previous record, second sample must be tested to confirm ABO and RhD.
	<b>Serologic Crossmatch</b>	Antiglobulin test if clinically significant antibodies detected, currently or in the past

cells and plasma, and the results must be concordant for the unit to be labeled. Red cells are tested with anti-A and anti-B; and the plasma is tested against A<sub>1</sub> and B red cells. Anti-A,B and/or A<sub>2</sub> red cells are often used to detect weak subgroups of A that may be non-reactive in direct tests with anti-A.

Rh typing for the D antigen on blood donor samples must be performed by a method that will detect weak expression of the D antigen, as D is highly immunogenic and weak expression of the antigen can evoke an immune response if transfused to a D negative person. Donor red cells that initially type as Rh-negative are further tested for weak D expression by an indirect antiglobulin test (IAT), or more commonly at donor centers enzyme treatment of the RBCs is used to enhance the reactivity of weak D antigen. All D-positive and weak D-positive donor blood is labeled as Rh-positive.<sup>6,9</sup> Rare RBCs that express very weak D antigen, including those only detected serologically by adsorption/elution of anti-D (termed Del), are not detected as Rh-positive.<sup>6</sup> This is a limitation of serologic methods, and these units are labeled as Rh-negative. Hence, the production of anti-D in a patient receiving blood products labeled as Rh-negative should be reported to the blood center for follow-up testing of the donor.

### Transfusing facility

Confirmation of the ABO/Rh of a red cell donor unit is performed on a segment from the unit after the unit has been labeled and before transfusion by the transfusion facility. Testing of the red cells only is required, and Group O units are confirmed by testing with anti-A,B only. Red cell units labeled as Rh-negative must be confirmed by direct testing with anti-D; weak D testing is not required.<sup>6,9</sup> Repeat testing of donor units for unexpected antibodies, markers of infectious diseases or minor antigens (non-ABO/Rh) for which a unit is labeled, is not required.

### Patient testing

#### Sample collection and storage

A major avoidable cause of fatal, hemolytic transfusion reactions is ABO-incompatible transfusion resulting from patient and/or sample misidentification somewhere in the process from specimen collection to transfusion.

Although considerable resources have been spent to reduce infectious disease transmission, the elimination of process errors in transfusion deserves equal serious attention and resource allocation. These include misidentification of the patient at the time of sample collection or mislabeling of the collection tube; mistransfusion with transfusion of the wrong unit or transfusion to the wrong patient; and inappropriate transfusion, which exposes patients to the hazards of transfusions that they did not need.

Facilities must have validated processes and procedures that define each step in the sample collection process. Some considerations include:

- 1 Requisition.** Forms requesting blood and blood components must contain two independent patient identifiers, usually the first and last names and a unique numerical identifier such as a hospital identification number. The name of the requesting physician, self-identified gender, date of birth, diagnosis, and previous transfusion or pregnancy history are additional helpful information.
- 2 Patient identity.** The collection of a properly labeled sample for testing from the correct patient is critical to safe blood transfusion. The person collecting the sample must positively identify the patient from the wristband containing two unique patient identifiers that remain attached to the patient throughout hospitalization and blood transfusion. The information on the requisition form must be compared with that on the wristband; any discrepancy encountered must be resolved prior to collection of blood samples.

- 3 **Labeling.** Blood samples must be clearly labeled at the bedside with the patient's unique identifiers. There must be a mechanism to identify the date and time of sample collection and the individual who collected the sample.
- 4 **Confirmation of sample identity.** Prior to testing, the transfusion service compares the information on the blood sample label with that on the requisition. A new sample must be obtained whenever there are discrepancies or if there is any doubt about the identity of the sample. It is unacceptable to correct a mislabeled sample.
- 5 **Type of sample.** Either serum or plasma may be used for pretransfusion testing. EDTA anticoagulated plasma samples are more commonly used.
- 6 **Age of specimen.** The specimen used for compatibility testing must represent the patient's current immune status; thus, if a patient has been pregnant or transfused in the previous three months, or if this information is uncertain or unavailable, pretransfusion samples should be drawn within three days prior to transfusion. It is often simpler to stipulate that all pretransfusion samples must be collected within three days before red cell transfusions rather than ascertain if each patient has been recently transfused or pregnant.
- 7 **Storage.** Blood samples used for compatibility testing, including a segment from the transfused unit, must be stored at refrigerated temperatures for at least seven days after transfusion. This ensures that appropriate samples are available for investigational purposes should adverse reactions occur.

### ABO typing

Reagent antisera and red cells are available commercially. Anti-A and anti-B used to test the red cells are monoclonal antibodies prepared by hybridoma technology. Reagent A1 and B red cells used to test the serum or plasma are usually suspended in a preservative medium containing EDTA to prevent lysis of the red cells by complement-binding anti-A and anti-B. Use of anti-A,B and A2 red cells is optional, but is generally considered unnecessary when routinely ABO typing potential transfusion recipients.<sup>6</sup>

The expected findings for each of the four ABO phenotypes are shown in Table 12.5. When interpreting the results of ABO grouping tests, the reciprocal relationship that exists between the absence of A and/or B antigens on red cells and the presence of anti-A and/or anti-B in the plasma/serum is considered. If cell and plasma/serum ABO tests are discrepant, group O blood must be provided for transfusion until the discrepancy is resolved and reliable interpretation of the patient's ABO type can be made.

**Table 12.5** The Expected Reactions of the Four Common ABO Phenotypes: Results of ABO Typing Tests

Blood Type	Tests with Patient Red Blood Cells		Tests with Patient Plasma/Serum	
	Anti-A	Anti-B	A <sub>1</sub> Red Cells	B Red Cells
O	0	0	4+	4+
A	4+	0	0	4+
B	0	4+	4+	0
AB	4+	4+	0	0

0: no agglutination; 4+: strong agglutination.

### Rh typing

Anti-D for testing patient samples is often a blend of monoclonal IgM and monoclonal/polyclonal human IgG. With blended anti-D reagents, the IgM component causes direct agglutination of D-positive red cells, and the IgG component permits the detection of the weak expression of D by application of the antiglobulin test. For patient samples, the antiglobulin test for weak D is not required. To avoid incorrect designation of a D-negative recipient as D-positive because of autoantibodies coating the cells or abnormal serum proteins causing spontaneous agglutination, a control system appropriate to the anti-D reagent is required.<sup>6</sup>

### Tests for unexpected antibodies

Table 12.2 lists the more common blood group alloantibodies encountered and provides the approximate percentage of compatible units that are likely to be found in donors of Caucasian and African descent.

Methods for testing samples for unexpected antibodies must detect clinically significant antibodies, and an antiglobulin test (IAT) after 37 °C incubation of patient serum or plasma with reagent red cells is required. Several methods for antibody detection exist (Table 12.6). Decisions relative to these options are within the purview of the medical director. They should be made based on the type of patients served and the availability of resources, with the realization that no one method will detect all clinically significant antibodies.

### Tube test methods

A variety of red cell suspending media or additives are used either to enhance antibody uptake or to potentiate the agglutination phase of antibody–antigen interactions (Table 12.6). Low-ionic strength saline (LISS) solution, normal saline, or red cell preservatives (modified Alsever's solution) are used as red cell suspending media. Enhancement media added directly to plasma/serum–red cell mixture include LISS additives, polyethylene glycol (PEG), or less commonly bovine serum albumin (22% or 30% w/v).

Antibody uptake is accelerated when red cells are suspended in LISS or PEG. The net effect of additives is that more antibody can be bound in a shorter period of time using LISS or PEG as opposed to saline. Consequently, incubation times can be reduced to 10–15 minutes (exact times vary by reagent manufacturer), compared to 30–60 minutes for saline. The enhancing effect of albumin on red cell antigen interactions can be attributed to its formulation as a low ionic solution.<sup>11</sup>

It is common practice to examine tube tests for agglutination before subjecting them to an IAT. These examinations can be made immediately after mixing cells and serum followed by centrifugation (immediate-spin tests) and again after incubation at 37 °C. For antiglobulin testing, either anti-IgG or polyspecific AHG (containing anti-IgG and anti-C3) may be used. Use of polyspecific AHG may lead to the detection of a number of unwanted positive reactions due to the detection of cold autoantibodies of no clinical significance. PEG tests are not examined for direct agglutination, and AHG containing anti-C3 is not routinely used when PEG is utilized.

Tube testing is considered the gold standard for antibody detection and is the primary method of testing used in reference laboratories when investigating samples from patients who have become alloimmunized. Tube methods are useful because they can easily be adjusted to incorporate treated RBCs or changes in incubation time or temperature. A significant limitation of tube testing is

technologist time and competence required and the subjective nature of grading agglutination reactions.

#### Gel column testing

A gel matrix material for detecting agglutination due to red cell antigen–antibody interactions was first described in 1990 by Lapierre and colleagues.<sup>12</sup> Cards consisting of six microcolumns, each containing agarose gel suspended in neutral saline or containing anti-IgG, are commercially available. Atop each card is an incubation chamber in which reagent red cells and test plasma are dispensed. The cards are incubated at 37 °C and then centrifuged. As the red cells pass through the gel, if they were coated with antibody during incubation, visible agglutination will be observed as the red cells become trapped in the gel; unagglutinated red cells pellet to the bottom of the microcolumn (Figure 12.4).

When compared to tube tests, the time savings are reflected in the elimination of direct agglutination reading, washing, addition of AHG, and validation of negative tests with IgG-coated red cells. Reproducibility is increased through the use of measured volumes of reactants and less subjective reading of tests. The stability of reactions facilitates validation and review of results. Testing can be automated or semiautomated using liquid sample handling devices. Limitations of this method include increased sensitivity that may detect clinically insignificant reactivity and interference of plasma proteins (rouleaux).

**Figure 12.4** The gel test for detecting unexpected antibodies.

#### Solid-phase adherence methods

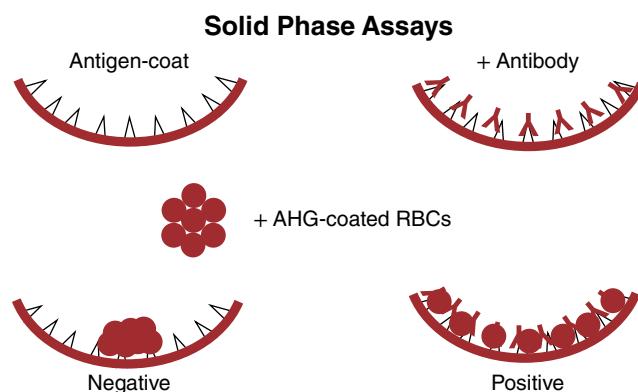

Two forms of solid-phase adherence assays are available for red cell serologic testing. For direct tests, antibody is fixed to wells of a microplate (e.g., anti-A and anti-B for donor/recipient ABO typing), and red cells are added. Following centrifugation, red cells expressing the corresponding antigen will efface across the well; red cells lacking the antigen will pellet to the bottom of the well.

For indirect tests (e.g., for detecting unexpected antibodies), red cells or red cell membranes are affixed to microplate wells; test serum or plasma is added along with LISS and incubated at 37 °C. The plates are washed to remove unbound globulins. Indicator red cells, which are coated with anti-IgG, are added and the plates are centrifuged. The indicator red cells efface across the well in a positive test and pellet to the center of the well in a negative test (Figure 12.5).

One advantage of solid-phase testing is the ability to automate. Limitations include subjective interpretation of results and reports of nonspecific or unidentified reactivity.<sup>13</sup>

#### Automated pretransfusion testing

Automated systems for pretransfusion testing are particularly suited for large hospital-based transfusion services. Automated systems perform sample and reagent pipetting and analysis of agglutination reactions. Standard features include positive sample identification, process control through automated documentation of reagent lot numbers and expiration dates, STAT sample interrupt, and image analysis. The test results can be transmitted via an interface into the laboratory computer system. The benefits of automation include technologist time savings, positive sample identification, standardized testing, and increased workload capacity.

**Figure 12.5** Solid-phase adherence assays.

## Reagent red cells for antibody screening

The FDA mandates that reagent red cell samples licensed for use in pretransfusion antibody detection tests carry the C, c, D, E, e, Fy<sup>a</sup>, Fy<sup>b</sup>, Jk<sup>a</sup>, Jk<sup>b</sup>, K, k, Le<sup>a</sup>, Le<sup>b</sup>, P<sup>1</sup> M, N, S, and s antigens. Reagent red cells for antibody detection are available commercially as sets of either two or three samples. The Rh phenotypes present in two-sample sets are R<sub>1</sub>R<sub>1</sub> (D+C+c-E-e+) and R<sub>2</sub>R<sub>2</sub> (D+C-c+E+e-). In three-sample sets, an rr (D-C-c+E-e-) sample is also provided. Use of three red cell samples facilitates antibody identification and enables the inclusion of red cells homozygous for particular blood group antigens. Such red cells often have a stronger expression of an antigen when compared to red cells from individuals heterozygous for the same gene; this phenomenon is known as *dosage*.

## The principles of antibody identification

When unexpected antibodies are present, as indicated by positive antibody screening tests, they must be identified. This involves testing the patient's serum or plasma against a panel of fully phenotyped reagent red cell samples and the patient's own cells. A typical panel is shown in Table 12.7, which illustrates the results of antibody identification tests with a sample containing both anti-M and anti-K. Tests performed in this example include a reading for agglutination after room temperature incubation (RT) and after incubation at 37 °C. Results of the reactivity seen with LISS additive or with ficin-treated red cells after incubation and washing with addition of antihuman globulin (IAT) are displayed.

A typical approach follows:

- 1 The reactions with the patient's own red cells (AC: autocontrol) are examined. If the AC is positive, autoantibodies may be present and the patient may have a positive direct antiglobulin test (DAT). Therapy with certain drugs can also cause the AC and DAT to be positive.<sup>6</sup> Alternatively, the AC may react because alloantibodies have formed to recently transfused red cells that are still circulating in the recipient. The AC is negative in the case shown, so autoantibodies likely are not present.
  - 2 The graded reaction strengths are examined. Variability in reaction strength may indicate either multiple antibodies present or dosage; dosage is observed when an antibody reacts stronger with red cells from homozygotes (double-dose) than with red cells from heterozygotes (single-dose). Given the varying degrees of reactivity and significant difference in the reactivity at

different phases (room temperature vs IAT, for example) in Table 12.7, more than one antibody appears to be present.

- 3** A process of “ruling out” antibodies is undertaken by evaluating the antigens present on the nonreactive cells. Only reagent red cells 2 and 4 are nonreactive at all phases of testing. The presence of antibodies to antigens present on these two cells (D, C, c, E, e, N, S, s, P<sub>1</sub>, Le<sup>a</sup>, Le<sup>b</sup>, Jk<sup>a</sup>, Jk<sup>b</sup>, Fy<sup>a</sup>, Fy<sup>b</sup>, and Xg<sup>a</sup>) can be eliminated from initial consideration. This leaves the possibility of antibodies to M, K, C<sup>w</sup>, f, Kp<sup>a</sup>, and Js<sup>a</sup>. C<sup>w</sup>, Kp<sup>a</sup>, and Js<sup>a</sup> are low-prevalence antigens not present on reagent red cells used for antibody detection, so these specificities are not responsible for the positive antibody screen. Given the pattern of reactivity, these results suggest the presence of anti-M and anti-K. Importantly, facilities will have policies for how many “rule outs” of each antibody must be performed, and it is often preferred to rule out antibodies using a cell with a double dose rather than a single-dose expression of the corresponding antigen. Testing patient plasma with additional reagent red cells may be necessary.

**4** The test phase and strength of the reactivity are evaluated. Antibodies that are often IgM (Table 12.2), such as anti-M, anti-N, anti-Le<sup>a</sup>, and anti-P1, react as direct agglutinins at room temperature. Antibodies that are usually IgG (e.g., anti-Rh, anti-K, anti-Fy, anti-Jk, and anti-S) react preferentially by the IAT, although during the early stages of the immune response, IgM antibodies of these specificities can be encountered.

With the example here, the anti-M appears to react best at room temperature, and the anti-K reacts best by IAT. This is consistent with the anti-M being IgM, although many examples of anti-M do have an IgG component,<sup>3,7</sup> whereas the anti-K is most likely IgG (Table 12.2). Anti-f does not appear to be present because f-positive cells 1, 6, 8, and 11 are nonreactive by IAT.

In addition, the anti-M and anti-K in this example are both demonstrating dosage. The double dose M+N- cells react stronger at all phases than the single dose M+N+ cells. Only the double dose M+ cells continue to react at IAT. Reagent red cell 7 is the only double dose K+k- cell; this cell reacts by IAT stronger than single dose K+k+ cells (3 and 10).

- 5 The results of tests with enzyme-treated red cells, if performed, are evaluated. Enzyme treatment denatures some antigens, while antibodies to antigens in other blood group systems are enhanced when tested with enzyme-treated cells. In this way, tests with

enzyme-treated cells can be helpful when dealing with sera containing mixtures of alloantibodies. Common antigens such as M, N, S, s, Fy<sup>a</sup>, Fy<sup>b</sup>, and Xg<sup>a</sup> are cleaved by the treatment of red cells with proteolytic enzymes such as papain or ficin; thus, negative or weak reactions are observed when corresponding antibodies are tested with ficin- or papain-treated red cells. In contrast, the treatment of red cells with proteolytic enzymes enhances reactivity with Rh antibodies, as well as antibodies such as anti-Le<sup>a</sup>, anti-P1, and anti-Jk<sup>a</sup>.

In this example, the reactivity attributed to anti-M is not observed when testing ficin-treated cells, as expected. In contrast, K antigen is not affected by ficin treatment, so there is no difference in the IAT reactions of ficin and LISS tests with cell samples 3, 7, and 10. Anti-f can now be completely ruled out because, if present, it would have reacted with all the K-negative ficin-treated cells from donors with r (ce) haplotype.

- 6 There must be sufficient negative test results with red cells that lack the corresponding antigen and sufficient positive test results with red cells that carry that antigen. To obtain a confidence level of >95% ( $p = 0.05$ ), there should be at least three nonreactive antigen-negative reagent red cells and at least three reactive antigen-positive cells. Importantly, when multiple antibody specificities are present, the antigen positive cells should be positive for just one of the antigens (K+,M- and M+,K- in this example). Utilizing the ficin results, and considering that ficin-treated cells are M-, this requirement has been met for both the anti-M and the anti-K.
- 7 The patient would be negative for the corresponding antigen. If the patient has not been recently transfused, the red cells from the patient are tested with anti-M and anti-K and should lack both M and K antigens. (There are exceptions of alloantibody formation when the corresponding antigen appears to be present on the red cells. Most notably, this is seen in the Rh system in individuals with partial antigens who make antibody to the portions of antigen that are absent from their red cells.)

The above illustration represents a basic approach to antibody identification. More complex cases involving autoantibodies, multiple alloantibodies, mixtures of both auto- and alloantibodies, and antibodies to high-prevalence antigens often will require the resources of an immunohematology reference laboratory.

### **Monoclonal antibody therapy interference in pretransfusion testing**

Use of monoclonal antibody immunotherapy is growing in efforts to treat various malignancies. CD38 is highly expressed on myeloma cells, and various anti-CD38 agents, including Daratumumab and Isatuximab, are approved for use in patients with multiple myeloma. Because red blood cells also express CD38, drug therapy with anti-CD38 interferes in pretransfusion antibody detection and compatibility test.<sup>14</sup> While not affecting ABO typing, anti-CD38 causes positive (1+) agglutination in antibody screens, antibody panels, and crossmatching. This reactivity interferes with the ability to detect and identify clinically significant blood group antibodies and precludes the demonstration of compatibility between patient and donor units, delaying issue of blood for transfusion.

While several strategies exist to circumvent anti-CD38 interference, a commonly used approach is to treat the test reagent red cells with dithiothreitol (DTT) to denature CD38 on the red cell membrane and to use these DTT-treated cells for testing. DTT treatment also destroys some clinically significant blood group antigens, including those in the Kell system. Thus, if DTT treatment is used

to mitigate anti-CD38 interference in pretransfusion testing, units transfused should be negative for the K antigen unless the patient's red cells are known to be K positive. Doing an extended red cell phenotype or genotype on the patient prior to initiation of anti-CD38 therapy is recommended.<sup>15</sup> This informs the transfusion service of alloimmunization risk and allows for the transfusion of antigen-matched donor units to avoid alloimmunization in patients that may be facing long-term transfusion support.

Anti-CD47 therapy also causes interference in pretransfusion compatibility testing. CD47 is expressed on all cells, including platelets and red blood cells, and is thought to regulate phagocytosis. Anti-CD47 agents are in clinical trials to treat hematologic malignancies and solid tumors. Interference with some anti-CD47 agents can be observed as robust reactivity (agglutination) in all phases of testing;<sup>16</sup> thus, ABO typing, antibody screens, and serologic crossmatches may be invalid. Treatment of reagent red cells with enzymes or chemicals does not remove CD47 to mitigate interference. Multiple adsorptions of the anti-CD47 drug onto red cells or platelets have been shown to be successful. For those anti-CD47 agents that are IgG4, utilizing an antihuman globulin reagent that does not detect IgG4 can circumvent the interference in the IAT.<sup>16</sup> Importantly, different anti-CD47 agents differ in ability to interfere in pretransfusion testing.<sup>17</sup>

In summary, monoclonal antibody therapies that target molecules also presented on red cells and platelets represent a challenge for pretransfusion laboratory testing that relies on serologic methods to demonstrate compatibility. A key component to reduce delays in selection of units for transfusion is effective communication between the clinical team and the transfusion service when patients are receiving monoclonal antibody therapy.

### **Blood group DNA-based typing in pretransfusion testing**

Blood group antigens other than ABO and RhD are often referred to as *minor blood group antigens*. Testing for antigens beyond ABO and RhD is referred to as performing an *extended phenotype*. Knowing which common antigens are expressed on the patient's red cells and which antigens the patient lacks, and hence could make the corresponding antibody, is very useful for clinical decision making in transfusion, especially if the patient has made a red cell antibody. In the past, this information has not been readily available because performing extended typing for minor antigens by serologic methods is time consuming and costly. In contrast, with DNA-based testing, an extensive antigen profile on the patient (and blood donor) can be obtained in a single assay.<sup>18</sup>

DNA-based typing was introduced more than two decades ago following cloning of several blood group genes. Many blood group antigens result from single nucleotide gene polymorphisms (SNPs) inherited in a Mendelian manner, making assay design and interpretation straightforward. Current methods for testing include the amplification of target gene sequences by polymerase chain reaction (PCR), followed by manual or automated downstream analysis. Semiautomated systems enable large-scale typing of patients and donors for multiple antigens.<sup>18,19</sup> There are FDA-licensed assays that interrogate dozens of minor blood group antigens; however, ABO and RhD genotyping is more complex and requires higher resolution than is required for minor antigen typing. Next generation sequencing (NGS) of whole genomes or exomes, or targeted exome sequencing, or use of massive arrays offers the potential to provide a comprehensive determination of all blood groups. Test design and development of algorithms for interpretation are being developed and validated.<sup>20</sup>

There is nearly complete concordance between DNA (genotype) and serology (phenotype). Discrepancies are most often due to gene mutations that weaken or silence expression of the antigen, or in many cases they are due to human error in the manual process associated with serologic testing and recording of results.<sup>20</sup>

DNA-based typing is useful in several clinical situations (Table 12.8). These include typing of patients who are multiply transfused, who have a positive DAT (with or without serum autoantibody), or who are receiving chronic transfusion therapy for sickle cell disease or thalassemia.<sup>21</sup> DNA-based testing also assists in locating donor units with rare blood types, especially when no serologic reagent is available. Applications in prenatal medicine include the assessment of risk for hemolytic disease when the mother has a blood group antibody and the accurate determination of the RhD status of a mother to guide Rh immune globulin prophylaxis.<sup>22,23</sup>

## Donor-recipient testing

### Recipient prior records check

As part of blood transfusion safety and quality assurance, the results of current pretransfusion tests must be checked against records of any previous tests, if performed. This must be performed before blood is released for transfusion, preferably when a sample is first received for testing. The records must be reviewed for ABO and Rh, difficulties in typing, clinically significant antibodies, severe adverse events related to transfusion, and any special transfusion requirements.<sup>9</sup> Discrepancies between past and present ABO and Rh typing results must be thoroughly investigated. Previously identified clinically significant antibodies must be taken into consideration when selecting blood for present and future transfusions to avoid delayed transfusion reactions, as a majority of clinically significant antibodies drop to serologically undetectable levels.<sup>24</sup>

### Selection of blood for transfusion

#### ABO and Rh

Red blood cells or whole blood selected for transfusion must be compatible with the plasma or serum of the intended recipient. To avoid the hemolytic and potentially fatal consequences of an ABO-mismatched transfusion, red cells carrying A and/or B antigens should not be transfused to a patient unless the patient's red cells also carry those antigens. Group O individuals must receive only group O red cells, whereas AB individuals can receive red cells of any ABO type. Rh-negative individuals, particularly females of childbearing potential, should receive Rh-negative blood.<sup>9</sup>

### Unexpected antibodies

When a patient currently has, or has previously had a clinically significant antibody, defined as one known to cause accelerated destruction of transfused incompatible red cells, blood selected for transfusion must be shown to lack the corresponding antigen by testing with FDA-licensed methods and reagents, if available.<sup>9</sup>

Examples of potentially significant antibodies include those directed toward antigens of the RH, JK, KEL, and FY systems, and the S and s antigens of the MNS system, as well as some other antibodies reactive at 37 °C and/or by the IAT. In the case of antibodies against M, N, P<sub>1</sub>, and Lewis antigens, particularly those that react best at or below room temperature, blood selected for transfusion should be compatible by IAT following 37 °C incubation; demonstrating that compatible units lack the relevant antigen(s) is optional and not required. When autoantibodies are present, testing must be performed to demonstrate the autoantibody is not masking a concomitant, clinically significant alloantibody.<sup>6,9</sup>

### Crossmatch

Before issue of red cells or whole blood, a sample of the recipient's serum or plasma must be tested against the donor cells from an integrally attached segment (exception for emergency release). The method used should be capable of detecting ABO incompatibility and demonstrate clinically significant antibodies, including an IAT. However, if no clinically significant antibodies were detected in the antibody screening and there is no history of clinically significant alloantibodies, only testing to detect ABO incompatibility is required.<sup>9</sup>

### Serologic detection of ABO incompatibility

Detection of ABO incompatibility can be done serologically by performing an immediate-spin crossmatch between the prospective recipient's serum or plasma and donor red cells.

### Computer detection of ABO incompatibility

Computer software may be used to detect ABO incompatibility between the patient sample and the donor unit selected for transfusion.<sup>9</sup> This is termed an *electronic crossmatch* (EXM) and replaces the immediate-spin test for detecting ABO incompatibility.

There are several requirements, including that the computer system be an FDA-cleared medical device that is validated on site. The system must recognize and correlate antibody detection results, comparison of previous records, concordant recipient ABO from at least two determinations, donor component, unit number, and ABO/Rh retype results, as well as logic to alert the user to

discrepancies in ABO/Rh confirmatory testing and ABO/Rh incompatibilities between the recipient and the donor unit. FDA guidance on requirements is available.<sup>25</sup> The advantages of implementing an EXM include technologist time savings, reduced sample handling, avoidance of “false”-positive test results on immediate-spin crossmatch due to cold agglutinins or rouleaux, decreased turnaround time, and potential increased inventory management efficiency.

#### ***Antiglobulin crossmatch***

When clinically significant unexpected antibodies are present, or a patient's records indicate that such antibodies were detected previously, blood selected for transfusion must be negative for the corresponding antigen and tested with the patient's serum or plasma by the IAT. Any of the methods described in this chapter for antibody detection can be used.

An antiglobulin crossmatch can also be performed routinely on recipients with nonreactive screening tests for unexpected antibodies. However, the predictive value of a positive IAT crossmatch following nonreactive screening tests for unexpected antibodies is sufficiently low that many large hospital transfusion services do not perform an IAT crossmatch except as required above. Those that choose to perform an optional IAT crossmatch aim to detect ABO incompatibility, detect unexpected antibodies to low-incidence antigens that are missed in pretransfusion screening tests, detect antibodies manifesting dosage, and consider this testing as a second safety check for antibodies potentially missed in screening tests.

#### ***Extended antigen matching by DNA-based typing***

Increased use of genotyping of both patients and donors also allows for matching the antigen profile of donors to that of patients for the most common blood group antigens. This strategy is especially helpful for chronically transfused patients or in cases where serologically compatible units cannot be provided, such as in cases of warm autoantibodies or in patients receiving monoclonal antibody therapy. In these cases, rather than issuing “least incompatible” red cells for transfusion, units that are “antigen matched for common blood group antigens” can be issued to mitigate delayed transfusion reactions and minimize alloimmunization.

#### **Labeling**

Before blood is released for transfusion, the unit shall have an affixed label or tie tag indicating the recipient's two independent identifiers (usually first and last names, and hospital identification number), the donor unit number, and the interpretation of compatibility tests, if performed.<sup>9</sup>

#### **Issue**

When a blood component is issued, there must be a final check of the following items: transfusion service records to include the recipient's two independent identifiers, ABO group and Rh type; the unit number (or pool number for platelets and cryoprecipitate), ABO group and, if required, Rh of the donor; the product expiration date and, if applicable, time; the interpretation of crossmatch tests, if performed; special transfusion requirements, if applicable; and the date and time of issue.<sup>9</sup> Visual inspection of the unit must be performed and documented, and it should not be issued if any abnormality in appearance is noted.

#### **Emergency release**

When a patient's ABO group is not known, group O red cells are issued.<sup>9</sup> For female patients of future childbearing potential, these should also be Rh-negative. If the ABO group and Rh type have been determined on a current sample, type-specific or ABO-compatible red cells may be issued. The container label or tie tag should conspicuously indicate that compatibility testing was not completed at the time the unit was released. Testing should be completed expeditiously with a patient sample collected as early as possible, and the records should contain a signed statement from the requesting physician indicating the need for transfusion before completion of compatibility testing (or any other testing, including for infectious diseases) testing.

#### **Administration of blood and blood components**

The transfusion service director should participate in the development of policies regarding recipient consent for transfusion, as well as protocols for administration of blood and components, including the use of infusion devices and the identification, evaluation, and reporting of adverse events related to transfusion. At a minimum, recipient consent should include an explanation of the risks and benefits of transfusion, along with treatment alternatives, the opportunity to ask questions, and the right to accept or refuse transfusion.<sup>9</sup>

The physician's written order must be reviewed, and after issue from the laboratory and immediately before transfusion all information must be verified bedside, including the recipient's two independent identifiers and ABO/Rh, donation number and donor ABO/Rh, interpretation of compatibility test, special transfusion requirements, and that the unit is satisfactory in appearance and has not expired.

The patient's medical records must include the transfusion order, documentation of patient consent, name of component, donation number, date and time of transfusion, pre- and post-transfusion vital signs, amount transfused, identification of the transfusionist, and documentation and follow up of any adverse events.

#### **Biovigilance and transfusion safety**

Blood transfusion is not without risks, ranging in severity from febrile nonhemolytic reactions to red cell alloimmunization, disease transmission, and death from bacterial contamination or transfusion of incompatible blood.

Biovigilance systems and networks have been established to track adverse reactions and incidents associated with blood collection and transfusion. In many countries, these programs gather and analyze data to identify trends and risks and to recommend best practices and interventions with the goal of providing improved patient care and safety, while reducing overall costs. Biovigilance programs provide benchmarking internally and against national averages, consistent definitions for adverse reactions, and analysis by experts for the purpose of recommending nationwide health and safety enhancements, for risk mitigation, and to facilitate better understanding of reactions.<sup>26,27</sup>

Adverse event reporting of patient outcomes in the United States occurs through AABB working with patient safety organizations (PSOs) dedicated to confidentially analyzing data on adverse reactions and incidents associated with blood transfusion to communicate best practices and to design interventions to improve patient safety. Some hospitals have created a position of transfusion safety officers (TSOs) to identify, resolve, and monitor organizational weakness leading to unsafe transfusion practice. New technology is becoming available to improve sample labeling and the bedside

clerical checks including wireless handheld portable devices, bar coding, radiofrequency identification, and chip technology.<sup>28</sup>

## Conclusion

Compatibility testing is performed to detect serologic incompatibility between the donor unit and the intended recipient, and to prevent both clerical and technical errors that may have serious, if not fatal, consequences. Most importantly, there can be no substitute for proper patient identification, proper sample labeling, and proper performance of serologic tests.

### Introduction

The main function of red blood cells, the erythrocytes, is to transport oxygen from the lungs to the other tissues of the body. Oxygen delivery is finely controlled by the number of erythrocytes circulating in the blood, which is a function of the rate of senescent erythrocyte removal and the rate of new erythrocyte (reticulocyte) entry. Circulating erythrocytes are maintained in an extremely narrow range because the normal bone marrow produces almost the same number of new erythrocytes each day as is lost through senescence. This daily turnover of approximately 1% of circulating erythrocytes represents 200–250 billion erythrocytes in a healthy adult. When increased numbers of erythrocytes are lost, such as with bleeding or hemolysis, the production of new erythrocytes increases rapidly, replacing the lost erythrocytes and reestablishing the steady-state number of erythrocytes. The rapid expansion of erythrocyte production in response to bleeding or hemolysis is so well regulated that rebound polycythemia does not occur. This exquisitely controlled production of erythrocytes is mediated through a negative feedback mechanism that involves renal oxygen supply and utilization, the hormone erythropoietin (EPO) that is produced in the kidneys, and the erythroid progenitor cells in the bone marrow that depend upon EPO to survive. Normal red blood cell production also depends upon adequate supplies of specific nutrients, among which iron, folate, and vitamin B<sub>12</sub> are the most important. Disorders of the hematopoietic system or other diseases such as those associated with chronic inflammation inhibit the erythropoietic process.

mainly from studies of mice and humans. These studies have included direct morphologic and immunologic analyses of cells in hematopoietic tissues, in vitro culture of hematopoietic cells, transplantation studies with hematopoietic cells, and genetic studies of mice with natural mutations, transgene expressions, or targeted gene knockouts.

Labeled endothelial cells in the ventral part of the aorta in developing mice transform into HSCs<sup>1</sup> by a mechanism that does not require mitosis.<sup>2</sup> Among the various functions of blood cells, tissue oxygenation by the erythrocytes is the first required during embryonic development and the most tightly regulated in postnatal life. Erythropoiesis has two sequential but overlapping phases during development. In the first or primitive phase, erythrocytes are produced in “blood islands” of the yolk sac during weeks 3–6 of human gestation, with primitive erythrocytes comprising the large majority of circulating erythrocytes at 8 weeks but declining to undetectable levels by 12 weeks of gestation.<sup>3</sup> In the subsequent definitive erythropoiesis phase, erythrocytes are produced mainly in the human fetal liver from 6 to 22 weeks of gestation, and mostly in the bone marrow at later times.<sup>3</sup> Definitive erythroid cells arise from HSCs that are first detected in the aortogonadomesonephros (AGM) region of the mesoderm,<sup>4</sup> circulate, seed the fetal liver, and then migrate from the fetal liver to the developing bone, where they initiate marrow hematopoiesis.<sup>5–7</sup> The hemoglobin of the primitive erythrocytes contains embryonic ε- and ζ-globins, whereas the hemoglobin of the definitive erythrocytes contains adult α-globin and either fetal γ-globin from mid-gestation through the first few postnatal months or mainly adult β-globin after the first few postnatal months.<sup>8</sup>

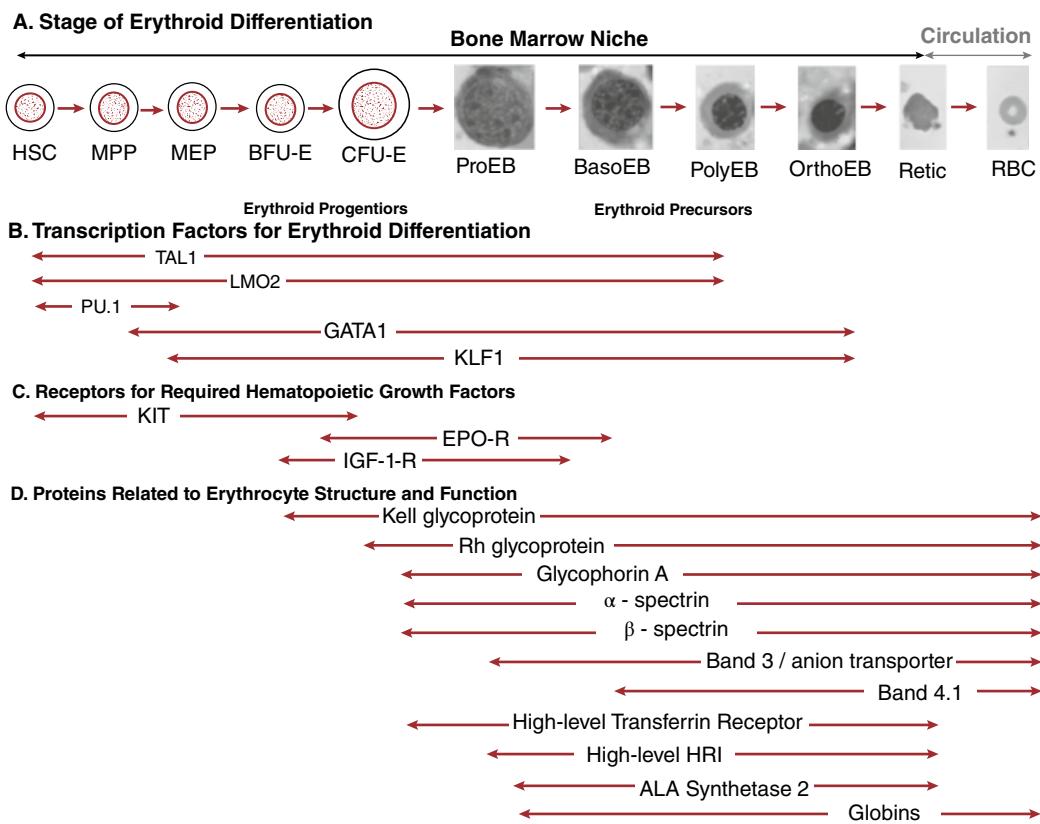

### Erythropoiesis

#### Erythropoiesis: a component of hematopoiesis

Erythropoiesis, the process of erythrocyte production, is part of the larger process by which a pluripotent hematopoietic stem cell (HSC) proliferates and differentiates into all of the cell types of the blood and immune systems, including platelets, granulocytes, monocytes and macrophages, T lymphocytes and B lymphocytes, as well as erythrocytes. Thus, normally regulated hematopoiesis is required for effective hemostasis, inflammation, immune responses, and tissue oxygenation. Current concepts of hematopoiesis are derived

#### Stages of erythropoiesis

Erythroid progenitor cells arise from HSCs that commit to differentiation and are termed *multipotent progenitors* (MPPs). MPPs proliferate and undergo a series of decisions based on specific transcription factor activities that determine their progeny's fate in terms of blood cell lineage (see Figure 13.1). The myeloid transcription factors PU.1 and GATA1 direct differentiation toward the nonlymphoid lineages, and, if the activity of the GATA1 transcription factor is increased, differentiation toward the bipotent megakaryocytic-erythroid progenitor (MEP) is promoted.<sup>9,10</sup> MEP fate, in turn, is determined by the activities of two other competing

**Figure 13.1** Cellular events in erythroid differentiation. (A) Stages of differentiation: hematopoietic stem cells (HSCs), burst-forming units-erythroid (BFU-Es), colony-forming units-erythroid (CFU-Es), proerythroblasts (ProEBs), basophilic erythroblasts (BesoEBs), polychromatophilic erythroblasts (PolyEBs), orthochromatic erythroblasts (OrthoEBs), reticulocytes (Retics), and erythrocytes (RBCs). (B) Transcription factors: basic helix-loop-helix factor (TAL1), Lim domain partner of TAL1 (LMO2), factor binding purine-rich GAGGAA sequence (PU.1), zinc finger factor binding GATA-containing sequences (GATA1), and Krüppel-like factor (KLF1). (C) Growth factor receptors for stem cell factor (KIT), erythropoietin (EPO-R), and insulin-like growth factor-1 (IGF-1-R). (D) Proteins related to erythrocyte structure and function and heme-regulated inhibitor (HRI; eIF2 $\alpha$  kinase). Periods of expression for erythroid-specific forms of proteins are shown. Transferrin receptors are present in all stages, but the period of high-level expression that characterizes hemoglobin-producing erythroblast is shown. Band 4.1 shown for the spliced form found in circulating erythrocytes. Content of each protein may vary during the period shown. Source: Based on Koury.<sup>76</sup>

transcription factors: erythroid Krüppel-like factor-1 (KLF1), which promotes erythroid differentiation, and FLI1, which promotes megakaryocytic differentiation.<sup>9,11</sup>

In Figure 13.1, the hematopoietic stages committed solely to erythroid differentiation begin with the burst-forming units-erythroid (BFU-Es),<sup>12</sup> which produce large colonies or multiple colonies of human erythroblasts after 2–3 weeks in tissue culture. BFU-Es can circulate in the blood, but after they differentiate in marrow to the next defined stage, the colony-forming units-erythroid (CFU-Es),<sup>12</sup> they associate with a macrophage, forming an erythroblastic island (EBI), the basic unit of terminal mammalian erythropoiesis.<sup>13</sup> Coordinated KLF1 activity in both the central macrophage and the erythroid cells<sup>14,15</sup> of an EBI directs the development of as many as 30 or more adherent erythroblasts at various stages of differentiation from CFU-Es through enucleating orthochromatic erythroblasts. BFU-Es and CFU-Es were originally defined by in vitro colony-forming activity and erythroblasts by their morphological appearances in Giemsa-stained films of aspirated marrows. More recent studies using flow cytometry have enabled the identification and isolation of all stages of human erythroid progenitors BFU-Es, CFU-Es and their erythroblast progeny, the

proerythroblasts (ProEBs), basophilic erythroblasts (BesoEBs), polychromatophilic erythroblasts (PolyEBs), and orthochromatic erythroblasts (OrthoEBs) based on the surface expressions of CD34, CD36, endoglin (CD105), and the transferrin receptor (CD71) for the progenitors; or glycophorin A, anion transporter (Band 3), and  $\alpha 4$  integrin for the precursors.<sup>16</sup>

OrthoEBs enucleate within the bone marrow forming reticulocytes, very irregularly shaped cells containing hemoglobin and residual organelles (the “reticulum”) that allow them to be distinguished from the mature erythrocytes. The extruded nucleus with its thin shell of hemoglobin-containing cytoplasm, termed a *pyrénocyte*, is rapidly phagocytosed by the central macrophage, which degrades the nucleus and hemoglobin and recycles the nucleosides and iron.<sup>17</sup> The final stage of differentiation, the erythrocyte, is achieved after the reticulocytes have entered the circulation, lost their residual internal organelles via autophagy,<sup>18</sup> and remodeled their irregular shapes by shedding of exosomes<sup>19,20</sup> and forming uniform biconcave disks. Reticulocyte maturation to an erythrocyte occurs within 1–2 days after entering the circulation, but mature erythrocytes continue to shed microvesicles until they are removed 110–120 days later as senescent cells.<sup>21</sup>

## Intracellular requirements for normal erythroid differentiation

A series of intracellular and extracellular events are needed for successful completion of the erythroid differentiation scheme as shown in Figure 13.1. The intracellular events include the expression of (1) hematopoietic and erythroid-specific transcription factors; (2) specific microRNAs and long, noncoding RNAs involved in the differentiation process; (3) proteins involved in the proliferation and differentiation of the erythroid cells; and (4) proteins such as hemoglobin, intrinsic membrane, and membrane skeleton proteins that comprise the mature erythrocyte.

GATA1, KLF1, and the transcription factor complex of TAL1/SCL, LMO2, and LDB1 are essential for erythropoiesis from the pre-EPO-dependent stages through late erythroblast stages.<sup>11,22,23</sup> In addition to regulating expression of erythroid-specific genes such as those encoding the EPO receptor, globins, and glycophorins, these transcription factors also regulate long, noncoding RNAs that can influence other erythroid gene expressions in the later stages of differentiation, such as the gene encoding Band 3 and the anion transporter.<sup>24</sup> The expression of transcription factors and other crucial erythroid proteins, in turn, are partially controlled by specific microRNAs, which regulate mRNA stability and translation at all stages of erythroid differentiation.<sup>23,25</sup> In fact, post-transcriptional regulation of protein synthesis by microRNAs allows the control of the reticulocyte maturation process that occurs days after the erythroid cell has lost its nucleus.<sup>26</sup>

During the terminal stages of erythropoiesis in the EBI, the erythroblasts undergo progressive decreases in size, nuclear condensation, and subsequent enucleation. Decreased cell size between the ProEB and OrthoEB stages is achieved by a shortened duration of the G1 phase of the cell cycle, resulting in less protein accumulation between cytokineses.<sup>27,28</sup> These terminal erythroblast divisions are regulated by cyclin D3, a G1-phase cyclin,<sup>29</sup> and direct contact with the central macrophage shortens the G1 phase of the erythroblasts.<sup>30</sup> During these more rapid cell divisions, the ratio of heterochromatin to euchromatin increases with a progressive condensation and reduction in nuclear size<sup>31</sup> that are associated with histone deacetylation<sup>32</sup> and DNA demethylation in the mouse.<sup>33</sup> In humans, nuclear condensation occurs earlier (around the BasoEB stage) and involves the nuclear lamins.<sup>34,35</sup> In the formation of the reticulocyte and pyrenocyte, the condensed erythroblast nucleus is extruded by an active process similar to cytokinesis that requires filamentous actin,<sup>36</sup> nonmuscle myosin IIB,<sup>37</sup> and tropomodulin 1 (Tmod1).<sup>34</sup> KLF1 expression in the central macrophage regulates the phagocytosis of the pyrenocyte and subsequent degradation of its DNA and hemoglobin.<sup>14,17</sup>

Hemoglobin, the predominant protein of erythrocytes, is synthesized in a highly regulated process that begins in the BasoEBs and continues through the reticulocyte stage. Extremely large quantities of heme are produced without intracellular accumulations of iron or protoporphyrin. As iron accumulates in the basophilic erythroblast, it upregulates heme synthesis through a 5'-iron-responsive element (IRE) in erythroid-specific 5-aminolevulinic acid synthase (ALAS2, the first step of heme synthesis) mRNA that controls translation;<sup>38</sup> GATA1 activity induces heme synthetic enzymes and protein kinase A phosphorylates and activates ferrochelatase, which catalyzes the last step of iron incorporation into protoporphyrin;<sup>39</sup> and the amino acids glycine and glutamine (as source of succinyl CoA) provide the substrates for porphyrin synthesis.<sup>40</sup> Similarly, heme is incorporated into globin chains without accumulating

intracellular excesses of globin chains or heme, and 2 $\alpha$ -hemoglobin and 2 $\beta$ -hemoglobin chains are assembled into hemoglobin A tetramers without accumulating unpaired hemoglobin chains.<sup>41</sup>

Multiple layers of regulation that are specific to erythroid cells control heme and hemoglobin synthesis including (1) heme regulation of erythroblast GATA1 activity<sup>42</sup> and iron acquisition from endocytosed transferrin receptors,<sup>38</sup> (2) heme upregulation of erythroblast protein synthesis through inactivation of heme-regulated eIF2 $\alpha$  kinase (heme-regulated inhibitor [HRI]), which in the absence of heme phosphorylates the translation initiation factor eIF2 $\alpha$ , thereby inhibiting its ability to initiate general mRNA translation,<sup>43</sup> and (3) heme induction of rRNA and ribosomal proteins.<sup>42</sup> In the regulation of hemoglobin production, heme derepresses  $\beta$ -globin transcription by binding and enhancing the degradation of BACH1, a transcription repressor at the locus control region (LCR). With the loss of BACH1, the NFE2-Mafk transcription factor complex binds and activates  $\beta$ -globin transcription,<sup>44,45</sup> which combined with GATA1 and KLF1 activities leads to coordinated  $\alpha$ -globin and  $\beta$ -globin transcriptions.<sup>46</sup> While  $\beta$ -globin transcription is upregulated, heme indirectly downregulates  $\gamma$ -globin transcription through increased translation of its major target gene, translation of activating transcription factor-4 (ATF4), which in turn induces BCL11A that inhibits  $\gamma$ -globin transcription.<sup>47</sup> Finally,  $\alpha$ -hemoglobin-stabilizing protein (AHSP) regulates intracellular free  $\alpha$ -globin chain content by coordination of heme insertion, appropriate folding, and assembly of  $\alpha$ -globin chains into hemoglobin.<sup>48</sup>

In the terminal stages of erythroid differentiation, the plasma membrane and associated membrane skeleton undergo large changes in their composition. From the CFU-E through reticulocyte stages, several patterns of intrinsic membrane protein expression are found: (1) from a baseline of little or no expression, large increases occur in proteins that are major components of erythrocyte membranes, such as glycophorin A, glucose transporter 1 (GLUT1), and Band 3; (2) more gradual increases from low baseline levels occur in glycophorin C, and RhAG, RhD, and Lutheran antigens; (3) from a stable baseline, late declines of moderate degree occur in Kell antigen and transferrin receptor 1 (CD71); and (4) prominent declines occur in adhesion proteins such as CD36 and CD44, and integrin components  $\alpha$ 4,  $\alpha$ 5, and  $\beta$ 1.<sup>16</sup> Most of the membrane skeletal proteins, including  $\alpha$ - and  $\beta$ -spectrins, ankyrin, adducin, Band 4.1, Band 4.9, and tropomodulin, increase, whereas actin declines slowly during terminal erythroid differentiation.<sup>16</sup> This pattern of accumulation of membrane skeletal proteins during terminal erythropoiesis is mainly related to the accumulation pattern of Band 3, to which the membrane skeleton is bound,<sup>49</sup> and mRNA splicing of the skeletal proteins, such as Band 4.1.<sup>50</sup> In addition to regulating cellular structure, alternative splicing of transcripts plays a role in the regulating cell cycle and chromatin function during terminal erythropoiesis.<sup>51</sup> Once hemoglobin synthesis has been completed during normal steady-state erythropoiesis, the transferrin receptor 1 (CD71) is completely lost during reticulocyte maturation through the exosomal pathway.<sup>52</sup>

## Extracellular requirements for erythroid differentiation

The extracellular requirements for erythroid differentiation include (1) stromal cell and matrix support within the marrow, (2) required hematopoietic growth factors, and (3) nutrients required for progenitor cell proliferation and differentiation. HSCs and BFU-Es can circulate in the blood, but to complete differentiation they must

adhere to and be retained in specific areas in marrow termed *niches*. HSCs home to and are retained in the marrow by cytokines and chemokines that are produced by mesenchymal stem cells. The most prominent marrow cytokine is secreted and membrane-bound KIT ligand (SCF), which binds its receptor, KIT, on HSCs. The most prevalent marrow chemokine is stromal-cell-derived factor 1 (CXCL12), which binds its receptor, CXCR4, on HSCs.<sup>53</sup> In the marrow, HSCs differentiate through the MPP and MEP stages to reach the BFU-E stage. The marrow matrix protein laminin binds the p67 nonintegrin receptor on circulating BFU-Es, thereby promoting their retention and proliferation in the marrow.<sup>54</sup> When BFU-Es differentiate to CFU-Es, they associate with stromal macrophages forming the EBIs. At least five interacting surface membrane protein pairs mediate macrophage–erythroid interactions in EBIs: (1) macrophage vascular cell adhesion molecule 1 (VCAM1) binds erythroblast  $\alpha 4\beta 1$  integrin, (2) macrophage  $\alpha_v$  integrin binds erythroblast interstitial cell adhesion molecule-4 (ICAM4/LW), (3) erythroblast–macrophage protein (EMP) on both macrophages and erythroblasts binds with itself on the other cell type, (4) macrophage CD169–Siglec1 binds erythroblast sialylated glycoproteins, and (5) macrophage hemoglobin–haptoglobin receptor (CD163) binds an unknown erythroblast ligand.<sup>13</sup>

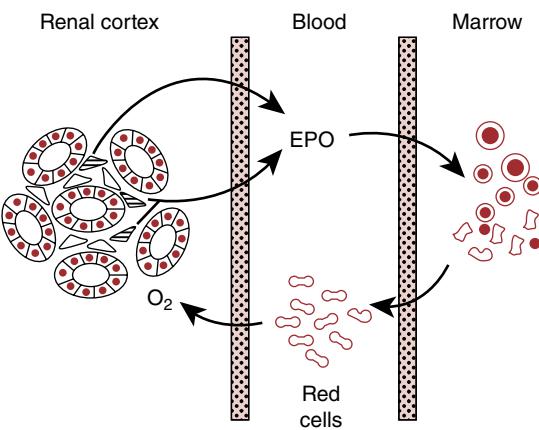

In Figure 13.1, receptors for the hematopoietic growth factors necessary for normal erythropoiesis are shown for the period when they are required. The principal growth factor regulating erythropoiesis is EPO, which is discussed in detail in the “Erythropoietin” section. Prior to EPO dependence, specific growth factors maintain progenitor cell survival and proliferation, with the most prominent being SCF and insulin-like growth factor-1 (IGF1) supplied by the marrow environment.<sup>55</sup> CFU-Es and ProEBs lose SCF and IGF-1 responsiveness, respectively, while they are dependent on EPO for survival. However, in contrast to normal erythropoiesis, during periods of hypoxic stress, CFU-Es and ProEBs can expand their numbers greatly without any further differentiation. The two main extracellular mediators of this expansion are (1) glucocorticoids,<sup>56,57</sup> which are produced in the adrenals and appear to induce a protein in erythroid progenitors that binds the mRNAs that direct terminal erythroid differentiation;<sup>58</sup> and (2) bone morphogenetic protein 4 (BMP4),<sup>59</sup> a member of the transforming growth factor- $\beta$  family of cytokines that can be produced by the central macrophage of the erythroblastic islands.<sup>60</sup> A major intracellular mediator of the erythroblast expansion in response to hypoxia is the upregulation of *Bmi-1* and *BMI-1* expressions in mice and humans, respectively.<sup>61,62</sup>

Included among the vitamins and minerals that cause anemia during deficiency states are copper; cobalt; vitamins A, C, and E; pyridoxine; riboflavin; and nicotinic acid.<sup>63</sup> However, the most common nutritional deficiencies that cause anemia are those of folate, vitamin B<sub>12</sub>, and iron. The roles of these three nutrients are described in the “Nutritional Requirements for Erythropoiesis” section.

## Erythropoietin

### Regulation of EPO production by tissue hypoxia

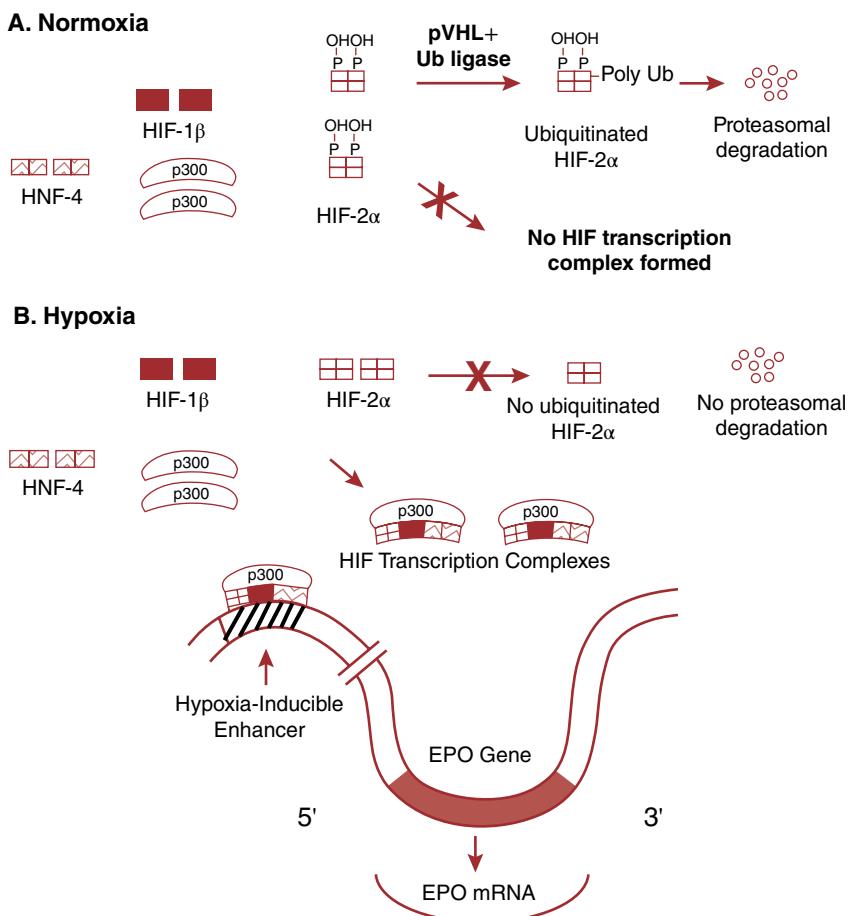

EPO, a glycoprotein hormone, is a major component of the oxygenation–EPO negative feedback mechanism shown in Figure 13.2. The major determinant of oxygen delivery from the lungs to the peripheral tissues is the number of circulating erythrocytes. With anemia, when erythrocyte numbers are decreased, oxygen delivery decreases and the peripheral tissues become hypoxic. All tissues

**Figure 13.2** Oxygenation–erythropoietin (EPO) negative feedback mechanism. Circulating erythrocyte numbers determine the amount of oxygen ( $O_2$ ) delivered from the lungs to other tissues. A specific subset of renal cortical interstitial cells (hatched) produces EPO when hypoxic. EPO is promptly secreted into the blood and prevents programmed death (apoptosis) of marrow erythroid progenitor cells. Erythroid progenitors that survive the EPO-dependent period of differentiation develop into reticulocytes (irregularly shaped, anucleate cells in marrow and blood) and subsequently mature into biconcave erythrocytes. Increased erythrocyte numbers resulting from increased plasma EPO deliver more oxygen to the kidneys, relieve renal hypoxia, and thus decrease EPO production.

experience hypoxia during anemia, but those organs that respond with EPO production are the kidneys and, to a much lesser extent, the liver.<sup>64</sup> The kidney cells that produce EPO are a subset of interstitial fibroblasts located adjacent to proximal tubules, with EPO-producing cells in small foci of the inner cortex in slight anemia, larger areas within the inner half of the cortex in moderate anemia, and distributed throughout the cortex in severe anemia.<sup>65,66</sup> These progressive increases in the areas of EPO production in the kidney correspond to increasing areas of cortical hypoxia, which are a function of oxygen supply from the blood and local oxygen tissue utilization, which is mainly determined by the metabolic demands of the tubular epithelium. Rapid increases in EPO production after blood loss or hemolysis are not due to increased production by each EPO-producing cell but rather to recruitment to active EPO production of increased numbers of cells with the potential to produce EPO.<sup>65</sup> With a linear decrease in hematocrit, the number of cells actively producing EPO and the resultant plasma EPO levels increase exponentially,<sup>65,66</sup> as was originally reported for plasma EPO levels in most clinical anemias, except for those involving patients with renal disease, chronic inflammation, or malignancies.<sup>67–69</sup>

Hypoxia sensing by EPO-producing cells involves hypoxia-inducible transcription factors (HIFs), a multicomponent complex that binds hypoxia-inducible transcription enhancer elements of various genes, including *EPO*, *VEGF*, and genes encoding several glycolytic enzymes.<sup>70,71</sup> Under normoxic conditions, the steady-state HIF- $\alpha$  component of the complex does not accumulate intracellularly because it is rapidly degraded by the ubiquitin–proteasome pathway (Figure 13.3).<sup>72</sup> However, when a cell with EPO-producing capacity experiences hypoxia, the degradation of HIF- $\alpha$  decreases and intracellular levels promptly increase. Polyubiquitination of HIF- $\alpha$  depends upon the von Hippel-Lindau protein (pVHL) interacting with those HIF- $\alpha$  molecules that have hydroxylation of two specific proline residues (Figure 13.3).<sup>73–75</sup> These prolyl hydroxylations are directly linked to the oxygenation because they are catalyzed by prolyl

**Figure 13.3** Induction of erythropoietin (EPO) gene transcription by hypoxia in renal cortical fibroblasts. (A) In cells capable of producing EPO, two components of hypoxia-inducible factor (HIF-2 $\alpha$  and HIF-1 $\beta$ ) are constitutively produced under normoxic conditions. However, the molecular oxygen present in the EPO-producing cells under normoxic conditions is used in the hydroxylation of two prolines in HIF-2 $\alpha$  in a reaction mediated by specific HIF-prolylhydroxylases (HIF-PHDs). The prolyl hydroxylations (P-OH) lead to recognition by von Hippel–Lindau protein (pVHL), which targets HIF-2 $\alpha$  for polyubiquitination (Poly Ub) by ubiquitin ligase. The polyubiquitinated HIF-2 $\alpha$  is rapidly degraded by proteasomes. (B) When renal EPO-producing cells are hypoxic, HIF-2 $\alpha$  is not hydroxylated and accumulates because it is not degraded by the ubiquitin–proteasomal pathway. HIF-2 $\alpha$  forms heterodimers with HIF-1 $\beta$  and associates with two other components of the HIF transcription complex, hepatocyte nuclear factor-4 (HNF4) and p300. The HIF transcription complex binds to a hypoxia-inducible enhancer located 6–14 kilobase pairs upstream of the EPO coding sequences, and thereby increases EPO transcription and accumulation of EPO messenger RNAs. EPO mRNA is promptly translated, and EPO is secreted into the blood such that increases in circulating EPO can be detected within two hours of experiencing hypoxia.

hydroxylases (HIF-PHDs) that contain nonheme iron at their active sites and have molecular oxygen as a substrate. The transcription complex containing HIF-2 $\alpha$  regulates renal EPO transcription through an enhancer that is located 6–14 kbp upstream of the EPO coding region.<sup>71</sup> Once hypoxia reaches the threshold that triggers EPO transcription, the resultant EPO messenger RNA is translated into the EPO glycoprotein, which is immediately secreted.<sup>65</sup> When an individual cell is triggered to produce EPO, it does so in an all-or-none manner.<sup>65,76</sup> Thus, EPO concentrations in the blood increase sharply within two hours after loss of blood, hemolysis, or a sudden decrease in atmospheric oxygen.

### Effects of erythropoietin on erythroid progenitor cells

In the marrow, EPO binds to transmembrane glycoprotein erythropoietin receptors (EPO-Rs), which are first displayed on the surface of erythroid progenitor cells before the CFU-E stage and persist until the late basophilic erythroblast stage (Figure 13.1).<sup>76</sup> The bind-

ing of EPO to EPO-Rs leads to three major events: (1) homodimerization and conformational alterations of EPO-Rs, (2) initiation of intracellular signaling by the EPO-Rs, and (3) endocytosis of the EPO–EPO-R complexes, which are degraded via lysosomal activity.<sup>77,78</sup> Dimerization and structural changes of EPO-Rs after EPO binding induce both signaling and endocytosis. The endocytosis and intracellular degradation of the EPO–EPO-R complexes appear to be the normal mechanism for the clearance of EPO from the blood.<sup>79</sup> EPO-Rs have no intrinsic enzyme activity, but they interact with several signal transduction pathways through Janus tyrosine kinase-2 (JAK2). JAK2 physically associates with the cytoplasmic portion of EPO-Rs, chaperones EPO-Rs to the surface of the erythroid cell, and is activated by the conformational changes in the EPO-Rs produced by the binding of EPO.<sup>80,81</sup> Activated JAK2 phosphorylates itself and EPO-Rs as well as initiates signal transduction pathways that include signal transduction and activator of transcription-5 (STAT5), RAS–RAF–MAP kinases, and phosphoinositol-3 kinase/AKT kinase (protein kinase B).<sup>82,83</sup>

Although the mechanisms linking EPO-R signaling to the biological effects of EPO have not been determined, EPO prevents the apoptotic death of erythroid progenitor cells in CFU-E through early BasoEB stages.<sup>84–87</sup> During EPO dependence, individual erythroid cells at the same stage of differentiation can display wide variation in their degree of dependence on EPO for survival.<sup>88</sup> Such variable susceptibility to apoptosis among EPO-dependent progenitors appears to be due to expression levels of FAS, a membrane protein of the tumor necrosis factor (TNF) family, which triggers apoptosis when it binds FAS ligand.<sup>89</sup> EPO, in turn, acts to decrease FAS expression in erythroid progenitors. FAS ligand, which binds and activates FAS, is produced in a constitutive manner in the marrow, mainly by mature erythroblasts in humans.<sup>90</sup> Thus, within the EBI, a negative feedback loop from the terminally differentiating erythroblasts can modulate the rate of CFU-E–ProEB apoptosis and indirectly control rates of erythrocyte production.<sup>89</sup> By a more indirect mechanism, EPO signaling also appears to protect late-stage erythroblasts from apoptosis, including in the post-EPO-dependent period, by inducing large amounts of the antiapoptotic protein BCL-X<sub>L</sub>.<sup>91,92</sup>

### Erythrocyte production kinetics based on EPO levels

A model that incorporates varying plasma EPO levels and heterogeneity in EPO dependence among the EPO-dependent progenitors has been proposed to explain various physiologic and pathologic rates of erythrocyte production.<sup>93</sup> In an expanded version of this model, erythroid progenitors enter the EPO-dependent period of differentiation, left of the dotted line in Figure 13.4, extending from the CFU-E through the early BasoEB stage and encompassing three generations of cells. The proportion of total cells that survive in a generation is shown under the population. The surviving cells are represented by circles, each of which contains a large black dot representing an intact nucleus. The cells lost to apoptosis are shown by circles containing an X. The number of surviving cells in a generation results in twice that number for the total cells in the subsequent generation. Most cells reaching the CFU-E stage need more EPO than the low levels found in normal plasma to sustain them and their progeny through the EPO-dependent period of differentiation. As a result, approximately 200–250 billion erythrocytes produced daily by a normal, healthy adult are the descendants of a minority of all the potential erythroid progenitor cells that could be generated during the EPO-dependent period (Figure 13.4A). When blood loss, hemolysis, or decreased atmospheric oxygen is encountered, plasma EPO increases, allowing the survival of many EPO-dependent progenitors that would die by apoptosis under normal conditions (Figure 13.4B). This enhanced survival increases reticulocyte production within a few days after encountering blood loss, hemolysis, or decreased atmospheric oxygen. The increased reticulocytosis leads to increasing erythrocyte numbers until oxygen delivery recovers to normal, accompanied by declining plasma EPO levels until normal levels are achieved. In pathologic states of chronically decreased oxygen delivery, such as lung disease or cardiac diseases with right-to-left shunts, the persistently increased EPO levels (and increased glucocorticoids and BMP4) allow greater-than-normal survival of EPO-dependent cells such that the total number of erythrocytes is maintained in the polycythemic range. Likewise, the acquired somatic mutation of JAK2 (V617F) that is associated with hyperactivity of EPO-R signaling most commonly results in polycythemia vera.<sup>94</sup>

When plasma EPO levels fall below normal, many erythroid progenitor cells that would survive the EPO-dependent period of

differentiation under normal conditions die by apoptosis resulting in anemia from decreased reticulocyte production (Figure 13.4C). Renal disease is the major cause of decreased EPO. In mouse models of renal disease, EPO-producing renal cortical fibroblasts are transformed by TNF $\alpha$  signaling through NF $\kappa$ B into proliferating myofibroblasts that do not produce EPO.<sup>95</sup> Other clinical diseases noted to have decreased EPO levels are inflammatory disorders<sup>68</sup> and malignancies,<sup>69</sup> which are associated with increased inflammatory cytokines including TNF $\alpha$ , indicating that decreases in plasma EPO contribute to the anemia of chronic inflammation.

### Nutritional requirements for erythropoiesis

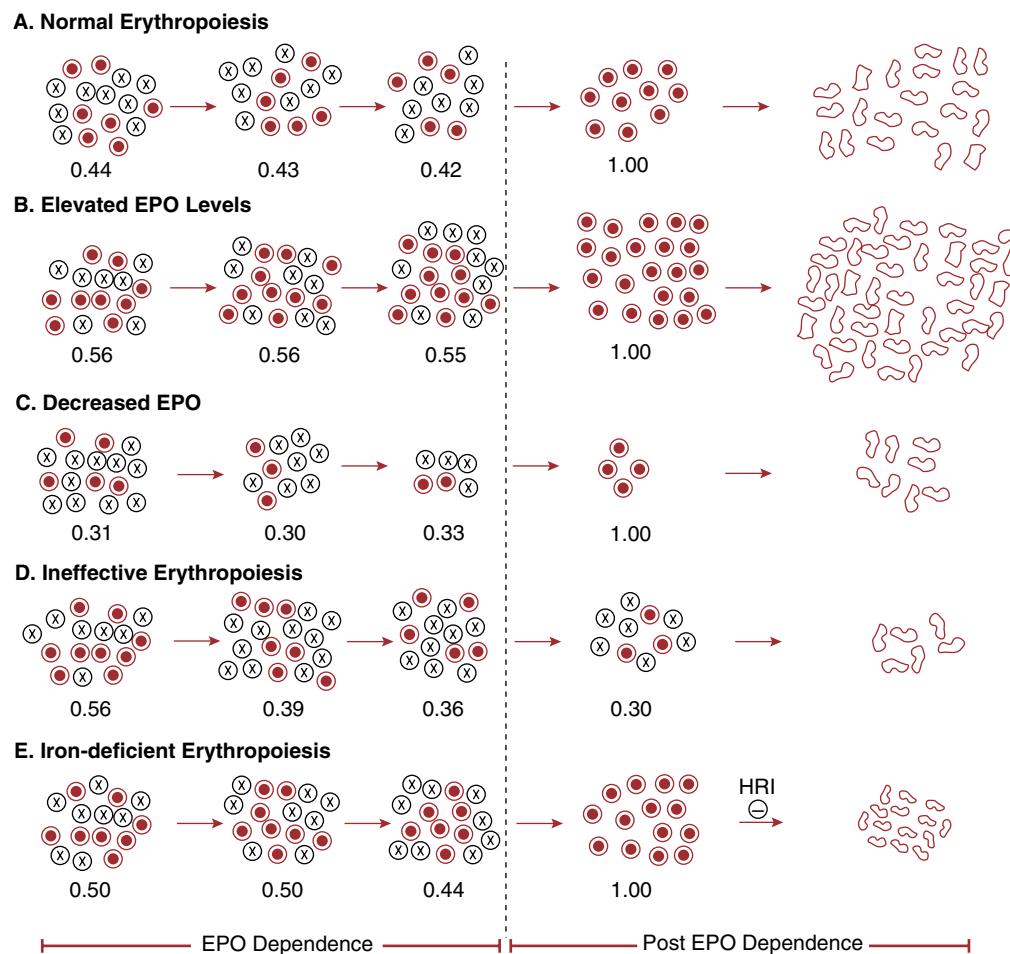

Although erythropoiesis is finely regulated by the oxygenation-EPO feedback mechanism shown in Figure 13.2, the erythropoietic process is frequently limited by an insufficient supply of folate, vitamin B<sub>12</sub>, or iron. Folate and vitamin B<sub>12</sub> (cobalamin) are required for the synthesis of DNA, and the daily production of very large numbers of erythrocytes results in a large DNA synthesis requirement. Although iron is also needed by all proliferating cell populations, the erythroblasts need much more iron than any other cell type because they produce hemoglobin. Through the hypoxia-feedback mechanism, these nutrition-related anemias are associated with increased EPO levels,<sup>67</sup> but the increase in EPO is more limited in iron deficiency, as described in the “Iron Deficiency and Development of Microcytic Anemia” section, and increased EPO can only partially compensate for the decreased erythropoiesis caused by a specific nutrient deficiency. Administration of the deficient nutrient, however, results in the resolution of anemia in each of the deficiency states.

### Deficiencies of folate or cobalamin and development of macrocytic anemia

After reduction to tetrahydrofolate (THF), folate functions as a carrier of one-carbon molecules and becomes a cofactor in the synthesis of three deoxyribonucleosides (dGTP, dATP, and TTP) that are required for DNA synthesis.<sup>96</sup> In two separate reactions, formyltetrahydrofolate (CHO-THF) provides two of the carbons in the synthesis of the purine precursor of adenosyl and guanosyl deoxyribonucleosides; in both of these reactions, 10-CHO-THF is converted to THF. In a third reaction, methylenetetrahydrofolate (CH<sub>2</sub>-THF) provides a methylene group and reducing equivalents in the methylation of deoxyuridylate to form thymidylate; in the process, CH<sub>2</sub>-THF is converted to dihydrofolate (DHF). To regenerate THF, the active one-carbon acceptor-donor form, DHF must be reduced by dihydrofolate reductase (DHFR).

Thus, drugs that inhibit DHFR such as methotrexate or trimethoprim-sulfamethoxazole cause a deficiency of THF, the functional form of folate. Cobalamin is a cofactor in the conversion of methyl-tetrahydrofolate (CH<sub>3</sub>-THF) to THF. CH<sub>3</sub>-THF, the most prevalent form of folate in plasma, is imported into cells and retained there by addition of polyglutamates. Cobalamin deficiency results in the trapping of folate in the CH<sub>3</sub>-THF form, from which it cannot be converted to THF and subsequently to the CHO-THF and CH<sub>2</sub>-THF forms required for deoxyribonucleoside synthesis.<sup>97,98</sup> Furthermore, CH<sub>3</sub>-THF is the poorest THF form for polyglutamation, resulting in generalized loss of intracellular folate.<sup>96</sup>

Folate deficiency, cobalamin deficiency, or drugs that inhibit DHFR will decrease intracellular levels of folate coenzymes needed for de novo synthesis of all the deoxynucleosides used in DNA synthesis, except for deoxycytidine. An inadequate supply of deoxynucleosides

**Figure 13.4** Model of erythropoiesis based on suppression of apoptosis by EPO and heterogeneity in EPO dependence among erythroid cells. From CFU-E through early basophilic erythroblast stages, erythroid progenitor/precursor cells depend on EPO for survival. The EPO-dependent period is left of the dotted line and encompasses three generations and two cell divisions. Each division is represented by an arrow. In the post-EPO-dependent period, to the right of the dotted line, two cell divisions occur. Surviving cells in each generation are shown as circles containing large black dots representing intact nuclei. Cells succumbing to apoptosis are shown as circles containing Xs. The proportion of the total cells that survive is shown below each generation. The number of surviving cells in a generation results in twice that number of total cells in the subsequent generation. The final populations of cells shown on the right represent the anucleate, irregular reticulocytes. (A) Normal erythropoiesis, with average survival rates of 43% in the EPO-dependent generations, produces 200–250 billion reticulocytes daily. (B) Elevated EPO levels as found after acute blood loss or hemolysis increase survival rates to 56% in the EPO-dependent generation, and reticulocyte production rate more than doubles. (C) Decreased EPO levels, as found in renal failure, decrease survival rates to 32% in the EPO-dependent generation, and reticulocyte production is less than one-half of normal. (D) Ineffective erythropoiesis increases rates of apoptosis due to a pathologic process such as folate or vitamin B<sub>12</sub> deficiency or β-thalassemia. High EPO levels in response to decreased erythrocyte production expand surviving cells in the early EPO-dependent generations, but the increased rates of apoptosis in the late EPO-dependent and post-EPO-dependent stages decrease daily reticulocyte production to less than one-third of normal. (E) Iron-deficient erythropoiesis with moderately elevated EPO activity for the degree of anemia slightly increases the survival rate during the EPO-dependent period, but in the post-EPO-dependent period, when hemoglobin is synthesized, heme-regulated inhibitor (HRI) prevents apoptosis by inhibiting general protein synthesis while enhancing the production of the mediator of stress erythropoiesis, the transcription factor ATF4. The inhibited protein synthesis decreases reticulocyte production rate, size, and hemoglobin content.

causes the accumulation of erythroid progenitors in the S phase of the cell cycle, which is followed by the induction of apoptosis.<sup>99</sup> Erythroid cells at the end of the EPO-dependent stage and the beginning of the period of hemoglobin synthesis appear to be most susceptible to this apoptosis. EPO-induced expansion of the EPO-dependent population at the CFU-E and proerythroblast stages leads to the presence of even greater numbers of these progenitor cells that subsequently undergo apoptosis just as they are beginning to produce hemoglobin.<sup>100</sup> The resultant clinical disease is megaloblastic anemia, which is characterized by ineffective erythropoiesis and macrocytic erythrocytes (Figure 13.4D). In ineffective erythropoiesis, progenitor cells in the

EPO-dependent period expand due to increased EPO levels. The number of reticulocytes formed, however, is less than normal because of the increased rates of pathologic apoptosis in the EPO-dependent and post-EPO-dependent periods of differentiation.

Although the degree of ineffective erythropoiesis is prominent in megaloblastic anemia, the same process of inhibited DNA synthesis but with less apparent apoptosis is common in many macrocytic anemias. Cell size reductions during normal terminal erythroid differentiation result from shortening of the G1 phase of cell cycle while the lengths of S and G2/M phases remain unaffected.<sup>27</sup> Terminally differentiating erythroblasts with delayed or prolonged

cell cycle durations produce larger-than-normal erythrocytes because they accumulate larger amounts of protein during the protracted periods between cell divisions.<sup>41</sup> With folic acid fortification of grain products, which began in the United States in 1998, folate deficiency related to dietary intake has been largely eliminated,<sup>101</sup> except for those with malabsorption disorders.<sup>102</sup> However, cobalamin deficiency and drugs that interfere with folate metabolism such as methotrexate, trimethoprim-sulfamethoxazole, and anticonvulsants remain clinically relevant causes of macrocytic anemias.<sup>103</sup> Drugs that directly inhibit DNA synthesis such as antivirals (azidothymidine or zidovudine), immunosuppressives (azathioprine), and ribonucleotide reductase inhibitors (hydroxyurea) are major causes of macrocytic anemia.<sup>103</sup> In addition, several inherited and acquired marrow failure syndromes that cause macrocytic anemia have either directly or indirectly inhibited DNA synthesis and increased apoptotic loss of erythroid progenitors.<sup>41</sup> Those with direct DNA synthesis inhibition include Fanconi anemia, in which increased DNA crosslinking requires more DNA repair before cell division is completed,<sup>104</sup> and dyskeratosis congenita anemia, in which chromosomal telomeres cannot be maintained.<sup>105</sup> In addition to direct DNA damage, the induction of p53 in these erythroblasts contributes to both delayed cell cycle and apoptosis.<sup>106</sup> Other marrow failure diseases show indirect inhibition of DNA synthesis, such as Diamond-Blackfan anemia<sup>107,108</sup> and 5q-myelodysplastic syndrome anemia,<sup>109</sup> in which impaired ribosomal biogenesis and/or function leads to secondary inhibition of DNA synthesis and accompanying apoptosis by p53 induction.<sup>108</sup>

### **Iron deficiency and development of microcytic anemia**

In addition to its oxygen transport function in hemoglobin, iron has essential roles in heme as part of myoglobin, mitochondrial cytochromes, and peroxidases. Among many nonheme enzymes, iron is required by four enzymatic processes described in other sections of this chapter: prolyl hydroxylation in HIF- $\alpha$  stability, mitochondrial ferrochelatase insertion of iron into protoporphyrin, ribonucleotide reductase in deoxynucleoside synthesis, and aconitase in glucose metabolism. Two-thirds of the body's iron is in the hemoglobin of circulating erythrocytes, and iron deficiency most commonly arises from blood loss. Two milliliters of blood contains about 1 mg of iron, which is approximately the amount absorbed daily by the duodenum, balancing the 1 mg normally lost through shedding of gastrointestinal tract and skin cells. Erythroid progenitor cells are the greatest consumers of iron in the body, using about 25 mg daily under normal conditions, with most of the iron that is supplied to erythroid cells being recycled from macrophages that phagocytose senescent erythrocytes and degrade their hemoglobin. When erythropoietic demands are increased after bleeding or hemolysis, duodenal iron absorption is increased indirectly by erythroferrone, a hormone produced by erythroblasts that decreases hepatic production of hepcidin.<sup>110</sup> Hepcidin, a 25-amino-acid hormone produced in the liver, is induced by increased plasma iron and by inflammatory cytokines.<sup>111</sup> Hepcidin binds and downregulates surface expression of ferroportin, the cellular iron exporter of iron for all cells, including duodenal enterocytes, which are responsible for iron absorption.<sup>112</sup> The increased absorption mediated by erythroferrone is limited, however, and chronic blood loss of as little as 5 mL per day may cause iron deficiency.<sup>113</sup>

Specific regulators of iron and heme metabolism protect cells from the toxic effects of iron while assuring that crucial cellular

processes that rely on iron are sustained in nonerythroid cells during iron deficiency. Therefore, as iron deficiency develops, erythropoietic utilization of iron becomes restricted and anemia develops. In iron-deficient cells, iron regulatory proteins (IRP1 and IRP2) bind to iron responsive elements (IREs) in 5'- and 3'-untranslated regions (UTRs) of mRNAs controlling production of proteins involved in cellular iron import, export, and storage.<sup>114,115</sup> Under iron-replete conditions, IRP1 functions as the enzyme aconitase with an iron-sulfur cluster in its active site; under iron-deficient conditions, IRP1 lacks the iron-sulfur cluster and binds IREs. IRP2 is rapidly degraded under iron-replete conditions but is stable and binds IREs during iron deficiency. IRP binding of IREs in the 5'-UTR of mRNAs inhibits their translation, decreasing their production. Two important examples are mRNAs for ferroportin and ferritin, the intracellular storage protein, both of which decrease during iron deficiency, allowing the maintenance of normal intracellular iron levels. In contrast, IRP binding of IREs in the 3'-UTR of mRNAs stabilizes them and enhances their translation. An example is transferrin receptor mRNAs, where IRP binding increases transferrin receptor production, thereby increasing cellular iron importation.

Although translation of ferroportin mRNA is controlled by the 5'-IRE in most cells, alternative splicing in duodenal enterocytes and erythroid precursor cells produces ferroportin mRNAs without 5'-IREs.<sup>116,117</sup> Thus, during iron deficiency, ferroportin expression is sustained in these two cell types, allowing uncompromised iron exportation into the plasma from duodenum and diminished accumulation within erythroid precursors and erythrocytes.<sup>118,119</sup> During iron deficiency, IRPs increase binding to 5'-IREs of two key mRNAs involved in erythropoiesis. IRP1 binds a 5'-IRE in HIF-2 $\alpha$  mRNAs, leading to decreased translation of HIF-2 $\alpha$  messages in the renal cortical fibroblasts that are capable of producing EPO.<sup>120-122</sup> The decreased intracellular HIF-2 $\alpha$  protein results in less EPO production despite the hypoxia of the renal cortex from the decreased numbers of circulating erythrocytes. As a result, renal EPO production may be relatively diminished in the anemia of iron deficiency when compared to other anemias of similar severity. In erythroid progenitors, HRI-mediated increases in ATF4 and its target *GRB10* can dampen EPO signaling.<sup>43</sup> The decreased EPO activity in iron deficiency, relative to anemia from blood loss or hemolysis, leads to relatively increased apoptosis of erythroid cells in the EPO-dependent stages that immediately precede the stages that synthesize hemoglobin (compare Figures 13.4B and 13.4E).

In the later hemoglobin-producing stages of iron-deficient erythropoiesis, IRP1 binds a 5'-IRE in mRNAs encoding ALAS2, which is the rate-controlling enzyme in porphyrin synthesis.<sup>38</sup> The resultant decreases in ALAS2 lead to less accumulations of protoporphyrin and heme in the erythroblasts. The decreased heme in erythroblasts increases HRI activity, which inhibits protein synthesis in general and globin syntheses in particular.<sup>43</sup> The combined effects of relatively decreased EPO activity and HRI-mediated restriction of protein synthesis in iron deficiency result in a slower rate of completion of the terminal stages of erythroblasts, with decreased rates of red blood cell production resulting in hypochromic, microcytic anemia as shown in Figure 13.4E.

In addition to iron deficiency anemia, HRI plays a role in other microcytic anemias in which heme production is limited. Inherited disorders of ALAS2 cause sideroblastic anemia as iron accumulates in mitochondria when porphyrin synthesis does not provide sufficient protoporphyrin IX for heme formation. Likewise, mutations in ferrochelatase decrease intracellular heme.

Mice deficient in HRI that become iron-deficient or have impaired porphyrin synthesis die from anemia when excess globin chains that cannot form hemoglobin without heme precipitate, denature, and cause oxidative damage resulting in apoptosis of erythroblasts.<sup>123,124</sup> Thus, HRI rescues iron-deficient erythroblasts from the thalassemia-like phenotype of oxidative damage from excess globin chains by restricting globin chain synthesis when heme synthesis is insufficient.

### **Thalassemia and the development of ineffective erythropoiesis and microcytosis**

Thalassemia is the other major type of microcytic anemia. When thalassemia is severe, it is treated with chronic red cell transfusions. Thalassemias are caused by mutations that decrease the synthesis of either  $\alpha$ - or  $\beta$ -globin with intracellular accumulations of the excess unpaired  $\alpha$ - or  $\beta$ -globin chains.<sup>125</sup> Compared to the excess  $\beta$ -globin chains in  $\alpha$ -thalassemia, which form tetramers of hemoglobin H, the excess  $\alpha$ -globin chains in  $\beta$ -thalassemia are relatively insoluble. Excess free  $\alpha$ -globin chains in  $\beta$ -thalassemia are partially decreased by accumulation of  $\gamma$ -globin chains producing fetal hemoglobin, binding to AHSP, ubiquitination–proteasomal degradation, and autophagy of aggregated  $\alpha$ -globins.<sup>126</sup> If unpaired globin chains are not removed by these intracellular adaptations, they can precipitate and denature, leading to the formation of methemoglobin and hemichromes that bind, oxidize, and disrupt the function of erythroid membrane and membrane skeletal proteins.<sup>127</sup> When the cytoplasmic domain of Band 3 is affected by this oxidative damage, it leads to aggregation, deposition of anti-Band 3 IgG, complement fixation, and phosphatidylserine externalization that in turn targets the cells for erytrophagocytosis.<sup>128,129</sup> The decreased solubility of unpaired free  $\alpha$ -globins in  $\beta$ -thalassemias results in ineffective erythropoiesis due to intramedullary apoptosis of erythroblasts, whereas  $\alpha$ -thalassemias have relatively less erythroblast apoptosis but more erythrocyte hemolysis.<sup>130</sup> Apoptosis in the  $\beta$ -thalassemias affects the late stages of erythroblast differentiation, and, because the mitigation of the EPO response due to IRP activity in iron deficiency does not occur in thalassemia, erythroid progenitors and early-stage erythroblasts expand in response to increased EPO. These early-stage erythroid populations expand extensively, with the degree of expansion directly related to the rate of apoptosis in the late-stage erythroblast populations.<sup>131</sup> The large expansion of erythroblast populations in the more severe cases of  $\beta$ -thalassemia increases erythroferrone, which increases iron absorption and results in iron overload that complicates and limits transfusion therapy in these patients.<sup>110</sup>

Depending upon the severity of thalassemia, the oxidative stress due to denatured globin chains, heme, and nonheme iron can overwhelm the erythroblast's normal antioxidant enzymes, such as superoxide dismutase, catalase, and glutathione peroxidase, and toxic oxygen species scavengers, such as reduced glutathione and peroxiredoxin.<sup>132</sup> In these oxidation-stressed thalassemic erythroblasts, HRI has also been found to have an antioxidant effect via increased Atf4, which induces expression of antioxidant genes, including heme oxygenase-1 (HO1), the first step in the degradation of heme.<sup>133</sup> In mice, HRI deficiency converts the moderate anemia of  $\beta$ -thalassemia intermedia into an embryonic lethal anemia with extensive accumulations of precipitated and denatured  $\alpha$ -globin chains.<sup>124</sup> The antioxidant activity of HRI is accompanied by its general restriction of protein synthesis so that the phenotype in thalassemias is a microcytic, hypochromic anemia.

### **Anemia of chronic inflammation**

Diseases that can secondarily decrease erythropoiesis include those that directly displace the EBIs in the bone marrow, such as metastatic neoplasms, lymphoid neoplasms, and myelofibrosis.<sup>134,135</sup> However, the most common cause of secondary inhibition of erythropoiesis is anemia of chronic inflammation (ACI), which occurs in patients with chronic infections, neoplasms, and inflammatory diseases. ACI has multiple components in common with the various mechanisms shown in Figure 13.4. These components include direct and indirect inhibitory effects of specific inflammatory cytokines on erythropoietic cells and their hematopoietic progenitors. Inflammatory cytokines with recognized inhibitory mechanisms include interleukin-1 (IL1), IL6, TNF $\alpha$ , and interferon- $\gamma$  (IFN $\gamma$ ).<sup>136</sup> Direct inhibition of cell survival and growth by IFN $\gamma$  involves the induction of PU.1 in MEPs which suppresses erythroid differentiation and promotes megakaryocytic differentiation. In the subsequent stages of EPO dependence, IFN $\gamma$  enhances the expression of members of the apoptosis-inducing TNF receptor family, including receptors for TNF $\alpha$ , FAS, TNF-related apoptosis-inducing ligand (TRAIL), TNF-like weak inducer of apoptosis (TWEAK), and receptor-binding cancer antigen expressed on SiSo cells (RCAS1).<sup>137–139</sup> The EPO-dependent stages are also affected indirectly by decreased EPO production that is induced by TNF $\alpha$ . Although the concentrations of TNF $\alpha$  to which the EPO-producing fibroblasts in the renal cortices are exposed are lower than when the inflammation is within the renal tissue, plasma EPO levels are lower in ACI than in other anemic states without inflammation.<sup>68,69</sup>

The later stages of erythropoiesis when hemoglobin is produced have relatively restricted iron supplies due to IL6 and members of the bone morphogenetic protein (BMP) family that induce transcription of hepcidin in the liver.<sup>111</sup> Experimental models show that hepcidin induction can be mediated by IL6 signaling through the JAK2–STAT3 pathway<sup>140–142</sup> or by bacterial endotoxin signaling through the BMP–Smad1/5/8 signaling pathway.<sup>143</sup> Hepcidin downregulates ferroportin on all cells, but its effects on three specific types of cells are most important for the inhibition of erythropoiesis in ACI. In macrophages, decreased ferroportin greatly diminishes the recycling of iron recovered from phagocytosed senescent erythrocytes. This sequestration of iron in macrophages is partially offset in ACI erythroblasts because hepcidin-induced decreases in erythroid cell ferroportin limit their iron export compared to erythroid cells in iron deficiency.<sup>118</sup> In severe cases of ACI, the downregulation of ferroportin on duodenal enterocytes restricts iron absorption, and eventually iron deficiency can develop. When iron deficiency complicates ACI, HRI activity causes the usually normocytic anemia to become microcytic. Most of the studies have focused on the acute phase of inflammation. The long-term consequences and the development of an EPO-refractory anemia remain unclear.

### **Erythropoietic therapies**

Enhancement of erythropoiesis to reduce the frequency of RBC transfusion may be achieved by increasing erythropoietic progenitors, supplying exogenous stimulators of erythropoiesis, increasing endogenous production of erythropoietic stimulators, and reducing effects of negative regulators of erythropoiesis. In aplastic anemia, decreased numbers of HSCs and MPPs result in decreased erythroid progenitors that descend from them. Immune suppression with cyclosporine plus antithymocyte globulin and stem cell stimulation with the thrombopoietin mimetic, eltrombopag, separately or in combination are effective in these patients.<sup>144</sup> In Diamond–Blackfan anemia (DBA), decreased progenitor cells are confined to the erythroid lineage and

are the result of mainly mutant genes encoding ribosomal proteins. The majority of DBA patients respond, at least initially, to glucocorticoids hormones, prednisone or prednisolone, with expansion of erythroid progenitors.<sup>145</sup> In chronic, low-risk variants of myelodysplastic syndrome, the abnormal erythroid lineage involvement extends through the late-stage erythroblasts. About half of transfusion-dependent patients with the del(5q) karyotype can become RBC transfusion free with the immunomodulator, lenalidomide.<sup>146</sup> For those patients without del(5q) karyotype and low endogenous EPO levels, erythropoietic stimulating agents, recombinant human erythropoietin and darbepoetin, are effective alone and in combination with granulocyte-stimulating factor.<sup>147</sup> In patients with low-risk MDS<sup>148</sup> or beta-thalassemia,<sup>149</sup> luspatercept, which binds transforming growth factor-beta superfamily ligands including activin and growth-and-differentiation factor 11, increases erythropoiesis and reduces RBC transfusion requirements, but long-term effects are unknown. Patients with renal disease have EPO deficiency that is treated effectively with recombinant human erythropoietin rhEPO<sup>150,151</sup> or its modifications including hyperglycosylated rhEPO (darbepoetin)<sup>152</sup> and polyethylene glycol-conjugated rhEPO (CERA).<sup>153</sup> However, correction to or near normal ranges of hemoglobin or hematocrit is associated with increased thrombotic vascular events. HIF prolyl hydroxylase inhibitors stabilize HIF-2α and, thereby, increase endogenous EPO transcription, plasma EPO levels, and increase erythropoiesis in renal disease patients with anemia.<sup>154–157</sup> However, possible adverse long-term events of increased HIF such as VEGF-induced vessel growth in diabetic retinopathy or malignancies remain unknown.

## Summary and outlook

Erythropoiesis, a component of hematopoiesis, is required for normal maintenance of red blood cell numbers and responds with increased production rates following blood loss or hemolysis. In the erythroid differentiation process, the rate of erythrocyte production is regulated largely by EPO, which is produced in the renal cortex in response to the tissue hypoxia that results from decreased oxygen delivery in anemic states. The oxygen-EPO feedback mechanism finely controls rates of erythrocyte production that never overshoot and result in polycythemia. This feedback mechanism, however, responds promptly to physiologic changes such as blood

loss, hemolysis, or changes in atmospheric oxygen. Chronic underproduction of erythrocytes results in anemia, and effective treatments may prevent or reduce red blood cell transfusions for those with underproduction anemias. Use of recombinant EPO is routine for patients with the anemia of renal disease, an EPO deficiency state. Limited responses to EPO in patients with anemias due to malignancy or myelodysplasia, combined with an increased potential for thrombotic and cardiovascular complications of EPO therapy in general, have resulted in more restricted use of recombinant EPO or its modified forms in clinical practice. New therapeutic agents that increase endogenous EPO production or decrease the activity of negative erythropoietic regulators may help treat underproduction anemias. Deficiencies of folate and vitamin B12, which are required for the extensive cellular proliferation needed to produce erythrocytes, and iron, which is required to produce the major protein of erythrocytes, hemoglobin, are remediable causes of anemia. Chronic inflammation, another very common cause of anemia, is most improved by treating the primary disease, but new agents may enhance erythropoiesis in those cases in which treatment of the primary disease may be limited.

## Introduction

Human red blood cells (RBCs), mature and released from the bone marrow, lack nuclei, ribosomes, and mitochondria. They have a life span of 120 days, after which they are removed from the circulation in the natural course of aging.<sup>1</sup> RBCs pick up oxygen during a one-third second transit through the alveolar capillary (a billion O<sub>2</sub> molecules per cell) and deliver oxygen through capillaries with a diameter smaller than their own. RBCs can neither use oxygen for the extraction of energy nor synthesize proteins or polynucleotides. Their primary functions, transporting oxygen from the lungs to the tissues and carbon dioxide back to the lungs, do not require the expenditure of energy, though oxygen release from hemoglobin is tightly regulated by high-energy phosphate compounds—such as adenosine 5'-triphosphate (ATP) and 2,3-diphosphoglycerate (DPG). As such, maintaining hemoglobin in an optimal state for delivering of oxygen and keeping normal cell flexibility and morphology do require active metabolism and are prerequisites for appropriate RBC function and successful transfusion therapies.

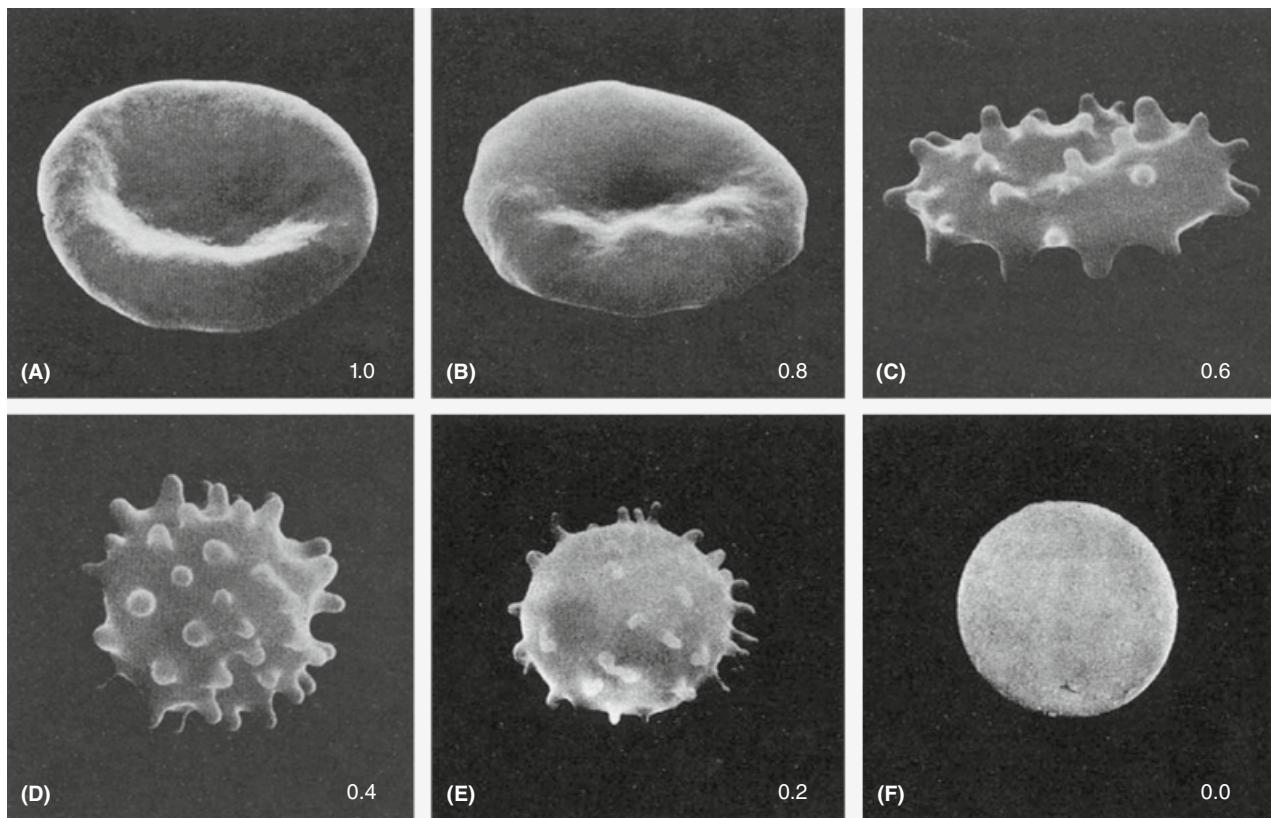

During standard storage at 4 °C for up to 42 days, significant and in part reversible changes in red cell morphology and metabolism occur, called storage lesions.<sup>2</sup> One striking example is the change in red cell shape (Figure 14.1) which can be reversed to a large extent by washing stored RBCs with albumin or by metabolic rejuvenation.<sup>3,4</sup> Recent advances such as imaging flow cytometry and cell sorting allow the precise measurement and isolation of cells with these changes.<sup>5</sup> In order to understand and further improve storage, it is essential to understand basic principles of red cell metabolism.

Critically, the binding and release of oxygen by hemoglobin is not completely reversible. Occasionally, the departing oxygen takes an extra electron, forming methemoglobin (Fe<sup>++</sup> → Fe<sup>+++</sup>) and superoxide (O<sub>2</sub><sup>-</sup>). The RBC is full of methemoglobin reductase and superoxide dismutase but needs energy to drive their activities. As the waste products of energy metabolism, lactate and protons, accumulate in closed storage systems and drive down pH, the reducing potential of the RBC's major antioxidant, glutathione, falls from 0.7 to 0.2 mEv and oxidant damage to proteins, lipids, and carbohydrates accumulates, despite methemoglobin reductase, superoxide dismutase, and other protective mechanisms.<sup>6</sup>

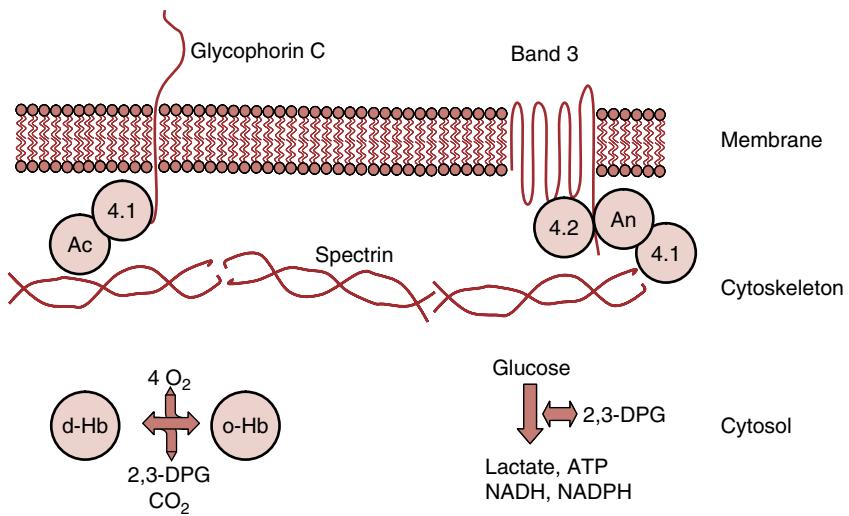

Understanding of RBC metabolism has increased greatly with the application of “-omics” technologies. Proteomics has identified 2200 separate proteins in RBCs that are the products of 5% of all

human genes.<sup>7</sup> This number includes 340 proteins specifically associated with the red cell membrane. Structural proteins, membrane receptors, metabolic enzymes, heat shock proteins, chaperonins, and others have been cataloged, sorted into pathways and functional groups, and provide the most complete overview of the molecule by molecule functioning of a human cell type, suggesting several roles for red blood cells in systems homeostasis beyond oxygen transport in like fashion to a circulating organ. Metabolomics can simultaneously measure the concentrations of thousands of small molecules and follow their activities in isotopic pulse-chase experiments.<sup>8</sup> Lipidomics can enumerate the many classes of lipids present, categorized on the basis of their hydrophobicity and fatty acyl composition (chain length, degree of unsaturation, and oxidation).<sup>9</sup> Transcriptomics reveals the presence of 400 different small RNA molecules serving a variety of roles.<sup>10</sup> Analysis to date confirms the view that red cells are complex, metabolically active cells using glucose to make ATP and reducing equivalents to ensure flexibility and oxygen delivery. The red cell may be 98% hemoglobin by protein weight, but it is much more than “a hapless sac of hemoglobin.”<sup>11</sup>

Integration of biochemical metabolism and biophysical discoveries in the last two decades by several research groups show that many molecular interactions are missed when the red cell is considered by itself without taking into account the physiologic vascular milieu in which it performs its main biological function.<sup>12,13</sup> For example, the interaction of the two most abundant proteins in the red cell cytosol and membrane, hemoglobin and the band 3 protein, respectively, is influenced by conformational changes that accompany oxygen binding to hemoglobin; this interaction in turn modulates the activity of glycolytic enzymes that compete with de-oxyhemoglobin for the same binding domain on band 3, which in turn regulates metabolic fluxes through glycolysis, as well as the structural architecture of the red cell membrane-cytoskeletal linkage (Figure 14.2). During storage, concentrations of red cell ATP, DPG, and glutathione decline leading to cell wall dysfunction and damage. Dysfunction can manifest as stiffer red cells, while damage can include membrane loss. Both of these effects can in turn affect vascular flow of transfused RBCs. On the arterial side, stiffer cells have trouble absorbing the energy of pulsatile flow and are projected more frequently into the normally cell-free layer of plasma at the vascular surface where they absorb endothelium-derived nitric oxide and lead to vasoconstriction.<sup>14</sup>

**Figure 14.1** Scanning electron micrographs showing representative red blood cells in various stages of shape change typical of prolonged storage. The cells progress from discocytes (A) through several stages of echinocytes (B–D), to spherocytoids (E), and finally to spherocytes (F). Scores based on the visual appearance as those shown in the lower right of the individual images can be assigned to several hundred individual stored cells and averaged to produce a morphology score for the unit. Such scores decrease in a linear manner during storage but can be substantially reversed by rejuvenation.

**Figure 14.2** Schemata of red cell components. In the past, it was believed that oxygen transport by hemoglobin and metabolism were cytosolic functions, and that the membrane and cytoskeleton merely enclosed them. We now recognize that the attachments of the membrane to the cytoskeleton from band 3 through ankyrin (An) and proteins 4.2 and 4.1 to spectrin, and from Glycophorin C through protein 4.1 and actin (Ac) to spectrin are destabilized by 2,3-diphosphoglycerate (2,3-DPG). 2,3-DPG released from deoxy-hemoglobin (d-Hb) binds to band 3 and partially detaches the membrane from the cytoskeleton allowing lateral movement of membrane structures. This could have implications for red cell flexibility when slipping into peripheral capillaries. Other abbreviations: oxy-hemoglobin O-Hb.

Band 3—whose main function is to exchange chloride for bicarbonate anions—closely interacts not just with hemoglobin but also with carbonic anhydrase in the cell membrane. In capillaries in the peripheral vasculature, where oxygen tensions are lower and carbon dioxide accumulates as a function of tissue metabolism, this complex in the red cells promotes the production of bicarbonate with the release of protons that, via the so-called Bohr effect, cause the release of oxygen from hemoglobin to the tissues.<sup>8</sup> On the venous side, damaged membranes can lead to procoagulant and proinflammatory events.<sup>15</sup> In the following sections, red cell metabolism will be discussed taking into account intermolecular interactions of importance for the primary function of hemoglobin, which is oxygen and carbon dioxide transport. This section is followed by a review of the development of red cell storage systems.

## Metabolism

### Metabolism of glucose

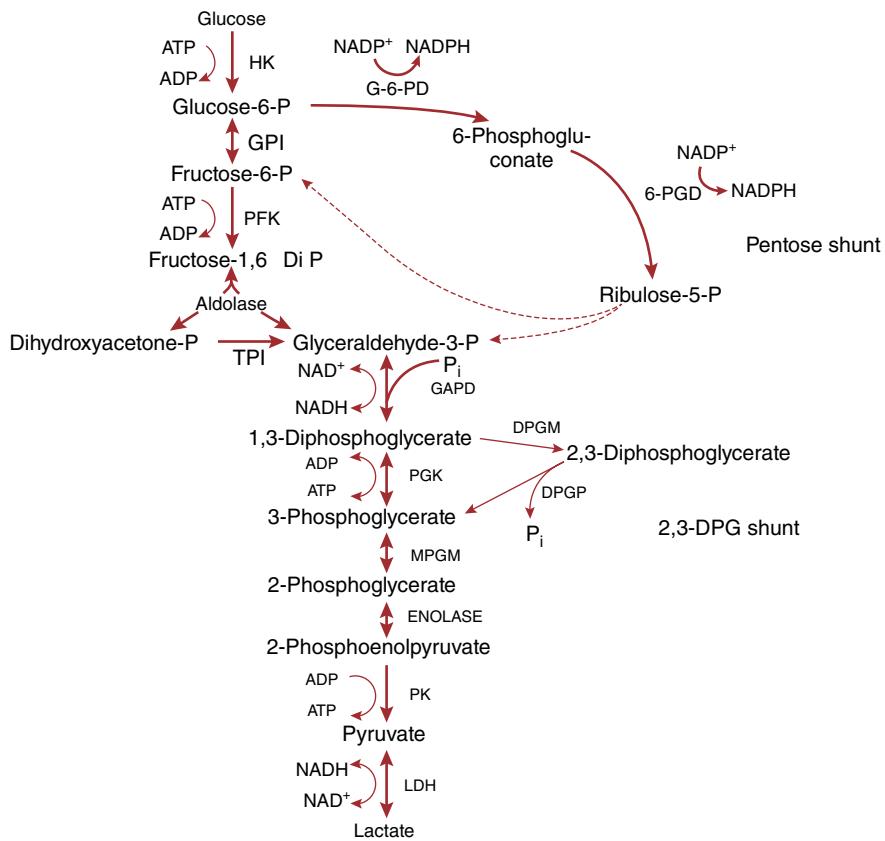

Under physiologic circumstances, the energy that the red cell requires is derived through the breakdown of glucose to lactate or pyruvate. The sequence of reactions is generally known as glycolysis or the Embden–Meyerhof–Parnas (EMP) pathway.<sup>16</sup> This pathway

is phylogenetically very old, and the sequence of reactions is the same in all mammalian tissues as well as in yeast and bacteria. Glycolysis is, however, inefficient, producing only 2 ATP molecules for each glucose broken down in contrast to the 34 ATP made from glucose in mitochondria.

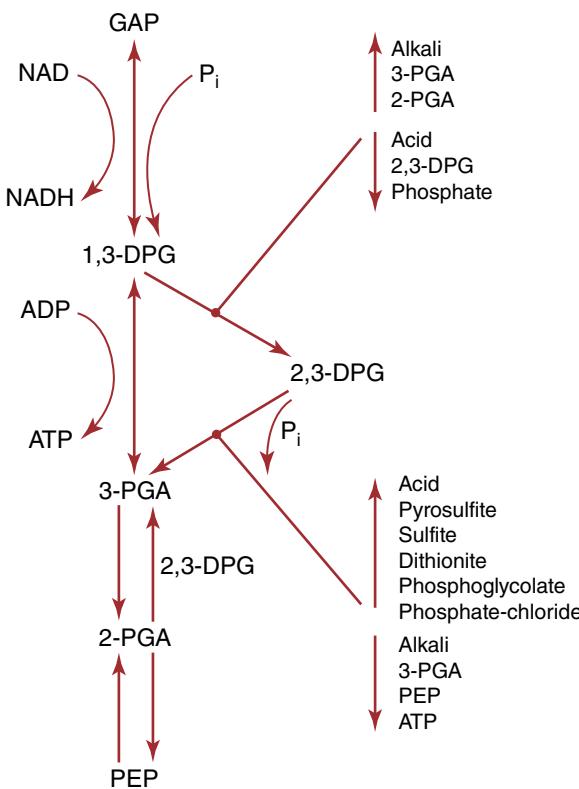

The reactions of the glycolytic pathway are shown in Figure 14.3. In this sequence of reactions, the six-carbon sugar glucose is phosphorylated, isomerized to fructose phosphate, phosphorylated again, and cleaved into three-carbon phospho-sugars. The three-carbon sugars are again phosphorylated. Finally, these carbohydrate-bound high-energy phosphates that have been synthesized are transferred to adenosine diphosphate (ADP), producing the high-energy compound ATP. The ATP synthesized is used by ATPases for the pumping of ions against concentration gradients, secreted to cause vasodilation, and very importantly used for the phosphorylation of glucose to make more ATP in the glycolytic pathway.<sup>17</sup>

### The 2,3-DPG shunt (Rapoport–Luebering shunt)

RBCs express a shunt that branches from the main glycolytic pathway after the formation of 1,3-diphosphoglycerate (1,3-DPG) and returns to it with the formation of 3-phosphoglycerate (3-PGA) (Figure 14.3). The Rapoport–Luebering shunt produces 2,3-DPG from 1,3-DPG, followed by the dephosphorylation of 2,3-DPG to 3-PGA

**Figure 14.3** The glycolytic pathway with the pentose and 2,3-DPG shunts of red cell metabolism. ATP, adenosine triphosphate; ADP, adenosine diphosphate; HK, hexokinase; NADP<sup>+</sup>, nicotinamide adenine dinucleotide phosphate, oxidized form; NADPH, nicotinamide adenine dinucleotide phosphate, reduced form; 6-PGD, 6-phosphogluconate dehydrogenase; P, phosphate; G-6-PD, glucose-6-phosphate dehydrogenase; PFK, phosphofructokinase; TPI, triosephosphate isomerase; NAD<sup>+</sup>, nicotinamide adenine dinucleotide, oxidized form; NADH, nicotinamide adenine dinucleotide, reduced form; GAPD, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; DPGM, diphosphoglycerate mutase; DPGP, diphosphoglycerate phosphatase; MPGM, monophosphoglycerate mutase; PK, pyruvate kinase; LDH, lactate dehydrogenase. Source: Adapted from the 3rd edition of Rossi's Principles of Transfusion Medicine.

**Figure 14.4** Regulation of the formation and breakdown of 2,3-DPG. The steady-state concentration of 2,3-DPG is governed by the rate of its formation from 1,3-DPG and by its breakdown to 3-phosphoglyceric acid. Both reactions are catalyzed by the same multifunctional enzyme modulated by a variety of substances. Depending on the reaction, the enzyme is abbreviated DPGM or DPGP in the figure. Abbreviations are as in Figure 14.3. Source: Adapted from the 3rd edition of Rossi's Principles of Transfusion Medicine.

(Figure 14.4). Both reactions are catalyzed by the same enzyme and are balanced at physiologic pH.<sup>18</sup> At higher pH, the enzyme acts only as a mutase moving phosphate in 1,3-DPG from position 1 to position 2 in the molecule; at lower pH it acts only as a phosphatase, transforming 2,3-DPG to 3-PG. As the 2,3-DPG shunt bypasses one of the two ATP synthesis steps in glycolysis, 2,3-DPG is made at the expense of ATP. In storage systems, a high pH can shut down ATP production, while a lower than physiologic pH leads to a burst of ATP production driven by the breakdown of 2,3-DPG.

The production of large quantities of 2,3-DPG is a unique feature of glycolysis in the red cell. Red cells contain approximately equimolar amounts of hemoglobin and 2,3-DPG to allow 1:1 binding. In its most well-known function, the binding of 2,3-DPG to the  $\beta$  subunits of deoxyhemoglobin serves to stabilize the T (tense, low oxygen affinity) state of hemoglobin which shifts the oxygen equilibrium curve to the right (favoring dissociation of oxygen). In the R (relaxed, high oxygen affinity) state, approximately 80% of 2,3-DPG is “free,” while in the T state over 80% of 2,3-DPG is bound to hemoglobin.<sup>19</sup> In the “free” state, 2,3-DPG at physiological concentrations performs the second function of modulating properties of the red cell membrane.<sup>8</sup> It binds directly to band 3 and thereby interferes negatively in the interactions between proteins 4.1 and 4.2, ankyrin, and band 3.<sup>20</sup> 2,3-DPG also releases spectrin from the membrane skeleton and interferes negatively in the interactions between spectrin, actin, protein

4.1 and the glycophorin C complex.<sup>8,21,22</sup> These effects decrease the number of connecting links between the cell membrane and the cytoskeleton and increase lateral mobility of integral membrane proteins.<sup>10,23</sup> The rise and fall of “free” 2,3-DGP concentrations with each pass through the circulatory system results in repetitive destabilization and restabilization of the membrane–cytoskeleton architecture (Figure 14.2). “Free” 2,3-DPG increases cell flexibility by weakening the links between the membrane and the cytoskeleton and facilitates gas exchange by allowing the red cell to slip through narrow capillaries and splenic sinusoids. However, further experiments are needed to clarify the full physiologic implications of the interactions between 2,3-DPG, cell membrane proteins, and the cytoskeleton.

### The pentose shunt (hexose monophosphate shunt)

Under normal, steady-state conditions, ~92% of glucose is metabolized in red cells by way of the glycolytic pathway. The residual 8% is oxidized through another important metabolic pathway called the pentose phosphate pathway (PPP) or hexose monophosphate shunt (Figure 14.3). Some of the glucose-6-phosphate (G-6-P) formed when glucose is phosphorylated in the hexokinase reaction enters this pathway. Glucose-6-phosphate dehydrogenase (G-6-PD) catalyzes the rate-limiting oxidation of G-6-P to 6-phosphogluconolactone, reducing nicotinamide adenine dinucleotide phosphate (NADP) to NADPH. After hydrolysis of the lactone to 6-phosphogluconic acid, another oxidative step reduces additional NADP to NADPH, and releases carbon dioxide from the six-carbon compound, forming the pentose sugar ribose-1-phosphate. After a series of rearrangements (in the nonoxidative steps of the PPP), two normal intermediates of the main glycolytic pathway, fructose-6-phosphate and glyceraldehyde-3-phosphate, are formed and rejoin the main metabolic stream.

The pentose shunt is important to the red cell as a source of NADPH, a key reducing equivalent that is involved in the recycling of oxidized glutathione by glutathione reductase,<sup>24</sup> as well as a cofactor for several NADPH-dependent enzymes such as glutathione peroxidase, catalase, peroxiredoxins, glutaredoxins, thioredoxins, biliverdin reductase B, and the ascorbate-tocopherol axis.<sup>25</sup> Reduced glutathione is important for the elimination of peroxide, protection of protein SH-groups, limitation of lipid peroxidation, and detoxification processes. The pentose shunt also plays an important role in the red cell by providing ribose-5-phosphate to make phosphoribosyl pyrophosphate (PRPP), an essential substrate for the synthesis of adenine nucleotides required for continuing synthesis of ATP (see below) and GTP, as required for cyclic purine signaling (e.g., cyclic-AMP and cyclic-GMP) and purine salvage reactions (e.g., hypoxanthine-guanosine-phosphoribosyltransferase).

### Alternative substrates for red cell metabolism

Glucose is the natural substrate for human red cell energy metabolism, but red cells are also capable of metabolizing other sugars (i.e., fructose, mannose, galactose, and the three-carbon sugar dihydroxyacetone). However, none of these other sugars have proven to be useful in the design of blood preservatives.<sup>26</sup>

The presence in red cells of the enzyme nucleoside phosphorylase also makes it possible for RBCs to use nucleosides such as inosine to support ATP synthesis:

In this reaction, ribose-1-phosphate is formed without the expenditure of ATP. Ribose-1-phosphate is then readily converted to

fructose-6-phosphate by the pentose shunt which feeds into the glycolytic pathway leading to the generation of ATP. In the rejuvenation of red cells (see later) inosine allows ATP-depleted red cells to prime their metabolic pump (the glycolytic pathway). It has not been possible to include inosine in blood preservatives since the product of its metabolism, hypoxanthine, is rapidly converted to uric acid with the concomitant generation of the pro-oxidant hydrogen peroxide in the body. Because many patients who receive blood transfusions have impaired liver function or may already have hyperuricemia because of hereditary or acquired factors, a blood product that increases plasma uric acid level is not considered safe.<sup>27</sup>

## Regulation of energy metabolism

### Rate of glucose metabolism

In nucleated cells, metabolic regulation is dependent on protein synthesis which in turn is regulated by increasing or decreasing the rate of DNA transcription or the translation of messenger RNA. Red cells do not have these options. Instead, the rate of glucose metabolism is regulated by feedback mechanisms acting on the glycolytic enzymes.<sup>28</sup> In spite of extensive studies, our understanding of the control of glucose metabolism by red cells is still incomplete.

The N-terminal cytoplasmic domain of the band 3 protein binds hemoglobin, cytoskeletal proteins, and glycolytic enzymes, including the rate-limiting enzymes phosphofructokinase, aldolase, and glyceraldehyde 3-phosphate dehydrogenase.<sup>29</sup> Based on current evidence, de Rosa *et al.*<sup>8</sup> point out that binding between hemoglobin in the T state and band 3 causes a release by displacement of glycolytic enzymes, which results in increased activity of the main glycolytic pathway. In contrast, hemoglobin in the R (highly oxygenated) state is associated with decreased glycolysis, as glycolytic enzymes bind to band 3, but increased activation of the pentose shunt (see later).<sup>30</sup>

The rate of glucose metabolism by red cells is influenced by many factors other than basal enzyme activity. Negative feed-back mechanisms are involved in the control of the glycolytic pathway. Both hexokinase and phosphofructokinase are inhibited by hydrogen ions (low pH)<sup>31</sup> or other metabolites (e.g., citrate inhibits phosphofructokinase in other cell types through the Randle effect).<sup>32</sup> As storage progresses, studies have shown the progressive accumulation of reversible and irreversible oxidation of hemoglobin and glycolytic enzymes at functional cysteines (e.g., Cys152 and 156 of GAPDH), as well as deamidation of asparagines facing the substrate accessible pocket of the active site of several glycolytic enzymes.<sup>33,34,35</sup>

However, the principal reason that the rate of glycolysis slows markedly during red cell storage is the accumulation of lactic acid.

### 2,3-DPG concentration

The concentration of 2,3-DPG depends on the rate of its formation and degradation. Many effectors determine whether the mutase or the phosphatase activity of the diphosphoglycerate mutase/phosphatase predominates (Figure 14.4). The hydrogen ion concentration is the most important physiologic modulator.<sup>36</sup> At low pH, phosphatase activity is stimulated and mutase activity is inhibited. Thus, high pH favors 2,3-DPG maintenance and production during storage at the expense of ATP formation, whereas low pH leads to the rapid loss of 2,3-DPG with an increase in ATP production as long as DPG lasts. Modulation of red cell metabolism by elevating pH has been the principal means used to retard the decline of 2,3-DPG levels that occurs during liquid storage of red cells (see later). After the depletion of ATP during storage, 2,3-DPG levels in transfused red cells return to 50% of normal in 7 hours and almost to 95% at 72 hours.<sup>37</sup>

### The pentose shunt activity

Pentose shunt activity is influenced by the availability of NADP and the concentration of NADPH. Under oxidative stress, NADPH is oxidized to NADP and the activity of the pentose shunt increases, which is consistent with the observation of increased pentose shunt activity when hemoglobin is in the R state as mentioned previously. Oxygenated hemoglobin has decreased affinity for the cytoplasmic N-terminus of band 3, which then becomes accessible for the inhibitory binding of glycolytic enzymes. As such, glycolysis slows and up to 90% of glucose is diverted toward the pentose shunt for NADPH synthesis to counteract oxidant stress that arises through Fenton chemistry in the presence of iron and high oxygen concentrations. Since 2,3-DPG is consumed as storage progresses, increases in hemoglobin oxygen saturation as a function of storage duration (especially after storage week 3) have been associated with an increased activation of the pentose phosphate shunt.<sup>38</sup> Oxidation of GAPDH is an alternative mechanism through which glycolysis slows and the pentose shunt activity increases in red cells as a function of oxidant stress *in vivo* or during storage in the blood bag.<sup>39</sup> However, fluxes through this pathway are constrained by the activity of the enzyme glucose 6-phosphate dehydrogenase (G6PD), a protein that is coded by a gene on the X chromosome and, as such, is expressed at higher levels in red cells from female than male donors. Also, aging of RBCs, or the host in general, has been associated with declines in G6PD expression/activity, in part explaining why older red cells or red cells from older blood donors are characterized by increases in oxidant stress.<sup>40,41</sup>

G6PD activity is also negatively impacted by donor differences.<sup>42,43</sup> Notably, G6PD is highly polymorphic and ~400 million people around the world suffer from impairments to G6PD activity (<10 or even <1% residual activity) as a function of single nucleotide polymorphisms. Recent studies suggest that red blood cells from donors with G6PD deficiency are characterized by improved energy metabolism (as fluxes through glycolysis cannot be diverted through the pentose phosphate shunt) but poorer antioxidant metabolism. Other studies have shown that end-of-storage red cells from G6PD deficient donors (especially the African American variant) show decreases in post-transfusion recoveries—i.e., the percentage of transfused red cells that still circulate at 24 hours from transfusion—in autologous volunteers.<sup>44</sup>

### Adenosine triphosphate

In the red cells, ATP is synthesized by the glycolytic pathway, but its regulation is complex. ATP is used in a number of different metabolic pathways, particularly by the kinases that phosphorylate sugars (i.e., hexokinase and phosphofructokinase) and proteins, and by ATPase-driven ion pumps (i.e., Na<sup>+</sup>-K<sup>+</sup>-ATPase, Mg<sup>2+</sup>-ATPase, and Ca<sup>2+</sup>-ATPase). Moreover, red cell membrane shape and rigidity are controlled by the ATP-dependent cytoskeleton.

ATP is in equilibrium with ADP and adenosine monophosphate (AMP) as shown above. Production of ATP from ADP in glycolysis normally keeps AMP concentrations low. As the level of ADP increases when glycolysis slows, some is converted to AMP. AMP, in turn, is deaminated in the AMP-deaminase (AMPD) reaction and the total red cell pool of adenine decreases. This demonstrates why, during storage, ATP levels are depleted if adenine is not added to the anticoagulant and/or additive solution. Since red cell-specific AMPD3 activity is inhibited by 2,3-DPG, but promoted by

intracellular calcium and oxidant stress, ATP breakdown and purine deamination products such as hypoxanthine have been identified as metabolic markers of the storage lesion and post-transfusion recovery in mice and humans.<sup>45</sup> ATP is also used extensively in red cells to fuel phosphorylation reactions, which is relevant in red cells as erythrocytes have a higher number of kinases than any other cell. Though the topic would require a whole thematic chapter, the interested reader is referred to comprehensive reviews/research articles that document the impact of red cell protein phosphorylation in the maintenance of the homeostasis of membrane cytoskeleton and band 3–hemoglobin interactions through the phosphorylation of tyrosine in the N-terminus of band 3.<sup>46</sup>

ATP, released by RBCs during hypoxia, contributes to vascular tone by signaling to endothelial cells directly or in the form of ADP acting on P2Y receptors. Additionally, further breakdown of ADP into AMP and enzymatic conversion of AMP to adenosine via extracellular ectonucleotidases (e.g., CD73) participate in responses to hypoxia via autocrine signaling to circulating RBCs through adenosine interactions with the receptor A2B (ADORA2b). ADORA2b receptors are G-protein coupled receptors on red cells that produce increased intracellular cAMP and activation of cAMP-dependent protein kinase A (PKA).<sup>47</sup> Following exposure to hypoxia, adenosine uptake via the transporter ENT1 can be decreased via PKA-dependent phosphorylation and subsequent proteasomal degradation.<sup>48</sup> A second exposure to hypoxia thus results in a faster acclimatization because reduced uptake of adenosine by RBCs leads to a faster rate of extracellular accumulation.<sup>49</sup> Since circulating adenosine levels >14 μM are potentially toxic (they can cause arrhythmias), breakdown by adenosine deaminase in the bloodstream is critical in many circumstances, for example in the context of sickle cell disease where the activity of this enzyme limits adenosine signaling through ADORA2b and sickling of deoxy HbS.<sup>50</sup>

### Guanine nucleotides

Red cells contain and turn over guanine nucleotides that perform at least three functions. First, G proteins play a role in the signal transduction of membrane shear into secretion of the local vasodilators cAMP and ATP, as described above.<sup>51</sup> Second, guanosine nucleosides contribute to salvage reactions through the hypoxanthine guanosine phosphoribosyltransferase route. The resulting inosine can be phosphorylated to inosine monophosphate (IMP). Tracing experiments suggest that residual activity of the salvage pathway can convert a minimal fraction (<5%) of IMP back to AMP.<sup>52</sup> Third, high concentrations of GTP inhibit red cell transglutaminase, a primitive coagulation system that also interacts with the cytoplasmic domain of band 3 and with protein 4.1.<sup>53</sup> When GTP concentration is reduced during RBC aging, the resulting disinhibition of transglutaminase, which has a Factor XIII like activity, can facilitate the removal of senescent red cells by binding them to fibrin clots. Finally, like inosine for rejuvenation solutions, guanosine has been used in some novel additives (e.g., PAGGSM or PAGGGSM) to fuel the phosphoribolysis reaction that results in the release of guanine and ribose phosphate, which can in turn fuel the synthesis of ATP without initial energy expenditure.<sup>54</sup>

### Synthetic processes

Red cells are only able to assemble a limited repertoire of important molecules from simpler precursors. They retain the capacity to synthesize nucleotides through a “salvage pathway” and to synthesize glutathione from its precursor amino acids. Adenine is able to enter

the erythrocyte by membrane transporters, and then purine nucleotides can be synthesized through the adenine phosphoribosyl transferase reaction:

This reaction is critical in blood storage. The beneficial effect of addition of adenine to stored blood depends on it. Phosphoribosyl pyrophosphate (PRPP), a substrate for the formation of AMP in this reaction, is synthesized from ribose-phosphate formed in the pentose shunt. Guanine nucleotides form in an analogous reaction that is catalyzed by a different enzyme, hypoxanthine-guanine phosphoribosyl transferase. Red cells also actively synthesize a number of other small molecules, including reduced glutathione, nicotinamide adenine dinucleotide (NAD), and S-adenosyl-L-methionine.<sup>13</sup> The latter is a critical methyl-group donor for methylation reactions, which are required for repairing isoaspartyl damaged by oxidant stress.<sup>55</sup>

### Carboxylic acids and transamination

Recently, omics approaches have identified the presence of cytosolic isoforms of Krebs cycle enzymes in the mature erythrocyte, including malate dehydrogenase 1 (MDH1) and isocitrate dehydrogenase 1 (IDH1). Tracing experiments with stable isotope-labeled glutamine and citrate have helped confirm that these enzymes are active and that they participate in reducing equivalent homeostasis (NADH and NADPH) as a function of oxidant stress and hypoxia.<sup>56</sup> Other than participating in the homeostasis of reducing equivalents, aspartate to fumarate conversion can result from the salvage reactions to restore deaminated purines (e.g., IMP to AMP) described above.<sup>57</sup> In parallel, carboxylate metabolism crosstalks with transamination reactions, to the extent that reactions that use glutamate as an amine group donor (e.g., pyruvate conversion to alanine and vice versa) concomitantly generate alpha-ketoglutarate, a substrate for isocitrate dehydrogenase.<sup>58</sup> This pathway is active in red blood cells and it responds to oxidant stress and hypoxia in the mature erythrocyte in vitro (e.g., blood storage) and in vivo (e.g., in response to hemorrhagic shock).<sup>59,60</sup>

### Glutaminolysis, glutathione synthesis, and cysteine metabolism

Glutamine uptake is increased at lower pH owing to the dependency of the glutamine transporters on proton gradients. Glutamine uptake contributes to intracellular glutamate levels, a precursor for the ATP-dependent synthesis of glutathione, the main soluble antioxidant in red blood cells. The synthesis of glutathione is mostly constrained by the availability of the sulfur-containing amino acid cysteine. As such, cysteine efflux is a marker of red blood cell aging in vivo and in vitro.<sup>61</sup> Cysteine metabolism is associated with iron-induced nonapoptotic cell death (ferroptosis) in other cell types, a phenomenon that may contribute to explaining nonapoptotic cell death in the mature, iron-rich (66% of bodily iron) red blood cell.<sup>62</sup>

### Sulfur metabolism and polyamines

Cysteine metabolism in red blood cells is intertwined with the metabolism of other sulfur-containing amino acids, methionine and taurine. While the transulfuration pathway—which interconverts cysteine into methionine—is not active in red blood cells, scavenging of reactive oxygen species by methionine and taurine has been extensively reported, to the extent that both metabolites have been suggested as supplements to current storage additives to counteract storage-induced oxidant stress.<sup>63,64</sup> Methionine also participates in one carbon metabolism: while only limited residual

activity of folate metabolism is detectable in mature erythrocytes (e.g., the methenyl-tetrahydrofolate metabolism step as it is impacted by NADPH homeostasis), most of methionine metabolism is observed in the context of (i) methylation of isoaspartyl groups resulting from oxidant stress-induced deamidation of asparagine or dehydration of aspartate residues in proteins; and (ii) purine catabolism and polyamine synthesis downstream to the breakdown and recycling of S-adenosylmethionine via methylthioadenosine intermediates. These pathways are relevant not just for protein recycling, but also for the role of newly synthesized polyamines in the scavenging of reactive oxygen species and alkalinization of the intracellular pH, to the extent that sub-millimolar concentrations of these metabolites contribute to scavenging activity.

#### **Arginine metabolism and nitric oxide synthesis**

Owing to the lack of mitochondria, red blood cells are characterized by an incomplete urea cycle. On the other hand, mature red blood cells can metabolize arginine as a substrate for a functional nitric oxide synthase and arginase 1.<sup>65</sup> While the former enzyme consumes arginine to generate citrulline and nitric oxide, a potent vasodilator, the latter competes for the same substrate to generate ornithine with no nitric oxide production. Because of these reactions, autologous transfusion studies have shown increased arginase activity and decreased vasodilatory capacity of red blood cells stored longer than 35 days.<sup>66</sup> Scavenging of circulating nitric oxide—including that released by endothelial cells—has been reported by the Gladwin group as a function of free hemoglobin levels, following red cell intravascular hemolysis, a mechanism that they posited to contribute to some of the rare adverse effects associated with transfusion.<sup>67</sup> On the other hand, intracellular metabolism of nitric oxide by hemoglobin has been proposed to play a role in the mechanisms of metabolic adaptation to high altitude hypoxia.<sup>68</sup>

#### **Membrane metabolism**

The red cell membrane is composed of a phospholipid bilayer containing cholesterol molecules and membrane proteins.<sup>69</sup> The phospholipids are arranged with a predominance of phosphatidyl choline (PC) and sphingomyelin in the outer leaflet and phosphatidylinositol, phosphatidylethanolamine (PE), and phosphatidylserine (PS) in the inner leaflet. Since PCs contain three methyl groups while PEs have two, the ratios of PC/PE contribute to methyl-group homeostasis (in like fashion to what is described for methionine above) and, thus, to isoaspartyl damage repairing following oxidant stress. Loss of phospholipid asymmetry results in exposure of PS that is an important apoptotic marker on the red cell surface. Exposure of PS on the outer cell surface promotes red cell removal from the circulation, while the surface glycoprotein CD47, which decreases during storage, inhibits phagocytosis.<sup>70</sup> The phospholipid asymmetry is maintained by the ATP-dependent flippase (aminophospholipid translocase) activity. This activity counteracts phospholipid scrambling which moves PS from the inner to the outer cell surface. Flippase activity decreases during storage, but can be corrected by rejuvenation of the red cells.<sup>71</sup> Phospholipid scrambling is normally low during storage, but is increased by photodynamic treatment for pathogen inactivation and by cell aging in association with rising intracellular  $[Ca^{++}]$ .<sup>72</sup>

Membrane proteins such as glycophorin and band 3 extend through the lipid membrane. Branches of carbohydrates anchored to membrane proteins protrude from the outer surface to produce the glycocalyx. The inner surface of the membrane is lined by the

cytoskeleton, which is anchored to the membrane through the N-terminal cytoplasmic domains of band 3 and glycophorin C. The tetrameric form of band 3 binds ankyrin that constitutes with proteins 4.1 and 4.2 a major attachment site for spectrin. A second attachment site for spectrin involves actin and protein 4.1 in the glycophorin C complex. Both attachments (Figure 14.2) are weakened when the concentration of “free” (nonhemoglobin-bound) 2,3-DPG is increased. As described above, these weakened interactions appear to be of importance for cell flexibility and gas delivery.<sup>8</sup> Membrane shape and deformability are controlled by the ATP-regulated cytoskeletal attachments. Because some capillaries in the microcirculation have a diameter of only half that of a red cell, loss of flexibility and deformability is a serious consequence of the storage lesion, and is responsible for the removal of rigid cells (Figure 14.1).

Sphingolipid signaling also contributes to membrane stabilization in response to hypoxia in vivo and in vitro. Activation of PKA following exposure to hypoxia (refer to the paragraphs above) also promotes the phosphorylation and activation of the red cell-specific enzyme sphingosine kinase 1.<sup>73</sup> This enzyme generates sphingosine 1-phosphate (S1P), a sphingolipid that binds to deoxyhemoglobin upon 2,3-DPG binding, resulting in the further stabilization of the tense state of hemoglobin.<sup>74</sup> S1P levels decrease during storage in certain additives (e.g., additive solution 3), while it increases with others (e.g., additive solution 1) as a function of the osmolarity of the solution.<sup>75</sup>

The red cell membrane also contains transport proteins such as the glucose transporter,  $Ca^{2+}$ -ATPase, the  $Na^{+}$ - $K^{+}$ -ATPase, the GSSG (oxidized glutathione) transport ATPases, and amino acid transporters, in addition to various other transport channels. A prime metabolic activity of the red cell is maintaining osmotic stability through the activity of its membrane pumps that are ATP driven. The  $Na^{+}$ - $K^{+}$ -ATPase is highly sensitive to changes in temperature and scarcely functions at 4°C. As a consequence, the normal diffusion of sodium into RBCs and the outward leakage of potassium are not effectively mitigated by the  $Na^{+}$ - $K^{+}$ -ATPase during refrigerated storage, and slow potassium leakage is ongoing. The leakage of potassium is further increased by irradiation. Increased potassium content in the plasma or suspending solution of stored red cells units (RBCs) presents a potential hazard to neonates and others receiving high-volume central infusions of RBC products.<sup>14</sup> Citrate in plasma increases potassium toxicity, while reducing RBC supernatant volume results in less potassium leakage before the new equilibrium is reached. Studies performed over 30 years ago indicate that the restoration of potassium after transfusion is slow and can take more than six days.<sup>14</sup> More recent studies in cells with better ATP concentrations show much faster restoration.

Although the macromolecules of the RBC membrane are produced during early erythroid stages prior to enucleation, some of the components of the membrane are metabolically quite active in mature erythrocytes. For example, cholesterol in the membrane exchanges readily with cholesterol in the plasma, phosphatidylinositol undergoes active phosphorylation, and some proteins are phosphorylated by protein kinases and dephosphorylated by phosphatases. These reactions may influence the functional status of membrane components, but their importance is not yet fully understood. Similarly, the fatty acyl composition of the membrane of freshly drawn red blood cells closely mirrors that of plasma and it varies as a function of diet. Diets high in fish oil will for example result in red blood cell membrane lipid enrichment in omega-3 fatty acids, which in turn affects membrane fluidity, mechanical properties, and post-transfusion recoveries upon storage.<sup>76</sup> While red cells are incapable of

synthesizing long chain fatty acids through the elongation of palmitate (the most abundant fatty acid in eukaryotic cells), the degree of fatty acid unsaturation can be affected by the activity of fatty acid desaturases, which have been identified and are active in red blood cells as a function of NADH/NAD<sup>+</sup> ratios and oxidant stress.<sup>77</sup> The degree of unsaturation of fatty acids in the red cell membranes also promotes membrane lipid oxidation since double bonds are more easily attacked by reactive oxygen species. Indeed, as refrigerated storage time increases, lipid peroxidation products accumulate as markers of storage lesions and a predictor of post-transfusion recoveries in humans and rodent models of blood transfusion.<sup>78</sup> Elegant genetic studies in mice have revealed a role for iron metabolism by the membrane ferroreductase STEAP3 (also known as tumor suppressor-activated pathway 6—as this protein is transcriptionally regulated by tumor suppressor protein p53) in the regulation of lipid peroxidation processes.<sup>79</sup> Of note, in nucleated cells p53 plays a central role in ferroptosis, i.e., iron-induced nonapoptotic cell death.<sup>80</sup> The red blood cell enzyme glutathione peroxidase 4 (GPX4) antagonizes ferroptosis by consuming glutathione to repair oxidized lipids. The role of GPX4 in blood storage, ferroptosis, and post-transfusion recoveries of stored red blood cells has not yet been investigated.

To recycle oxidized lipids, red blood cells also leverage a dedicated pathway that is known as the Lands cycle.<sup>81</sup> This pathway is regulated by hypoxia (e.g., pathologically, in sickle cell disease), and it relies on the activity of phospholipase A2 enzymes (to release the oxidized fatty acyl-moiety from the complex lipid) and lysophosphatidylcholine acyltransferase 1 (LPCAT1), which transfers a new fatty acid to the lysophospholipid to replace the missing fatty acyl group. Of note, in response to oxidant stress enzymes such as peroxiredoxin 6 migrate to the membrane and catalyze phospholipase A2-like activities.<sup>82</sup> The intermediate steps of this pathway also involve the transferring and conjugation of the damaged fatty acyl-moiety to carnitines, making carnitine a limiting factor in membrane lipid remodeling and a potential adjuvant to preserve membrane lipid homeostasis in stored units.<sup>83</sup> Alterations in carnitine levels and acyl-carnitines have been observed in stored red cells as a function of genetic defects and osmolarity of the storage additive, as well as the sex of the donor (higher in females).<sup>84</sup>

### **Eryptosis-programmed cell death in red cells**

While RBCs lack the nucleus and mitochondria that are required for apoptosis in most cell populations, they undergo a unique form of programmed cell death called eryptosis associated with low pH, increased cell calcium, or energy loss with low ATP concentrations.<sup>86</sup> The process is marked by irreversible shape change, loss of membrane by microvesiculation, and exposure of negatively charged phospholipids on their cell surface. Oxidative damage appears to play an important role. Alterations in membrane lipid homeostasis (including fatty acid unsaturation and conjugation to carnitines) have been observed in red cells in response to several proeryptotic stimuli.<sup>87</sup> Presumably eryptosis marks RBCs at the end of their normal lifespan for removal from the vascular system by splenic or other macrophages.<sup>88</sup>

Eryptosis is critically limiting in RBC storage because falling pH and ATP concentrations are a concomitant of closed system storage with the accumulation of acid breakdown products of glycolysis leading to acidic inhibition of glycolysis.<sup>89</sup> The accumulation of hemoglobin-containing microvesicles in the supernatant appears to be good marker of the process, as is increasing RBC calcium content with activation of calpain enzymes, but shape change and the appearance of microerythrocytes are now easily measured.<sup>5</sup>

### **Summary**

In the circulation, red cells metabolize glucose through the glycolytic pathway with its pentose and 2,3-DPG shunts. The energy gained provides ATP to maintain ion and glucose concentration gradients between the plasma and erythrocyte, and to support red cell deformability. It also secures NADH to keep hemoglobin in the reduced state and NADPH to protect SH-groups on hemoglobin and membrane proteins. Finally, the production of 2,3-DPG is important for the optimal dissociation of oxygen from hemoglobin while the rise and fall of nonhemoglobin-bound 2,3-DPG with each pass through the circulatory system induces repetitive changes in the membrane–cytoskeleton architecture, which has implications for red cell flexibility and gas transport.

### **Red cell preservation in transfusion medicine**

#### **General considerations and principles**

RBCs are the most commonly transfused blood components, and their use in a variety of physical circumstances and clinical conditions has shaped their development as products. As an example, the US military's need to reduce the weight and breakage of blood bottles during shipment led to the development and adoption of plastic blood bags.<sup>90</sup> This led to closed-system sterile component production and, fortuitously, exposing RBCs to the plasticizer diethylhexyl phthalate (DEHP), which reduced hemolysis four-fold during storage.<sup>91</sup> Arguments over the removal of plasma between blood bankers, who wanted to use plasma to make albumin and coagulation factors, and surgeons, who wanted to increase blood flow during rapid transfusions in trauma patients, led to the development of additive solutions.<sup>92</sup> Again, there were beneficial unforeseen consequences, as the removal of plasma led to better RBC storage and reduced transfusion reactions.

These examples of improved RBC storage methods notwithstanding, the development and adoption of new RBC storage technologies has been slow and limited.<sup>93</sup> There are two main reasons for this. First, the US Food and Drug Administration (FDA) recognizes that four million patients a year receive RBCs and that the product must achieve very high levels of safety.<sup>94</sup> Further modifications require a favorable risk:benefit ratio to pass regulatory review. For example, the idea of adding antibiotics to RBC units has been abandoned since the potential gain, preventing bacterial contamination that kills approximately two patients a year in the United States, would come at the risk of exposing millions to allergenic and toxic drugs with the probability of greater harm than good. Second, within the industry, there is limited perception of the need for change, limited investment in change, lack of understanding of the red cell storage lesions, poor developmental strategies, and conservative regulatory stances.<sup>95</sup> For these reasons, only five major improvements have occurred in the last 60 years: (1) the addition of phosphate, (2) the use of plastic bags, (3) the addition of adenine, (4) the development of additive solutions, and (5) the use of leukoreduction, which reduces hemolysis. The most significant ongoing efforts to further improve RBC products for transfusion, including the development of advanced additive solutions and pathogen reduction methods, have likewise made slow progress for similar reasons.

For 60 years, it has been a societal goal that RBCs for transfusion should be available, safe, effective, and cheap.<sup>37</sup> Making red cells readily available requires both the ability to take liquid units out of the refrigerator and administer them immediately to critically ill or injured patients and the ability to find rare units in frozen national or international inventories. Storage systems contribute to blood

safety by isolating individual units in closed systems and reducing product breakdown and bacterial growth through cold storage. A major goal of storage systems is to maintain effectiveness by preserving the lifespan and function of fresh red cells to the greatest extent possible. Keeping blood cheap requires controlling per-unit costs and not increasing health risks that will make new demands on other parts of the system. At the present time, the unit costs of RBCs remain low, and controlling those costs has been an additional factor in limiting progress on storage systems.

### A short history of RBC storage systems

Rous and Turner developed the first red cell storage solution in 1916, a simple mixture of citrate and glucose.<sup>96</sup> It was initially used to store rabbit red cells for heterophil agglutination testing for syphilis, but when the cells appeared to be intact four weeks later, they were reinfused back into the donor rabbits raising the hematocrit without increasing the reticulocyte count or bile in the urine suggesting that the reinfused cells were circulating.<sup>97</sup> A year later, Rous's postdoctoral fellow, Oswald H. Robertson, used this Rous-Turner solution to build the first successful blood bank in the Harvard Medical Unit attached to the British Expeditionary Force in France.<sup>98</sup>

The major problem with the Rous-Turner solution was that it could not be heat sterilized, as the sugar caramelized, so there was a risk of bacterial contamination from the open mixing of the ingredients and adding the solution to the bottles. In 1943, Loutit and Mollison solved this problem by lowering the pH of the solution to 5.0 to make acid citrate dextrose (ACD) solution.<sup>99</sup> ACD solution could be autoclaved in sterile vacuum bottles and was used as the standard blood collecting solution in the United States and Britain for many years. It was first intended to be used in a 1:4 ratio with collected whole blood; later the formulation was concentrated to be used at a 1:7 ratio, to reduce the dilution of the blood, and this remains the standard today.

In exploring why red cells seemed to survive better in the lower volume ratio of the anticoagulant-nutrient solution, it became clear that the cells passively lose phosphate. This loss could be prevented by adding phosphate to the solution.<sup>100</sup> Citrate phosphate dextrose (CPD) in a 1:7 volume ratio, 63 mL for 450 mL of whole blood, improved red cell survival during storage slightly better than did the older ACD.<sup>101</sup> CPD became the standard anticoagulant in the United States, while ACD persisted in Europe, and both were used for 21-day storage with recovery of 70–80% of the RBC 24 hours after reinfusion of the stored cells back into their original donor.

At about the same time, Gabrio and her colleagues recognized that nucleotides were important for red cell metabolism, but almost a decade passed before researchers determined that adenine was the critical intermediate.<sup>102,103,104</sup> In 1968, Shields formulated a mixture of CPD and adenine, CPDA-1, and showed that it markedly improved whole blood storage.<sup>105</sup> During the subsequent 11 years in which the FDA debated the safety of adenine, plastic bags revolutionized blood banking, allowing blood components to readily be separated from one another. Unfortunately, the excellent CPDA-1 whole blood storage solution turned out to work less well added to "packed" RBCs that were separated from whole blood.<sup>106</sup> Beutler and West showed that the higher the hematocrit of RBCs in concentrates, the lower the red cell ATP concentrations and the *in vivo* recovery.<sup>107</sup> The obvious answer was to add back more volume and nutrients in the form of an "additive solution," but the initial attempt to do this with a solution of bicarbonate, adenine, glucose, and phosphate (BAGP) did not work.<sup>108</sup> CPDA-1 was finally licensed as a five-week storage solution in 1979, but only

after Hogman had developed a simple additive solution of saline, adenine, and glucose (SAG) that also worked for five-week storage but without the adverse effects associated with the high pH.<sup>109</sup> SAG went on to immediate use in Sweden.

The use of SAG was associated with 1% hemolysis by the end of five-week storage, leading to the subsequent inclusion of mannitol (SAG-M) as a "membrane stabilizer."<sup>110</sup> This change reduced hemolysis by more than 50%. Drawing whole blood into CPD, making component products, and then storing the RBC concentrate with an additional 100 mL of SAG-M (CPD/SAG-M) remains the standard RBC storage system in Europe and Canada. Minimal variants of this basic solution, additive solution-1 (AS-1) and additive solution-5 (AS-5), are widely used in the United States. A somewhat different additive solution variant using citrate and phosphate in the place of mannitol (AS-3 or SAG-CP) is also in use. Despite differences in formulation, all these "first-generation" additive solutions appear to be equivalent and provide about 82% recovery with about 0.4% hemolysis after six weeks of storage.<sup>111</sup>

The most important limits of the first generation of additive solutions are the loss of membrane with resulting loss of deformability and viability that occur with prolonged storage. The progressive loss of 2,3-DPG may also be important in some situations, although its clinical impact is not well understood. More advanced additive solutions have been developed and licensed but are not yet routinely available.<sup>99</sup> They work by providing phosphate and buffering capacity, and can effectively maintain the viability of red cells over 7–8 weeks of storage. They are considered to be attractive more for their ability to improve recovery, reduce membrane loss, and improve 2,3-DGP and/or ATP concentrations for all stored RBCs than for their ability to extend the storage period.

### Collection and separation procedures

The volume of whole blood removed for storage, processing, and transfusion was historically 450 mL, a pint, in Western countries. For some newer collection systems, this amount has been increased to 500 mL, a half-liter, to increase the collection with each donation and to offset the losses associated with filtration leukoreduction. Products derived from both collection volumes, whether leukoreduced or not, are considered "one unit." The interdonor differences in hematocrit and platelet count are sufficiently great so that the yields of red cells, platelets, and plasma in components prepared from units of either whole blood collection volume show considerable overlap. Some have argued for a more standard definition of a unit, perhaps based on grams of hemoglobin, but it would make blood collection more difficult and wasteful.<sup>112</sup>

As noted, the volume of anticoagulant-nutrient solution is normally 1/7th the volume of the collected blood, 63 mL for a 450 mL whole blood collection and 71 mL for 500 mL. This volume ratio has been a standard for more than 50 years and has been used with the anticoagulant-nutrient solutions ACD-A, CPD, and CPDA-1. There was long a question of whether the first few drops of blood to enter the collection system are injured by their sudden immersion in the acid anticoagulant, but the red cells seem to tolerate this process with minimal hemolysis or loss of viability.<sup>113,114</sup> At the end of collection, venous blood with a pH of about 7.35 has been mixed with anticoagulant-nutrient solution with a pH of 5.0–5.6 with a resulting pH about 7.05 in the mixture. The low pH of anticoagulants is tolerated because of the high buffering capacity of the hemoglobin molecule which limits the effects of the acidic primary collection solution.

Whole blood in the anticoagulant-nutrient solutions CPD and CPDA-1 are licensed for storage for three or five weeks, respectively,

and there is renewed interest in their use for trauma patients. Increased storage as whole blood competes with making components which serve more patients and improve aspects of the storage of the individual blood elements. For example, red cells are best stored cold, platelets for prophylactic use in oncology patients at room temperature, and plasma as a frozen product. Removing the white blood cells (WBCs) also improves RBC storage by removing a cell population with high energy requirements and potential for damaging red cells by released enzymes.<sup>115</sup>

Schemes for separating whole blood into components are based on centrifugation. The standard “platelet-rich plasma” method used in the United States involves performing a low-speed “soft” spin to sediment the red cells against the pole of the bag opposite the connections to the satellite bags and then squeezing off the supernatant platelet-rich plasma from the top of the bag into the first satellite bag. Thus, typically, 500 mL of whole blood with a hematocrit (Hct) of 42%, consisting of 210 mL of red cells and 290 mL of plasma, is collected into 70 mL of anticoagulant–nutrient solution increasing the volume in the bag to 570 mL and reducing the Hct to 36%. Removing most of the supernatant plasma will increase the Hct in the remaining packed RBC component to 80–90%, consisting of the original 210 mL of red cells and the remaining 22–45 mL of plasma/anticoagulant–nutrient solution mixture. Of the original 290 mL of plasma and 70 mL of anticoagulant–nutrient solution, about 90% is removed in this initial separation process.

In Europe, an initial hard spin is generally preferred in order to harvest buffy coat for the production of platelets and increase the volume of the separated plasma. As noted above, the red cells do better if most of the plasma volume and anticoagulant–nutrient solution are replaced.

Separation of whole blood into plasma and RBCs by using a hollow-fiber filtration system has been described.<sup>116</sup> Red cell parameters were similar to those obtained when routine centrifugation methods were used, and the filters do not cause hemolysis. Levels of plasma Factor VIII and Factor XI were slightly reduced with this prototype; however, there was no evidence of activation of the coagulation or complement systems, and filters that do not interact with coagulation factors can be made.

### Anticoagulant–nutrient solutions

Anticoagulant–nutrient solutions were developed sequentially from ACD to CPD to CPDA-1. This path is the result of the discovery of the critical nutrients required by RBCs during prolonged storage: dextrose, phosphate, and adenine. The recognition that RBC concentrates occasionally ran out of glucose led to the development of CP2D, with twice the amount of glucose in CPD, and a never-licensed CPDA-2 with a third more glucose than CPDA-1.<sup>117,118</sup> The molar contents of the four licensed additive–nutrient solutions are shown in Table 14.1. Note that all of the anticoagulant–nutrient solutions are acidic, reducing the pH of the stored blood below 7.2 and leading to a burst of ATP production at the expense of the rapid depletion of 2,3-DPG as large amounts of 3-phosphoglycerate enter the glycolytic pathway.

The amounts of the nutrients in the additive solutions are critical depending on the intended storage times. There is enough glucose in whole blood to keep the red cells healthy for four days. Whole blood, stored in citrate alone for up to four days, was considered the safest form of storage before autoclavable solutions containing sugar were developed. The high glucose content of CP2D was necessary because it was first used with an additive solution that did not contain sufficient glucose, adenine–saline. Phosphate exists at

**Table 14.1** Compositions and Properties of Some of the Common Acid Citrate Preservative Solutions

	ACD-A	ACD-B	CPD	CPDA-1	CP2D
Citric Acid	35	21	14	14	14
Sodium Citrate	97	58	116	117	117
Dextrose	136	81	141	142	284
Monosodium phosphate			15.8	16	16
Adenine				2	
pH	5.0		5.6	5.6	5.6
Volume ratio used (mL anticoagulant:mL blood)	1:7	1:4	1:7	1:7	1:7

ACD is acid–citrate–dextrose and has two formulations (A and B); CPD is citrate–phosphate–dextrose; CPDA-1 is citrate–phosphate–dextrose, and adenine; a CPDA-2 was developed but never licensed. CP2D is CPD with double-dose dextrose. All concentrations are in mmoles/L.

1–1.3 mmol/L in plasma, but needs to be present at higher concentrations in the nutrient solutions to prevent diffusive loss of RBC phosphate, resulting from 2,3-DPG breakdown, which would otherwise leave red cells down its concentration gradient. Adenine is only needed for storage beyond three weeks and is an ingredient of all the additive solutions.

In emergencies in remote locations, it may be necessary to collect fresh whole blood before new supplies of fully tested components are available. Under these circumstances, drawing whole blood into the primary collection bag containing the anticoagulant–nutrient solution and holding the whole blood at room temperature for up to 24 hours is associated with good short-term preservation of function of the blood components.<sup>119</sup> The national blood services of Finland and Israel collect all of their whole blood on one day and process it on the next, holding it at 20 °C overnight in the anticoagulant–nutrient solution before separating it into components.<sup>120,121</sup> The Council of Europe Committee of Experts on Quality Assurance in Blood Transfusion Services has since 2005 advised that whole blood rapidly cooled after collection to 20–24 °C can be kept at this temperature up to 24 hours after collection before separation into red blood cells, platelets, and plasma.<sup>122</sup> A large international study has examined the metabolic trade-offs involved in the warm overnight hold of whole blood before processing.<sup>123</sup> The warm hold did reduce the initial storage pH and lead to a burst of ATP synthesis, but the differences are lost among larger individual donor differences by six weeks.

### Additive solutions

The first widely used additive solution, SAG, represented an attempt to replace the volume and sugar lost with plasma removal and add the adenine necessary for storage beyond three weeks.<sup>54</sup> It was made with normal saline supplemented with 4.5% weight/volume glucose and 2 mmol/L of adenine. Stored RBCs had good viability for five weeks, but nonetheless demonstrated 1% hemolysis. In screening a number of compounds for additives that would reduce the hemolysis, mannitol was identified as a compound that both reduced hemolysis and had an excellent safety record with IV infusion. The addition of 30 mmolar mannitol reduced hemolysis and increased the osmolarity of the solution further.<sup>55</sup> The solutions are made acidic to a pH of about 5.6 with hydrochloric acid to allow the glucose to be heat sterilized, but since the solutions have essentially no buffer capacity they do not make the RBC concentrates much more acidic than they were when separated from plasma. SAG-M and its close relatives, AS-1 and AS-5, are the most widely used additive solutions.

Other widely used first-generation additive solution systems include CP2D/AS-3 in the United States and CPD/MAP (mannitol, adenine, and phosphate) in Japan.<sup>124</sup> Table 14.2 provides a comparison of the ingredients and concentrations of the more common of these first-generation additive solutions. AS-3 is the only licensed mannitol-free additive solution. While the absence of mannitol was initially considered an advantage for transfusion of infants, studies of AS-1 in premature infant have shown it to be quite safe.<sup>125,126</sup>

Second-generation additive solutions started with attempts to rebalance the final suspending solution and to identify additional nutrients for the packed RBC concentrates. BAGP was the result of the original attempt by Beutler to preserve both ATP and 2,3-DPG by raising the pH.<sup>52</sup> However, raising the pH substantially above 7.2 led to high concentrations of 2,3-DPG at the expense of ATP and no improvement in storage function. The composition of a representative group of second-generation additive solutions is shown in Table 14.3.

As alluded to several times in this chapter, the pH of RBCs during storage is very important. Above pH 7.2, the bifunctional enzyme diphosphoglycerate mutase/phosphatase converts almost all 1,3-DPG into 2,3-DPG, depriving the cell of new ATP<sup>27</sup>. Below a pH of about 6.4, the activities of the initial enzymes of glycolysis, hexosekinase and phosphofructokinase, are too low to support ATP production. In this narrow pH range between 7.2 and 6.4, hemoglobin, the mineral salts in the suspension, and bicarbonate all serve to buffer the protons produced by glycolysis. Approximately 60 g of hemoglobin present in an RBC unit can buffer about 8 mEq of protons in that pH range.<sup>127</sup> However, conventional first-generation acidic additive solutions, which result

in an initial pH of 7.0, fail to take advantage of a quarter of that available pH range and buffer capacity. Adding 20 mmol/L of phosphate delivers 2 mmol in the 100 mL of additive solution and buffers about 1 mmol of additional protons. Adding 20 mmol/L of bicarbonate likewise delivers 2 mmol to the final RBC suspension which will be protonated to make carbonic acid, converted to CO<sub>2</sub> and water by red cell carbonic anhydrase, and buffer 2 mmol of protons as the CO<sub>2</sub> diffuses out of the plastic bag. These results demonstrate that adjusting the formulation and pH balance in the design of second-generation RBC additive solutions can almost double the amount of ATP energy available to stored red cells by depressing diphosphoglycerate mutase activity while sustaining glycolysis.

Of note, the storage of red blood cells under hypoxic and hypocapnic conditions provides similar benefits with respect to increased diphosphoglycerate mutase activity. Indeed, concomitant removal of oxygen and CO<sub>2</sub> promotes the alkalinization of the intracellular compartment through a series of compensatory events involving the activity of band 3 (exchanging chloride for bicarbonate), carbonic anhydrase (converting bicarbonate to CO<sub>2</sub>), CO<sub>2</sub> diffusion from the gas permeable plastic bag, and increased intracellular levels of hydroxide anions to achieve Donnan equilibrium. Hypoxic storage in the presence of 5% CO<sub>2</sub> still preserves the increase in glycolytic fluxes and ATP synthesis with no net benefit on the capacity to synthesize 2,3-DPG compared to conventional storage.<sup>128</sup> By decreasing the availability of O<sub>2</sub>, a substrate for Fenton chemistry, hypoxic storage mitigates the storage-induced oxidant lesion to metabolites and proteins, ultimately resulting in relative improvements in post-transfusion recoveries compared to paired normoxic counterparts in autologous transfusion studies using first-generation additive solutions.<sup>129</sup> Second-generation additive solutions achieve similar results with less disruption of blood bank processes.

Despite extensive efforts, finding additional nutrients critical to RBC viability during storage has been less successful. The only approved second-generation additive solutions are PAGGS-mannitol (phosphate, adenine, glucose, guanosine, and saline) and AS-7.<sup>130</sup> Guanosine was added because guanosine tri-phosphate was detected in red cells and known to decrease during storage. The solution worked only modestly better than first-generation additive solutions with a 74.6% 24-hour *in vivo* recovery after seven weeks in 10 units in the only published series. Experimental additive solutions with guanosine appear to improve DPG concentrations and reduce oxidative injury.<sup>131</sup>

**Table 14.2** Compositions of the Common Licensed First-Generation RBC Additive Solutions

	SAG	SAG-M	AS-1	AS-3	AS-5
NaCl	150	150	154	70	154
Phosphate				23

pH of RBC suspension		6.9	6.9	7.2	7.3	7.2
Volume	100	110	110	114	150	110

BAGPM is bicarbonate–adenine–glucose–phosphate–mannitol, the original additive solution developed by Beutler; PAGGS-M, which is phosphate–adenine–glucose–guanosine–saline–mannitol, is licensed in Germany; PAGGG-M is phosphate–adenine–glucose–guanosine–(sodium) gluconate–mannitol, and was developed by de Korte as a chloride-free variant of PAGGS-M; ErythroSol-1 and -2 were developed by Hogman; and AS-7 was developed by Hess and Greenwalt. All concentrations are in mmoles/L.

As ingredients were added to advanced additive solutions, the salt concentration was generally reduced to maintain osmotic balance. Reducing the chloride concentration in the suspending solutions caused intracellular chloride to passively leave the red cells, but this can only occur if other anions countered the flow, and phosphate, bicarbonate, and hydroxyl ions are the only available anions.<sup>132</sup> The influx of these anions initially increases the intracellular pH, but eventually the pH falls. PAGGG-M, in which the sodium chloride is replaced by sodium gluconate, is an example of an attempt to take advantage of the “chloride shift” phenomenon to maintain red cell 2,3-DPG.<sup>133</sup>

The ErythroSol solutions were developed based on the ideas of using the “chloride shift” to increase the intracellular pH while using a more alkaline final suspending solution and additional phosphate to simultaneously maintain ATP.<sup>134</sup> ErythroSol-1 used half-strength citrate (0.5CPD) and had problems with incomplete anticoagulation in blood collected from donors with low (but acceptable) hematocrit levels. ErythroSol-2 used full strength CPD and an alkaline additive solution made with disodium phosphate. In both systems, the glucose was placed in a separate bag from the rest of the additive solution during manufacture and sterilization and only added at the time of RBC component production. The original description of ErythroSol-2 suggested that the optimal pH had been determined to preserve both ATP and 2,3-DPG.<sup>135</sup> However, subsequent work and evaluation of ErythroSol-4 as part of an international trial showed no differences in ATP and DPG content or hemolysis between it and SAG-M or PAGGG-M.<sup>68</sup>

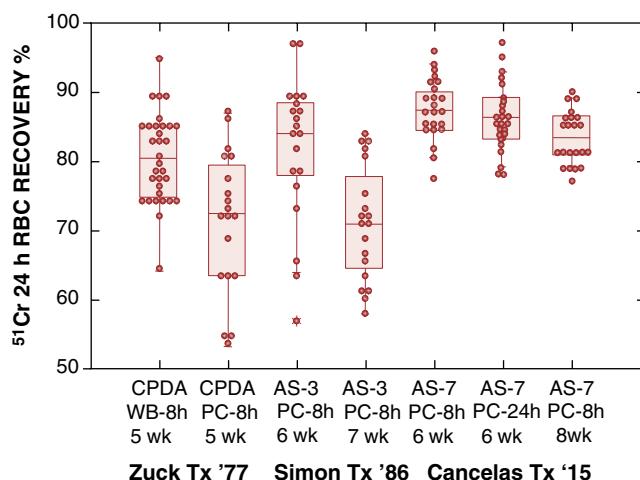

Experimental additive solution-81 (EAS-81) has now been licensed in the United States and Europe as AS-7.<sup>136</sup> It was the end result of work that re-examined the use of bicarbonate as a buffer to prevent erythro-apoptosis by maintaining high concentrations of red cell ATP and limited hemolysis with mannitol and hypotonic conditions.<sup>137</sup> Formulating the solutions to achieve a starting pH as close as possible to 7.2 preserved the 2,3-DPG concentrations for two weeks.<sup>138</sup> The buffering provided by the bicarbonate allowed RBC storage for eight weeks and storage with recoveries of 88% at six weeks based on a study involving 54 recovery measurements (Figure 14.5).<sup>139</sup> Metabolic studies have been recently performed to compare the performances of the above-mentioned alkaline storage additives. Results suggest significant improvements over conventional additives.<sup>140</sup>

Finally, increasing the volume of these advanced additive solutions increases the buffering capacity and allows greater storage time. With 300 mL additive solutions, Hess and his colleagues were able to achieve storage times of 10–12 weeks, but the higher volume and lower storage hematocrit probably make such solutions inappropriate for clinical use, especially in infants and massively transfused trauma patients with the potential to result in transfusion-associated circulatory overload (TACO) and dilutional coagulopathy.<sup>141</sup>

### Additional factors influencing RBC quality

#### *Temperature and time lapse during collection and component preparation*

Whole blood is collected at body temperature and must be maintained at room temperature if platelets are to be prepared from the collection. By present US regulations, whole blood must be separated into its components in eight hours if platelets and fresh-frozen plasma are to be manufactured. If only RBC and frozen plasma are to be made, the whole blood can be held on ice for up to 24 hours. The problems with holding blood at room temperature are two-fold.

**Figure 14.5** Chromium-51 autologous *in vivo* RBC recovery measures for RBCs stored in successive generations of storage systems. CPDA-1 shows the decrease in mean recovery from whole blood stored at a hematocrit of 38% to packed cells with a hematocrit of 80%. AS-3 is a representative first-generation additive solution showing 84% mean recovery at six weeks but failure at seven weeks. Bicarbonate buffered AS-7 allows better storage, storage for eight weeks, and storage after warm overnight hold. See Refs.<sup>53, 64, 80, 81</sup>.

Red cells metabolize glucose at higher rates when warm producing more lactate and protons that reduce the pH and further slow metabolism.<sup>70</sup> In addition, labile coagulation factors are lost. Attempts to validate the 24-hour warm hold for six-week RBC storage using first-generation additive solutions have not been successful, but in Israel and Finland, where this system is used, RBCs are stored for only five weeks because of the efficiency of their national blood services and short supply lines.<sup>142</sup> AS-7 is now licensed in Europe for eight-week storage after an overnight.

As noted above, fresh whole blood is occasionally collected in emergencies on the battlefield or in isolated locations such as Pacific Island nations and stored at room temperature for short periods. Based on the above experience and experimental data, blood probably maintains reasonable functionality for 24–72 hours if maintained between 19 and 25 °C.<sup>66</sup> However, such use can only be recommended in the most dire situations.

#### *Temperature and time lapse during storage*

RBCs that have been allowed to rewarm to greater than 10 °C during storage are considered unfit for transfusion and are destroyed according to FDA regulation. This has led to the wide use of a “30-minute rule,” which dictates that units are discarded if they have been outside of monitored refrigerated storage for more than 30 minutes. Experimental work has shown that glucose is metabolized about 10 times faster at 25 °C than at 4 °C, and that RBCs stored at 25 °C lose viability 10 times as fast. These changes can be extrapolated to suggest that a day of storage at room temperature would reduce the *in vivo* recovery to about the same extent as 10 days of 4 °C storage.<sup>143,144,145</sup> Thus, FDA regulations are very conservative with regard to temperature but are also intended to prevent bacterial overgrowth in contaminated units.

#### *Storage containers*

Polyvinyl chloride (PVC) bags plasticized with DEHP are the standard RBC storage containers. The presence of the DEHP reduces

hemolysis by four-fold during storage by intercalating into the red cell membrane.<sup>146</sup> Other plasticizers, such as butyryl-*n*-triethyl citrate, work almost as well, but are more expensive (~5% more for a multibag set with leukocyte filter), and have an unusual smell when initially unwrapped.

While questions about the safety of DEHP have been raised, they are based on very limited animal testing and must be balanced against the obvious safety value of being able to visually inspect the contents of blood bags through the clear plastic and the reduced RBC losses by extending shelf life. The trend in Europe to avoid the slowly degradable plasticizer, DEHP, has resulted in the introduction of butyryl-*n*-triethyl citrate plasticized multibag systems in Sweden, Spain, and Norway, but the use of PVC bags with DEHP remains prevalent in Europe and almost universal in the rest of the world. Other plasticizers are being explored.

### **Leukocyte reduction**

Leukocyte reduction improves RBC storage by removing highly metabolically active WBCs that make the bag more acidic sooner. WBCs also secrete cytokines, and when they die after exposure to the cold, they release proteolytic, glycolytic, and lipolytic enzymes that damage the red cell surface. On the other hand, some red cells are damaged and many red cells are lost in the leukocyte reduction filters (typically 15–35 mL of blood is lost in the filters depending on their size and whether whole blood or concentrated red cells are being filtered). Red cells from donors with sickle cell trait may also clog filters or hemolyze in them. Leukocyte reduction improves the red cell 24-hour *in vivo* recovery by several percent according to the best estimates.<sup>60</sup>

### **Washing**

Washing RBCs in saline to remove the plasma causes small losses of red cells in the bag transfers as well as loss of the supporting nutrients, glucose, phosphate and adenine. Because the cells are used soon after washing, generally within 6–24 hours, only the glucose loss is physiologically important. There is still a small amount of glucose inside the washed RBC, but it is metabolized quickly especially if they are not promptly refrigerated. In the absence of glucose, metabolism stops and the cells are very susceptible to oxidative stress and erythro-apoptotic changes. On the other hand, washing and resuspension in fresh media results in the removal of inhibitory factors of glycolysis (e.g., lactic acid) from the supernatant, promoting measurable improvement in red cell metabolism of stored cells.<sup>147</sup>

### **Irradiation**

During storage at 4 °C, red cells lose potassium. This potassium collects in the supernatant fluid in the closed storage bag at a rate of about one mEq/day until equilibrium is reached between the intra- and extracellular concentrations, usually at about 60–70 mEq/L depending on the storage hematocrit (Table 14.4). Gamma irradiation in doses of 2500 cGy, given to prevent graft vs. host disease, damages the red cell membranes and increases this rate of potassium loss to approximately 1.5 mEq/day. Irradiated red cells also show mildly reduced *in vivo* recovery.<sup>148</sup> The current FDA regulation that irradiated RBCs expire 28 days after irradiation limits the potential maximum potassium concentration by limiting the period of potassium loss. Nevertheless, care must be taken in all situations when large volumes of older, high potassium RBCs are used to prime cardiopulmonary bypass, dialysis, or apheresis circuits or infused into the central circulation and then administered at high flow rates.

**Table 14.4** Effect of Storage Duration of Characteristics of RBC Concentrates in AS-1

	<b>35-day</b> (n=25)	<b>42-day</b> (n=10)	<b>49-day</b> (n=10)	<b>56-day</b> (n=10)
% recovery	86	82	76	71
% hemolysis	0.28	0.32	0.51	0.68
ATP μM/g Hb	3.1	2.7	2.3	2.3
[K+] meq/L in plasma	45	50	52	60

Unpublished data obtained from the US FDA under the Freedom of Information Act.

### **Pathogen reduction**

Current pathogen reduction methods require additional manipulation of red cells and produce stresses on the stored RBC that are system specific. Examples from two such systems are as follows. Diethylenetriamine (DEA) was proposed as a red cell permeable nucleic acid crosslinker with broad pathogen killing potential and minimal direct red cell toxicity. However, the system required exposure of the RBC to DEA for 20 hours at room temperature and extensive secondary washing to reduce the remaining amounts of this carcinogenic chemical. When the time- and temperature-related decrease in RBC pH was added to the effects of washing the RBC with large volumes of acidic solutions and storing them in an acidic additive solution, red cell recovery suffered.<sup>149</sup> Riboflavin, a photoactive oxidizer, has also been proposed as a highly red cell permeable molecule for pathogen reduction in conjunction with UV light. However, RBCs are so optically dense that the units must be diluted and transferred to large bags only a few millimeters thick for phototreatment, and the phototreatment must be performed above a critical temperature. The bag transfers produce losses of red cells, the choice of diluent fluid is important, and the hemoglobin and other optically active molecules in the red cells are also damaged by the light exposure. The red cells need additional energy to attempt to correct the damage, and the reconstituted treated RBCs need to be stored in an additive solution that is balanced to maximize their lifespan. See also Chapter 42.

### **Effectiveness**

Since the discovery of the effect of 2,3-DPG on the oxygen affinity of hemoglobin, it has been common to discuss the functionality of stored RBCs in terms of their 2,3-DPG content.<sup>150</sup> This is an oversimplification for several reasons. First, while it is clear that low 2,3-DPG can affect oxygen delivery in animal models at critically low hemoglobin concentrations, these concentrations are well below standard transfusion triggers and may only be relevant in specialized transfusion situations such as sickle cell patients whose transfusion trigger may be set quite low to avoid alloimmunization.<sup>69</sup> Second, 2,3-DPG works in red cells by binding and stabilizing deoxyhemoglobin. This moves the base of the oxy-hemoglobin dissociation curve to the right and increases the P50, but most oxygen transport occurs at the top of the binding curve which is relatively unaffected, and even in critical situations the arterial PO<sub>2</sub> is higher than the P50. However, 2,3-DPG also plays a role in red cell membrane transport and cytoskeleton architecture because of its interaction with attachment points between the cell membrane and the cytoskeleton, and the interaction of deoxyhemoglobin with band 3. These interactions, the critical importance of oxygen transport, and the retrospective data that suggests an association between adverse patient outcomes and increased storage time of banked RBCs drive continuing efforts to reduce 2,3-DPG depletion during storage.

However, four randomized clinical trials showed no difference in the survival of critically ill patients treated with longer stored RBCs, and a fifth African child with severe malarial anemia showed no difference in the time to correction of lactic acidosis.<sup>151,152</sup>

Probably more important for normal red cell function is the loss of membrane, cell deformability, and ATP secretion that occurs with storage. Direct observation of the flow characteristics of fresh, stored, and stored rejuvenated RBCs suggests that ATP secretion in response to increased shear, by which red cells dilate small vessels to maintain their forward flow, is most important.<sup>153</sup> Membrane deformability, which is regulated by the ATP-modulated cytoskeleton, is also very important for the passage of red cells through capillaries which are half their diameter. Maintaining high ATP concentrations is therefore the critical function of modern additive solutions.

### **Rejuvenation**

Red cell loss of viability during storage is different than red cell senescence in the body. In the body, red cells undergo cumulative oxidative damage that leads to reduced enzyme activities and crosslinking of cytoskeletal components. These are essentially irreversible processes and are ultimately associated with macrophage clearance of old red cells possibly mediated by phosphatidyl serine exposure or neoantigen formation. The changes that lead to loss of viability during storage are largely reversible by a process called “rejuvenation.” Hogman showed that rejuvenating red cells at the end of six weeks of storage in SAG-M increased their 24-hour *in vivo* recovery from 77 to 89%.<sup>154</sup>

This rejuvenation is best understood as metabolic recharging of red cells at the end of their storage period. Such cells have a low pH as well as low ATP and 2,3-DPG concentrations. They can be rejuvenated by incubation in a high pH solution of phosphate, inosine, pyruvate, and adenine (PIPA, Rejuvesol®, Cytosol Labs, Braintree, MA) for two hours. Rejuvenation, through overnight incubation at 37 °C, of end-of-storage red blood cells has been associated with the restoration of energy and redox metabolism—with the caveat that irreversibly damaged erythrocytes that cannot be rejuvenated are removed at the washing step to remove excess hypoxanthine from the rejuvenated units.<sup>155,156</sup> Rejuvenation increases the RBC ATP and 2,3-DPG concentrations and *in vivo* recovery, probably by allowing them to internalize negatively charged membrane phospholipids that would otherwise signal for clearance by macrophages. Return to the normal distribution of phospholipids also prevents red cells from participating in plasma coagulation reactions. However, rejuvenation does not reverse the oxidative damage to band 3 of the cell membrane, desialylation of glycoproteins, or loss of membrane. Nonetheless, the fact that RBCs can be rejuvenated at the end of storage by increasing their pH and ATP suggests that improved storage could be achieved by a method designed to maintain pH and ATP. This was the fundamental idea behind the second-generation additive solutions.

### **Frozen storage of RBCs**

RBCs can be frozen, and in the frozen state they are stable for long periods. Valeri has reported on transfusion of RBCs stored for 37 years.<sup>157</sup> Four methods of freezing RBCs have been extensively tested, two have been developed for practical use, one of which remains in common use.<sup>158</sup>

During red cell freezing, water turns to ice and the salt concentration of the remaining intracellular water increases, drawing in more water, and expanding the cell. Under normal circumstances,

this leads to cell rupture. Rupture can be prevented by freezing the cells so rapidly that water does not have time to enter, or by diluting the total cellular water with a cryoprotectant so that not enough water enters to rupture the cell. While several cryoprotectants can work, glycerol is the standard material used because of its cost and safety.

The two systems for RBC cryopreservation that have been developed for clinical use both use glycerol. One system used a “low” glycerol concentration of about 20% and rapid cooling by plunge freezing in liquid nitrogen; the other uses a “high” glycerol concentration of about 40% and slow cooling in -80 °C freezers. The low glycerol frozen RBCs must be maintained in the vapor phase of liquid nitrogen whereas the high glycerol frozen RBCs are stable at temperatures below -65 °C. Both the high cost of maintaining liquid nitrogen freezers and the difficulty of transporting products frozen in liquid nitrogen limit the utility of the low glycerol system. High glycerol frozen RBCs, in contrast, can be transported on dry ice. When the RBCs are thawed, the glycerol must be removed promptly to prevent it from poisoning the red cell metabolism and to protect the recipient as the glycerol-loaded red cells would swell and rupture if placed directly into the bloodstream. Thus, once thawed, the RBCs must be deglycerolized by washing in a series of osmotically graded salt solutions.

In the past, the glycerolization and deglycerolization of RBCs for freezing were open manual processes, so the thawed RBCs had to be used within 24 hours or discarded. The recent partial automation of a closed system for glycerolizing and deglycerolizing RBCs now allows them to be kept post-thaw in the liquid state for 2–3 weeks. RBCs collected in any of the standard licensed systems can be frozen up to six days after collection and stored for up to 10 years. The deglycerolized RBCs are then stored in AS-3. Net losses of red cells in the freeze-thaw-wash process are of the order of 5–15%, and the 24-hour *in vivo* recovery of infused red cells is about 78% after two weeks.<sup>159</sup> Frozen RBCs entail substantial costs for processing and storage, probably four times that of a standard liquid unit, so only for the rarest blood units is there an advantage for frozen inventory.

Other systems of freezing and freeze-drying have been developed, but are associated with greater than 1% hemolysis and so would require a washing step before administration. This prevents their use in emergency medicine, and they are too costly and labor intensive to compete with glycerol frozen RBCs.<sup>90</sup>

### **Validation of red blood cell quality and *in vivo* recovery**

RBC storage systems have historically been validated by demonstrating that the stored cells do not hemolyze during storage and that they circulate normally after reinfusion. Measures of normal circulation have included increments in recipient hemoglobin, and determining the recovery and *in vivo* half-life of the transfused red cells. Transfused red cells have been counted using differential agglutination, radioactive tracer labeling, and flow-cytometric differential counting.<sup>160</sup>

Chromium-51 labeling has been the standard method used to measure RBC recovery in the United States for 70 years. Only a handful of laboratories perform the measurement, and a recent attempt to gather a decade's experience identified only 900 measurements.<sup>96</sup> Chromium-51 labeling persists in the United States because it is the only validated method compatible with autologous red cell reinfusion, and the infectious disease risks of

allogeneic RBCs are considered unacceptable for storage system development work. The methods of red cell labeling have been the subject of an excellent review.<sup>161</sup> Limitations of this approach have been noted, including (i) that these studies are performed in selected healthy autologous volunteers, and not in nonhealthy, heterologous recipients in which recoveries may be decreased by the inflammatory state of the recipient or other disease processes; (ii) early sequestration of the transfused red cells in the spleen and liver confounds the determination via regression of the baseline values, resulting in the overestimation of circulating cells at 24 hours; and (iii) the washing steps that are required to remove excess radiolabel from the transfused product may result in the lysis of the damaged end of storage red cells, resulting in an overestimate of the actual post-transfusion recovery values. These limitations and others (e.g., predicted shortages in chromium 51 supplies) have been recently reviewed by Hod and colleagues and, at least in part, can be addressed by novel approaches such as biotinylation or the use of Indium 111 or nonradioactive isotopes in place of chromium-51 labeling.

When performing chromium-51 labeling, it is important to recognize that red cells from different donors may have very different 24-hour *in vivo* recovery values. In a typical study of a modern additive solution with an 84% mean recovery, individual units of donor RBCs have recoveries as high as 95% and as low as 65%.<sup>62</sup> These differences in viability correlate with differences in the red cell ATP concentrations but poorly ( $r^2 = .4$ ).

There have been attempts to measure the functionality of red cells, as opposed to their survival. Presumably, the functionality of red cells is related to their ability to deliver oxygen to tissues and to flow in the microcirculation. However, none of these measurements, such as red cells rigidity or microcirculatory flow, is widely available or validated. The level of 2,3-DPG is just a surrogate marker for red cell function and is limited by the difficulty of performing the test. In a recent shared sample exercise, 12 of the world's premier labs could not consistently measure 2,3-DPG.<sup>162</sup> Ongoing efforts are focusing on the physiome, i.e., the comprehensive

characterization of physiological responses in the recipient with respect to tissue perfusion and oxygenation.<sup>163</sup>

Finally, in countries that do not perform chromium-51 recovery measures, there has been a trend to using the ATP concentration as a red cell quality measure. While the ATP is a poor surrogate for recovery in small clinical trials, its central role in the inhibition of erythro-apoptosis probably gives it special importance. Unfortunately, the measure is not very reproducible from laboratory to laboratory, so a wide margin of safety is required.<sup>95</sup>

## Summary

RBC storage systems work remarkably well, making red cells for transfusion available, safe, effective, and cheap for the populations who can organize effective national blood systems. Better RBC storage systems than those currently used exist, and even better ones combining buffering, chloride shift physiology, and the metabolic benefits of guanidine can be made using current understanding while maintaining the look, feel, and ease of use of current storage systems. They are, however, a product of historically slow and empiric development, and our present systems do not reflect our current understanding of the biology and physiology of red cells. We nonetheless hold out hope that this will improve in the future.

### Platelet production

Platelets are essential for normal hemostasis. In adult humans, a normal circulating concentration of  $150\text{--}450 \times 10^6$  platelets per mL is maintained by the production and release of at least 75–100 billion platelets into blood per day.<sup>1</sup> This chapter uses the term “megakaryopoiesis” as synonymous with “thrombopoiesis” to denote the complete pathway of cell production from earliest progenitor to the terminal circulating platelet (Figure 15.1). “Platelet biogenesis” is used as synonymous with “terminal platelet production” and refers to the final physical stages of megakaryopoiesis which result in circulating platelets.

### Early megakaryopoiesis: proliferation and differentiation of megakaryocytes

In mammalian physiology, circulating platelets in the blood are anucleate cells derived from their precursors, megakaryocytes (MKs).<sup>2</sup> Megakaryopoiesis, under homeostatic conditions, is primarily under the control of thrombopoietin (TPO), a growth factor that acts in synergy with other cytokines such as stem cell factor (SCF) and various interleukins to regulate platelet production.<sup>3–5</sup> Megakaryocyte development can generally be considered to proceed in three stages: (a) progenitor proliferation with a DNA content of 2N; (b) megakaryocyte endomitosis; and (c) cytoplasmic maturation of megakaryocytes preceding release of platelets—each of which is detailed in this section.

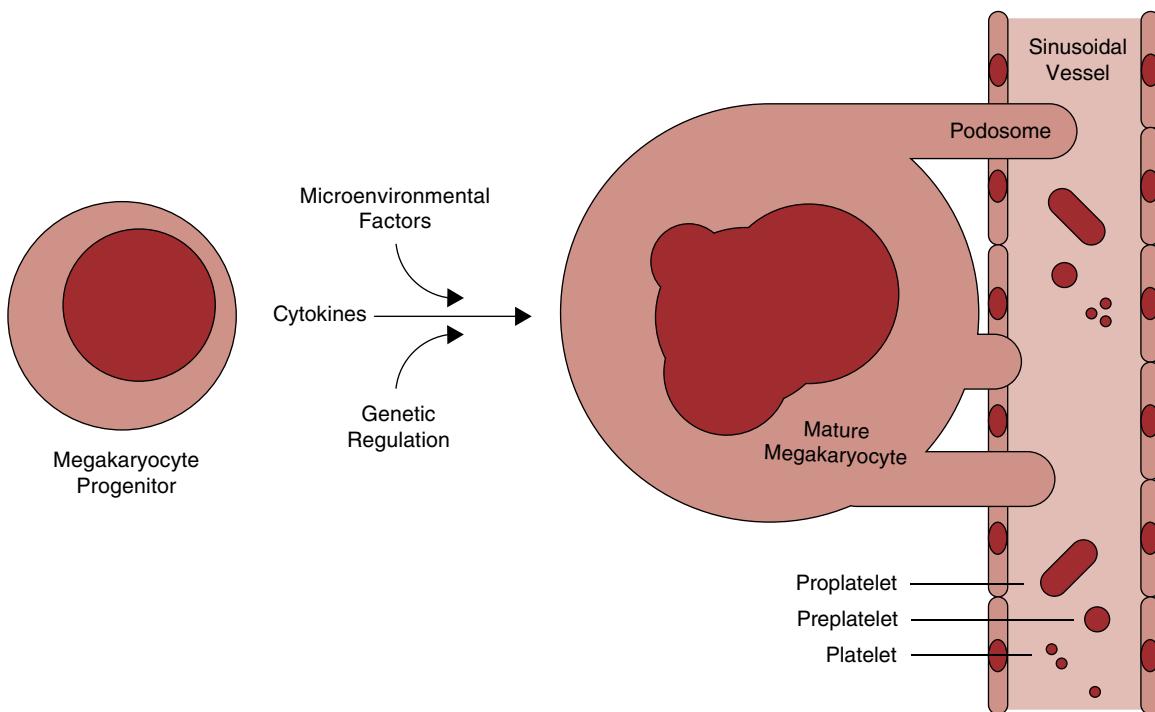

Human hematopoietic development begins in the embryonic stage and occurs in multiple locations including the yolk sac, the aorta-gonad-mesonephros region, and the fetal liver.<sup>6</sup> Bone marrow is the primary site of adult megakaryopoiesis, and terminal platelet production is thought to take place in the periphery.<sup>7</sup> Pulmonary contributions to platelet production have been historically recognized; recent studies have reinforced this concept, providing evidence that the lung-resident MKs contribute to megakaryopoiesis to a more substantial degree and may be responsible for 50% of platelet biogenesis in mice.<sup>7–10</sup> Furthermore, lung MKs and hematopoietic progenitors have the ability to migrate out of the lungs, repopulate marrow, reconstitute circulating platelets, and contribute to multiple hematopoietic lineages.<sup>8</sup> Interestingly, transcriptional and phenotypic profiling have supplied evidence that murine

lung MKs additionally play immunoregulatory roles like those of antigen-presenting cells.<sup>10–12</sup>

The classical model of MK migration within bone marrow has been challenged in recent years with the advent of imaging techniques allowing the spatiotemporal dissection of marrow hematopoietic activity. The earliest megakaryocyte progenitors have canonically been thought to proliferate near the cortical bone, i.e., in the osteoblastic or endosteal niche, where TPO acts in synergy with other cytokines to promote MK evolution from stem cell precursors and subsequent MK proliferation (discussion forthcoming, see the “Control of megakaryopoiesis: thrombopoietin and other cytokines” section).<sup>13</sup> As they mature, these MKs migrate from endosteal regions to perivascular sinusoidal regions.<sup>14</sup>

Recent *in vivo* and *in situ* imaging evidence suggests that the majority of murine marrow MKs are actually relatively sessile residents associated with sinusoids independent of their distance to endosteum.<sup>10,14–17</sup> Abundant vascular distribution seems to dictate this relationship, with the average vessel-to-vessel distance equaling approximately two average megakaryocyte diameters.<sup>14</sup> Furthermore, MKs exhibited a random distribution throughout the marrow space with respect to their maturity.<sup>10,14</sup> As such, endosteal and sinusoidal microenvironments may represent functional niches with considerable spatial overlap as opposed to niches with high spatial distinctness.<sup>14,18</sup> The degree and manner to which endosteal versus sinusoidal niches contribute to hematopoietic stem cell (HSC) derivation of MKs, MK maturation, and overall megakaryopoiesis remain to be definitively determined. Of note, this group’s findings also included a relatively low percentage of MKs observed within the vasculature, an observation potentially inconsistent with MK migration to other organs as a dominant facet of the megakaryopoiesis model.<sup>10,14</sup> Continued study of the spatiotemporal dynamics of megakaryopoiesis, as well as the interaction between marrow and extramedullary megakaryocytic compartments, is likely to offer new and clarifying insights into megakaryopoiesis, therapeutic strategies for thrombocytopenic disorders, and *ex vivo* platelet production.

On the cellular scale, megakaryopoiesis generally follows a hierarchical differentiation scheme with caveats. Canonically, HSCs give rise to a common myeloid progenitor (CMP) cell, followed by

**Figure 15.1** Canonical megakaryopoiesis overview. Megakaryocyte progenitors in the marrow differentiate and mature under the influence of factors including genetic regulatory elements, cytokines, and microenvironmental cues. Maturing megakaryocytes exhibit increased transcription of proteins that will eventually result in expression of platelet membrane components (e.g., GPIIb/IIIa) and platelet granule components (e.g., von Willebrand factor). Alpha and dense granules migrate along with the extension of podosomes and eventually into the tips of these proplatelet processes that form the preplatelet terminal ends. As these terminal ends extend into the sinusoidal vessels, shear causes release of the pro- and preplatelets into the blood circulation; mature terminal platelets are then derived from the preplatelets within the blood.

biphenotypic megakaryocyte–erythroid precursors (MEPs). TPO and other hematopoietic mediators (e.g., erythropoietin, SCF, and IL-11)<sup>19</sup> function synergistically to cause these bipotential precursors to differentiate toward the MK lineage and become promegakaryoblasts.<sup>13</sup> Promegakaryoblasts undergo endomitosis in order to increase their ploidy content (polyploidization)—a process that is probably necessary for normal maturation into MKs in the adult marrow but does not appear to be required for cord blood-derived MKs and platelet production *in utero*.<sup>20</sup>

Two major transcription factors involved in differentiation of the CMP are PU.1, which regulates granulocyte-monocyte precursors, and GATA-binding factor 1 (GATA1), which drives MEP differentiation.<sup>21</sup> The downregulation of PU.1 expression in the CMP is the first event associated with the restriction of precursor differentiation to erythroid and MK lineages.<sup>22</sup> In response to TPO, SCF, and other cytokines, the bipotential MEP can develop into the highly proliferative early MK burst-forming unit (BFU-MK), or the smaller, more mature MK colony-forming unit (CFU-MK), both of which express CD34.<sup>23</sup> GATA1 is thought to have a specific effect on fetal megakaryopoiesis; GATA1 mutations occur in trisomy 21-associated transient myeloproliferative disorder, which generally resolves spontaneously following the newborn period.<sup>24</sup> Furthermore, cell cycle activation or repression has also recently been shown to tune megakaryocytic versus erythroid differentiation of the MEP, with increased cell cycle speed being associated with erythroid differentiation and the inverse associated with megakaryocytic differentiation.<sup>25</sup>

Strict adherence to the canonical hierarchy of differentiation has been brought into question in recent years with the identification of

multipotent but megakaryocyte-biased HCSs and potentially unipotent megakaryocyte progenitors arising directly from the HSC compartment;<sup>7,10,26–32</sup> both postulated pathways would bypass the bipotent MEP defined in the classical megakaryopoiesis model. Self-renewing megakaryocyte-biased HSCs, dependent upon TPO for maintenance, have also been shown to give rise to lymphoid-biased HSCs, suggesting this HSC subset may exist at the apex of the HSC differentiation hierarchy.<sup>27</sup> However, differences between *in vitro* versus *in vivo* megakaryopoiesis, as well as interspecies differences, may influence fate-determination findings; hierarchical stages defined by clonal semisolid culture assays may also lack synonymy with murine-derived stages as defined by surface markers as well as those present in humans.<sup>10,28,32,33</sup>

The endomitotic cell cycle in MKs consists of phases G1, DNA replication in S, and then G2 but an aborted M phase. In the 2N to 4N transition, megakaryocytes fail to complete anaphase B, telophase, and cytokinesis. After the 4N stage, M phase is generally aborted prior to cytokinesis with cells demonstrating multiple pole spindles. MKs then enter a gap phase that enables reentry into the subsequent S-phase, which occurs repeatedly to form multilobulated nuclei that may reach ploidy levels as high as 128N. The mechanism of polyploidization is complex. Cyclin D3 is overexpressed (partly under the influence of TPO) in the G1-phase of maturing cells which helps overcome the normal block to polyploidization.<sup>34</sup> Aurora-B kinase (AIM-1 kinase), which mediates late anaphase and cytokinesis, had been hypothesized to be deficient during MK prophase and early anaphase, but others have found this critical kinase to be normally localized and completely functional in endomitotic MKs.<sup>35</sup> Other pathways mediating polyploidization include

MKL1-induced downregulation of GEF-H1 (discussion forthcoming, see the “Control of megakaryopoiesis: genetic regulation” section), which is critical for late cytokinesis.<sup>36</sup>

As alluded to earlier, 2N MKs can mature and produce platelets. Studies have demonstrated that neonatal MK progenitors are hyperproliferative. Low-ploidy neonatal MKs are generated at a much higher rate than their adult counterparts, likely mediated by upregulated TPO signaling. It is likely that rapid expansion of the fetal/neonatal bone marrow is the impetus for this developmental difference in megakaryopoiesis.<sup>20</sup>

Ploidy classes in MKs are identified as multiples starting with the diploid 2N baseline, i.e., 4N, 8N, etc. The ploidy distribution obtained by flow cytometry in both fractionated and unfractionated normal adult human marrow demonstrates a ploidy value of 16N in 50% of the total MK population, with the remainder of MKs equally split between cells having  $\leq$ 8N ploidy and MKs of ploidy  $\geq$ 32N.<sup>37</sup> Mature MKs eventually give rise to circulating platelets by the acquisition of cytoplasmic structural changes necessary for platelet formation and release into the circulation.<sup>38,39</sup> MKs reach cell sizes of 50–100  $\mu$ m in diameter, with peak ploidy values up to 128N.<sup>40,41</sup>

As the MK matures, the polyploid nucleus becomes eccentrically located within the cell, and the cytoplasm expands as it accommodates the formation of an extensive central invaginated membrane branching system termed the demarcation membrane system (DMS).<sup>42</sup> The DMS is similar to the open canalicular system (OCS) of platelets and is possibly the precursor of such. This DMS mass is the reserve membrane supply that will eventually form proplatelet projections in the next stage of megakaryopoiesis.<sup>43</sup>

While maturing, MKs also begin to express integrins, glycoprotein receptors, and granule components critical for eventual platelet function.<sup>7</sup> MKs synthesize some of their  $\alpha$ -granule constituents (e.g., von Willebrand factor), while other granule contents (e.g., fibrinogen) are incorporated into the granules by endocytosis and/or pinocytosis of plasma contents. There is growing evidence that  $\alpha$  granules are actually quite heterogeneous in their content and functionally have the capacity for differential release with activation.<sup>44</sup> Mature MKs will eventually exhibit three distinct cytoplasmic regions: a perinuclear zone containing the Golgi, ER, and mitochondria; a middle zone containing the DMS; and an organelle-devoid peripheral zone separated from the previous two by cytoskeletal components that must be extensively remodeled during late megakaryopoiesis.<sup>10</sup>

### **Late megakaryopoiesis: proplatelet, preplatelet, and terminal platelet production**

Mature MKs subsequently associate with the vasculature and, facilitated by matrix metalloproteinase proteins (MMPs), form extensive proplatelet processes, elongated branching projections that extend through the endothelial cells lining the sinusoidal blood vessels. Here, proplatelets are released into the circulation and fragmented by shear forces, giving rise to circulating preplatelets (sometimes termed “reticulated platelets”) and, ultimately, single platelets.<sup>10</sup>

It appears that the DMS of the differentiated MK is particularly adapted to the production of platelets via continuous directed remodeling of its underlying cytoskeletal structure. In fact, many platelet production defects have been associated with mutations in Rho-GTPases central to cytoskeletal remodeling, which include Ras homolog family member A (RhoA), Rac family small GTPases 1 and 2 (RAC1 and RAC2), and cell division cycle 42 (CDC42) as well as related proteins.<sup>10</sup> Investigations into this dynamic process

have focused on the roles of actin, microtubular rearrangements, and surface integrins. Platelet biogenesis from MKs starts with (a) microtubule reorganization into pseudopod structures; followed by (b) spreading of these structures and eventual development into proplatelet processes; accompanied by (c) organelle inclusion within the processes such that the organelles are eventually concentrated at the tips of the proplatelet branches; and finally (d) actin-dependent branching to extensively amplify proplatelet processes, with the DMS serving as the membrane reservoir for this expansion.<sup>45</sup>

Ultrastructural studies of the differentiated MK demonstrate that late stage MKs are characterized by peripheralization of the DMS membranes. This is accomplished by the membranes thinning out (evagination) such that they produce branching processes that finally extend into sinusoidal blood vessels. These processes have platelet-sized swellings all along their structure, but most importantly, the swellings at the branch tips appear to be the source of proplatelets.<sup>46</sup>

Microtubules are critical for proplatelet membrane process elongation.<sup>47</sup> Repeated rounds of microtubule extension (bundling) and bending to form proplatelet processes can be characterized by physical forces such that, on balance, final platelet size can be correctly predicted to be in the micron radius range.<sup>48,49</sup> The subsequent branching of these processes is the end result of multiple rounds of fission at both the midbody and the ends of the projections; these fission events are the result of actin-dependent bending and branching which amplifies the proplatelet ends, thereby resulting in an increased potential number of platelets to be released once membrane projections penetrate into the sinusoidal vasculature.<sup>50</sup> Live-cell imaging experiments examining MK-specific mechanisms of drug-induced thrombocytopenia in the setting of trastuzumab emtansine administration have provided insight into this process, showing that this drug is taken up by mouse MKs where it inhibits MK differentiation and disrupts proplatelet formation. The inhibitory effect of trastuzumab emtansine is mediated by its induction of abnormal tubule organization within MKs, resulting in abnormal tubule thickness and fewer branching processes.<sup>51</sup>

In vivo proplatelet extension is more polarized than that observed in vitro. F-actin is thought to play a role in megakaryocyte polarization; inactivation of various genes encoding F-actin-related proteins results in proplatelet extension defects and megakaryocyte fragmentation within the marrow space.<sup>7,52</sup> The aforementioned CDC42 is the most important Rho-GTPase for proplatelet transendothelial migration; increased activity results in not only hyperpolarization but also increased transendothelial migration of whole MKs.<sup>7,10,52</sup>

Penetration of proplatelet extensions into sinusoidal vessels precedes the release of platelet precursors and whole/partial MK fragments into blood; both processes will give rise to terminal circulating platelets.<sup>53–56</sup> Once extended into the sinusoidal vessel, vascular shear forces interact with proplatelet projections, causing the tips to separate and enter the circulation;<sup>10,46</sup> this process appears to be regulated by von Willebrand factor (vWF).<sup>57</sup> Based on ultrastructural images, barbell-shaped proplatelets and circular preplatelets are released from differentiated MKs into the blood. Thus, current studies suggest that terminal platelet formation actually occurs within the blood<sup>49</sup> and, as noted previously, within the pulmonary bed.<sup>8,10,54,58</sup> Circular preplatelets may be identical to reticulated platelets (RPs) and/or to the large platelets that are present in several of the defined macrothrombocytopenia syndromes. In studies of hemostasis in human immune thrombocytopenic purpura

(ITP), RPs have been found to contain twice as much  $\alpha$ -granule content as older circulating platelets.<sup>59</sup> RPs also have an increased density of membrane receptors than older platelet cohorts, bolstering evidence that the RP subset may represent the circular preplatelets or released proplatelets.<sup>60</sup>

There are also data suggesting that circular preplatelets can revert to a barbell proplatelet form. When barbell proplatelets divide, they form two platelets that are larger (demonstrably higher platelet volume) when compared with older circulating platelets. However, these intermediate stages of terminal platelet formation after proplatelet excision are relatively dynamic, and the exact sequence of platelet maturation has not been confirmed by independent studies.

Evidence also exists suggesting that a small fraction of in vivo circulating platelets, which are thought to be terminally differentiated, may duplicate in the bloodstream under the stimulation of thrombocytopenia;<sup>46</sup> this physiology may perhaps be analogous to circular preplatelets reverting to the barbell proplatelet form which subsequently is able to divide and form two distinct terminal platelets. Such young preplatelets should be differentiated from the majority of circulating platelets that can neither divide nor revert to a barbell shape. It is also likely that such younger platelets have greater ability for continued protein translation, and there is imaging evidence for higher content of ribosomes; hence, these platelets may also be RPs as defined by elevated RNA content in comparison to the majority of circulating, older platelets.

### **Pathological insights into megakaryopoiesis**

Much of what we know about megakaryopoiesis can be attributed to the study of clinical syndromes that decrease platelet production, often resulting in thrombocytopenia. Defects have been found in genes that affect all stages of megakaryopoiesis—from progenitor differentiation through platelet biogenesis. Some of these mutations have prognostic implications involving predisposition to hematologic malignancies, further supporting investigation of the molecular etiologies of thrombocytopenic syndromes.<sup>61</sup>

Defects in the TPO receptor gene, *MPL*, result in impaired fate differentiation of megakaryocyte progenitors as well as the maintenance of self-renewal in the HSC-compartment leading to congenital amegakaryocytic thrombocytopenia.<sup>61</sup> Defects in *RBM8A*, implicated in thrombocytopenia-absent radius syndrome, are hypothesized to affect MK differentiation by impeding TPO signaling downstream from the MPL-binding event.<sup>61</sup> Additional defects in transcription factor genes *HOXA11* and *MECOM* (encoding for EVI1) have been implicated in the development of radioulnar synostosis with amegakaryocytic thrombocytopenia.<sup>61</sup> All of these defects impair early megakaryopoiesis via disruption of multipotent progenitor differentiation.

Many genetic defects have been identified in relation to abnormal megakaryocyte maturation. Some of these include *RUNX1* defect, which results in familial platelet disorder with propensity to acute myelogenous leukemia; 11q23 deletion or *FLI1* missense mutation, both defects involving *FLI1* resulting in Paris–Trousseau thrombocytopenia/Jacobsen syndrome or *FLI1*-related thrombocytopenia respectively; and *NBEAL2* mutation, resulting in impaired membrane dynamics and vesicle trafficking seen in gray platelet syndrome. Other important loci with associated inherited thrombocytopenia include *ANKRD26*, *ETV6*, *GATA1*, *GFI1B*, *SLNF14*, *FYB*, and *SRC*.<sup>61</sup>

Defects in terminal platelet production (i.e., regulation of proplatelet formation, release, and/or maturation to preplatelets) often result in macrothrombocytopenia syndromes. There is evidence that  $\beta 3$  integrin plays a role in proplatelet formation and platelet

size. In Glanzmann thrombasthenia where there is a  $\beta 3$  integrin defect producing larger platelets in some instances, there appears to be inability to constrict the ends of the proplatelets.<sup>62,63</sup>

Proplatelet extension is driven by extension and bending of microtubules which, in turn, is dependent on actin motility and actin filament turnover. Filamin A anchors receptors (e.g.,  $\beta 3$  integrin and GPIb) to the cytoskeleton,<sup>50,64,65</sup> and human defects in filamin A result in macrothrombocytopenia.<sup>66</sup> Although MKs are normal in number in Bernard Soulier syndrome (BSS), there is a disordered central membrane invagination system that appears to be dependent on the normal expression of GPIb $\alpha$ .<sup>67,68</sup> Knockout mice lacking GPIb $\alpha$ , but not GPV, have an identical macrothrombocytopenic phenotype as in BSS, making this a possible pathway defect for terminal platelet production.

Another macrothrombocytopenia syndrome, May–Hegglin anomaly, appears to have defective microtubule extension based on abnormal thickness of the packed microtubule layers.<sup>46</sup> This defect results in larger proplatelet formation and release, but there is evidence that microtubule band thinning, and therefore normal extension, may also be inhibited through a distinct nontubule pathway. May–Hegglin anomaly is caused by an *MYH9* mutational defect in nonmuscle myosin IIA heavy chain<sup>69</sup> and produces an autosomal dominant macrothrombocytopenia in humans. Similar macrothrombocytopenia syndromes with varying associated phenotypes (e.g., Fechtner syndrome, Sebastian platelet syndrome, and Epstein's syndrome) have also been attributed to *MYH9* defects and are now all recognized as a single entity, *MYH9*-related disease.<sup>70–72</sup> The *MYH9* defect has been shown to have normal MK ultrastructure by EM, i.e., there is no early differentiation defect that affects the central membranes (DMS) nor is there disruption of internal granule structure.<sup>73</sup>

In vivo actin filament turnover is critical for the terminal processes of proplatelet formation and subsequent normal platelet sizing; actin filament turnover does not appear to have a prominent effect on MK maturation.<sup>74</sup> Actin depolymerizing factor (ADF)/cofilin severing proteins regulate actin turnover. Using murine knockouts, cofilin, but not ADF, was shown to be essential for normal platelet size and shape. Yet, if both proteins are knocked out, platelet formation is nearly absent; the latter is characterized by severe disruption of the MK central membrane system and disorganization and diminution of proplatelet processes. Thus, actin has a major role in proplatelet formation and preplatelet conversion to the terminal platelet with normal maturation/sizing.

MK motility at the vascular niche and subsequent proplatelet budding require rearrangement of the actin cytoskeleton such that podosomes form dynamic contacts with the extracellular matrix (ECM).<sup>75</sup> In the context of recent insights into the limited role of megakaryocyte migration and the spatial relatedness of the endosteal versus vascular niche, it may be that podosomes act primarily to probe their surroundings for regions of transendothelial permissibility<sup>76</sup> as opposed to facilitating transmarrow migration. This hypothesis is supported by the observation that megakaryocytes can shift their center of mass despite exhibiting low motility in vivo.<sup>14</sup> MKs from Wiskott Aldrich syndrome (WAS) cannot form podosomes, and WAS MKs prematurely release proplatelets into the marrow, not blood.<sup>77</sup> MK podosomes have a role in degrading ECM to enhance and subsequently promote extension of proplatelets processes into sinusoidal vessels. Normal MK formation of podosomes and their associated actin-rich protrusions across the sinusoidal basement membrane have been shown to be dependent on MMP function; both of these abilities are lost in WAS.<sup>75</sup>

Numerous additional clinical syndromes attributed to defects in platelet biogenesis have been documented.<sup>61</sup> Recently, large correlative human genetic studies utilizing strategies such as genome-wide association, whole exome sequencing, and whole genome sequencing in patients with inherited thrombocytopenia disorders have enabled identification of additional genes correlated with platelet production and kinetics and have also identified loci associated with other clinical traits and diseases.<sup>61,78</sup> For example, genetic correlations with platelet count and mean platelet volume (MPV) have been found between genes influencing lipid biology (e.g., *APOH*, *LDLRAP1*, *FADS1/2*, *MAP1A*, *PNPLA3*, and *GCKR*), G protein signaling (*RGS10* and *RGS18*), and even height (e.g., *CABLES1*, *DNM3*, and *MICA*). Techniques such as Mendelian randomization, which can shed insight into causative associations between MPV and various genes, identified associations with *SH2B3* and *MYL2*, genes associated with coronary heart disease. However, observational studies examining this association have provided mixed results, and systematic meta-analyses found a positive (opposite) association relationship.<sup>61,79–81</sup> Regardless, these strategies may continue to uncover genetic loci vital to platelet production and kinetics as sample size, depth, and diversity increase.

### Control of megakaryopoiesis

It is important to study megakaryopoiesis not only for physiological and pathological insights but also because of the hoped-for prospect of ex vivo production. Donation of blood or apheresis for platelet units that are eventually to be transfused is a significant undertaking, and the short shelf life of donor platelets is a major impediment to medical care. Hence, there is some impetus for developing alternatives to platelet products or artificial sources of actual platelet production.<sup>82</sup> For the latter, human CD34+ stem cell populations have been described that can generate ex vivo functional MKs with ploidy levels up to 32N.<sup>83–85</sup> However, the generation of sufficient MK numbers in culture and ensuring the subsequent production of adequate platelets per MK in a cost-efficient manner are still challenging goals. Studies that examine the regulatory layers of control over megakaryopoiesis improve not only our understanding of physiology but also our ability to manipulate such factors for the goal of therapeutic intervention or the eventual goal of ex vivo production of platelets.

### Control of megakaryopoiesis: thrombopoietin and other cytokines

Multiple cytokines are implicated in the control of megakaryopoiesis, but TPO is the primary factor stimulating the proliferation and maturation of MK progenitor cells into their terminally differentiated form.<sup>4</sup> TPO is encoded by the *THPO* gene, located on chromosome 3q26.3-3q27, which encodes a 30 kDa, 353-amino-acid precursor protein. The mature molecule, composed of 332 amino acids, is acidic and heavily glycosylated.<sup>5</sup> TPO shares high homology with erythropoietin (EPO) at its N-terminus.<sup>86</sup> TPO is produced in the liver and, to some extent, the kidney and marrow stromal cells.<sup>7</sup>

TPO initiates its effects via binding to its cognate receptor, MPL (encoded by *MPL* on chromosome 1p34).<sup>5,87,88</sup> MPL exists in both monomer and homodimer forms in its unbound state and possesses no intrinsic kinase activity. Upon TPO binding, MPL undergoes conformational changes that induce transphosphorylation, associated Janus kinase 2 (JAK2) activation, and subsequent phosphorylation of receptor tyrosine residues—facilitating the initiation of multiple signal transduction pathways including signal

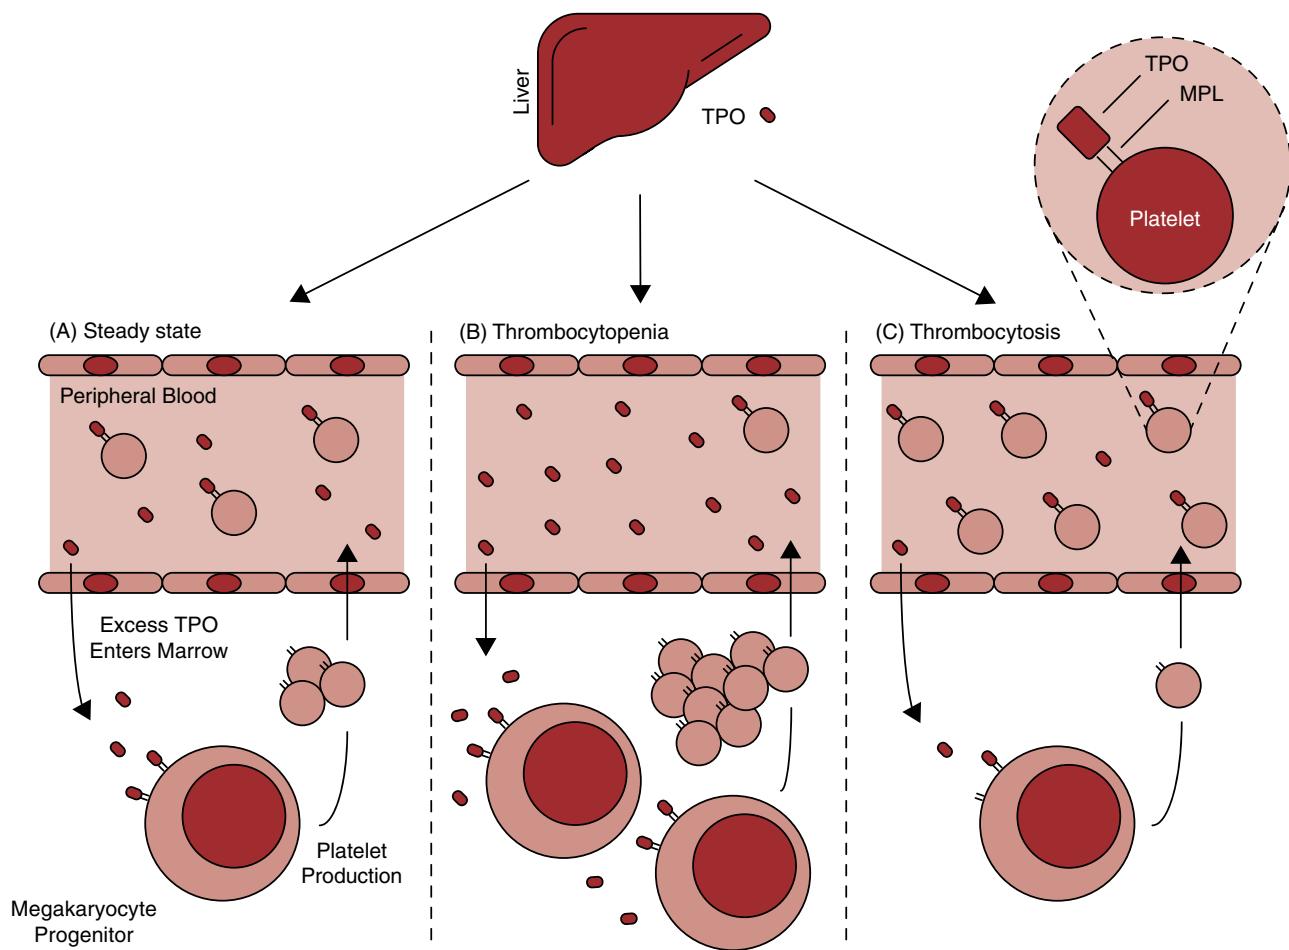

transducer and activator of transcription (STAT)-, phosphatidylinositol 3-kinase (PI3K)-, and mitogen-activated protein kinase (MAPK)-dependent processes.<sup>5,7</sup>

As noted previously, megakaryopoiesis is the process of differentiation of hematopoietic stem cells leading to platelet production; this is characterized by an initial phase of proliferation of MK progenitors and subsequent differentiation of maturing MKs that do not proliferate. Since both processes are mediated largely by TPO, this suggests that there is a physiologic balance in TPO's ability to both enhance and inhibit proliferation.<sup>89</sup> Regulation of this balance is important for timing and adequacy of platelet production. TPO has been shown to act via MAPK signaling to halt MK proliferation and induce the same MKs to undergo differentiation.<sup>90</sup> Besides MAPK, this balance of TPO-induced proliferation versus differentiation is also dependent upon JAK2 and MPL protein levels.<sup>89</sup> When either one of the JAK2 or MPL proteins is expressed at relatively lower levels, TPO exposure will induce preferential MK proliferation via weak MAPK signaling; by contrast, when both proteins are highly expressed and MAPK signaling is strongly activated, MK cell cycle arrest occurs,<sup>39–41</sup> which is accompanied by MK differentiation.<sup>91,92</sup>

Steady-state megakaryopoiesis supplies about  $10^{11}$  platelets every day into the circulation. MKs will respond to changes in platelet lifespan, increasing by 10-fold with destructive thrombocytopenic conditions,<sup>4,93</sup> and the proportion of higher ploidy MKs also increases.<sup>37</sup> Compensatory responses of marrow MKs are evident within 24–48 hours after inducing thrombocytopenia; in response to thrombocytapheresis and in thrombocytopenia caused by immune destruction, there is a marked increase in MK number and size.<sup>41,94</sup> Reciprocal decreases in MK size, ploidy, and volume occur with experimentally induced thrombocytosis.<sup>95,96</sup> These alterations, found in both experimental animals and human subjects, are primarily mediated by TPO.<sup>4</sup>

A large percentage of circulating TPO is produced constitutively by the liver, and its levels are partly regulated by the extent of TPO binding to MPL on circulating platelets and marrow MKs, which results in the internalization and elimination of TPO-MPL complexes.<sup>87,97</sup> However, data suggest that hepatic secretion of TPO is only partially constitutive, and significant regulation of TPO production occurs via the senescent platelet mass interacting with hepatocyte receptors (discussion forthcoming; see the “Platelet lifespan and its regulation” section).<sup>98</sup> Blood and marrow levels of TPO are usually inversely related to marrow MK mass and peripheral platelet counts;<sup>4</sup> hence, regulatory aspects of the platelet mass by circulating TPO levels is sometimes termed the “sponge model.” High-affinity MPL expressed on platelets binds TPO, which is then internalized and degraded, allowing the circulating platelet mass to affect, at least in part, the amount of TPO available to MKs for stimulation; low platelet counts allow more available TPO to induce megakaryopoiesis. In the sponge model of TPO regulation, as long as constitutive liver production of TPO occurs, the total platelet mass is preserved (Figure 15.2).

Accordingly, the elimination of a functional *MPL* gene, or its congenital absence, results in severe thrombocytopenia accompanied by decreased hematopoietic stem and lineage-committed progenitor cells.<sup>4</sup> Studies in mice lacking MPL expression in only MKs and platelets resulted in thrombocytosis with increased megakaryocytic ploidy and progenitor counts, further suggesting that TPO maintains circulating platelet mass primarily via stimulation of MPL-expressing progenitors and that megakaryocytic and platelet MPL expression primarily serves the role of restricting the amount

**Figure 15.2** The “sponge” model of megakaryopoiesis. The liver constitutively secretes thrombopoietin (TPO) into the blood; MPL receptors on platelets bind, internalize, and degrade TPO. In this model, the platelet mass determines the amount of free TPO in the circulation. At steady state (A), the normal platelet count reflects balanced platelet production and destruction; free TPO in blood moves to the marrow to stimulate megakaryocyte progenitors and normal ploidy distribution. When thrombocytopenia occurs (B), free TPO is increased because there are too few platelets available for binding; a larger amount of TPO is available to the marrow, which results in an increased number of megakaryocytes with higher average ploidy. In contrast, reactive thrombocytosis (C; e.g., with chronic inflammation) results in less free TPO available to transit to the marrow; decreased megakaryopoiesis results in fewer megakaryocytes with lower average ploidy levels.

of TPO available to progenitors,<sup>5,99,100</sup> despite evidence of TPO involvement in megakaryocytic maturation.<sup>20</sup>

The sponge model does well to explain why plasma levels of TPO are increased by several orders of magnitude in patients with hypoproliferative thrombocytopenia, and why TPO levels decline after recovery of hematopoiesis.<sup>87,101</sup> However, when severe platelet destruction via Fc $\gamma$ R binding causes thrombocytopenia, such as in ITP, TPO levels are not as escalated as might be expected from the degree of thrombocytopenia. This was thought to be due to the markedly increased platelet turnover rate,<sup>102</sup> but data on platelet clearance via hepatic interaction suggest otherwise, i.e., that ITP bypasses normal senescent mechanisms of platelet loss that are partly responsible for upregulating TPO production.<sup>98</sup> Thus, megakaryopoiesis appears to be regulated by plasma levels of unbound TPO, which reflects the balance between constitutive TPO production, the rate of platelet and MK binding dictated by overall platelet levels, and TPO production regulation by senescent platelet clearance by the liver.

While TPO is a major physiologic driver of megakaryopoiesis, other cytokines have been shown to potentiate or promote megakaryopoiesis. Stem cell factor (SCF) is one such cytokine thought to

augment TPO's effects through JAK2 and Src kinase signaling and may facilitate important cell-to-cell relationships within the marrow.<sup>103</sup> Additional cytokines including IL-3, IL-6, IL-9, IL-11, GM-CSF, Flt3-ligand (FL), and leukemia inhibitory factor (LIF) have been shown to potentiate megakaryopoiesis in vitro, though many appear dispensable for steady-state megakaryopoiesis in murine studies.<sup>5</sup> Note should also be made of additional TPO-independent pathways including IGF1 and YRS<sup>ACT</sup>-, CCL5-, and IL1 $\alpha$ -dependent pathways.<sup>7,31,104</sup>

The CXCR4-CXCL12 axis has also been identified as influential upon megakaryopoiesis regulation. Upregulation of the chemokine receptor CXCR4 is associated with MK maturation and differentiation.<sup>105</sup> Although its ligand CXCL12 (a.k.a. stromal cell-derived factor 1) by itself cannot stimulate MK growth and differentiation, this finding has importance for nonhomeostatic regulatory mechanisms of platelet production since CXCL12 acts synergistically with TPO both in vitro and in vivo.<sup>7,106-108</sup> Deregulation of the CXCL12-CXCR4 axis is associated with human thrombocytopenia.<sup>5</sup> Binding of chemokine CXCL12 to CXCR4 stimulates secretion of matrix metalloprotease 9 (MMP-9), enabling motility along the CXCL12

gradient.<sup>5,109</sup> While megakaryocyte migration from spatially distinct niches may not be as important as initially thought,<sup>14,15</sup> podosome extension and subsequent vascular interaction may be affected by CXCL12-mediated signaling, either through interaction with CXCR4 or another pathway such as the Src–Syk–PLC $\gamma$ 2 axis.<sup>14,110</sup>

Other megakaryopoiesis-mediating cytokines include FGF4, which has been shown to mediate megakaryocyte adhesion to endothelial cells.<sup>5,107</sup> Bioactive lipid sphingosine 1-phosphate (S1P) and its receptor, S1pr1, are important for directing proplatelet extensions, with deficiency of either resulting in extension in random directions without vascular directional bias.<sup>111,112</sup>

Inflammation is a significant and frequent cause of thrombocytosis, perhaps as a compensatory process to promote angiogenesis and wound healing. The proinflammatory VEGFR1-mediated pathway has now been shown to stimulate further upregulation of CXCR4 on megakaryocytes in a murine model, and the VEGFR1 pathway additionally stimulates MK endomitosis; hence, inflammation mediated by VEGFR1 enhances platelet production on multiple levels.<sup>113</sup> IL-1 $\alpha$  has also been shown to promote platelet production under inflammatory conditions leading to rapid megakaryocyte fragmentation, termed megakaryocyte rupture, to release large numbers of platelets into circulation.<sup>5,114</sup> Other inflammatory agents and mediators including lipopolysaccharide (LPS) and tumor necrosis factor alpha (TNF $\alpha$ ) have also been shown to influence megakaryopoiesis by promoting megakaryocytic protein expression within the HSC compartment.<sup>5,115</sup>

### Control of megakaryopoiesis: genetic regulation

Genetic regulation of megakaryopoiesis takes place on multiple levels and includes involvement of transcription factors, noncoding/regulatory RNA, and epigenetic effectors. GATA1 is a transcription factor mentioned previously that drives MEP differentiation. While largely studied for its association with erythropoiesis, GATA1 is also necessary for megakaryopoiesis and the expression of MK-specific glycoprotein IIb. GATA2 has been shown to promote megakaryopoiesis at the expense of erythropoiesis.<sup>31</sup> MDS1 and EV11 complex locus protein (MECOM); nuclear factor, erythroid 2 (NFE2); and ETV6 are additional transcription factors involved in megakaryocyte maturation.<sup>7,116</sup> Patients possessing mutations in gene ETV6, a tumor suppressor that interacts with FLI1 and regulates CDC42 and RhoA, have been shown to exhibit increased megakaryocyte proliferation along with various cytoskeletal defects that lead to decreased proplatelet formation and altered platelet shape and spreading. ETV6 variants have also been associated with increased circulating CD34+ progenitors and predisposition to myelodysplastic syndrome and leukemia.<sup>116</sup>

Myocardin-like transcription factors A and B (a.k.a. MKL1 and MKL2) have also been identified as important regulators of megakaryopoiesis. Mutation of the *MKL1* gene is part of the t(1;22) translocation found in some infantile AMKLs, where *MKL1* is fused to the RNA binding motif protein 15 gene (*RBM15*).<sup>47</sup> MKL1 is known to act as a cofactor for serum response factor (SRF) to induce muscle differentiation.<sup>117,118</sup> However, SRF can also regulate cytoskeletal genes critical for MK differentiation, and it has a role in the actin cytoskeleton development of stem cells.<sup>119</sup> SRF, in association with cofactors other than MKL1, is also a downstream target for MAPK signaling.<sup>120-124</sup>

In murine models, hematopoietic-specific SRF knockouts demonstrated decreased platelet counts, concomitant with a reduction in polyploid MKs and an increase in immature MKs with abnormal morphology.<sup>47</sup> The morphologic dysplasia and macrothrombocytopenia

induced by SRF deletion is accompanied by the downregulation of actin cytoskeletal regulatory proteins in the MKs, clearly disruptive of essential MK mechanisms for megakaryopoiesis.<sup>125</sup> Additional studies found that SRF is required with MKL1 to produce polyploidization during MK differentiation. The effects of SRF depletion are more extreme than MKL1 deletion, which also causes a decrease in platelet counts and an increase in MK progenitors in the bone marrow. These findings suggest that (a) SRF-transcription is critical for terminal MK processes that lead to proplatelet formation and platelet release and (b) there are additional factors besides MKL1 that promote SRF-mediated megakaryopoiesis.<sup>47,126</sup> The authors suggested that MKL2 expressed in MKs might redundantly function with MKL1 in murine MK maturation.<sup>126</sup>

When both MKL1 and MKL2 are absent, the arrest of MK polyploidization is more dramatic than with MKL1 alone (a majority of MKs exhibit ploidy of 4N or less).<sup>126</sup> Expression of guanine nucleotide exchange factor GEF-H1, which promotes RhoA activity to complete cytokinesis,<sup>36</sup> is linked to MKL1 regulation of MK maturation.<sup>10</sup> GEF-H1 expression is normally decreased early in MK endomitosis and subsequently rises with maturation, and SRF is known to bind to the GEF-H1 promoter in hematopoietic cells.<sup>127</sup> By contrast, GEF-H1 is increased when MKL1 is absent. Hence, MKL1 regulation of SRF-influenced transcription is probably most relevant to early MK maturation. RUNX1 also plays a role in early MK maturation since it silences the nonmuscle myosin IIB heavy chain, MYH10, a required event for the transition from mitosis to endomitosis.<sup>128</sup>

While transcription factor mediated regulation is one mechanism of genetic control, other layers of regulation are also important. Post-transcriptional regulation via noncoding RNA has also been explored, with the silencing of growth factor interdependent 1 (GFI1) expression via *miR-22* identified as a promoter of megakaryocyte differentiation.<sup>7,129</sup> Other megakaryopoiesis-regulating miRNAs identified include *miR-34a*, *miR-105*, *miR-125a-5p*, *miR-142*, *miR-146a*, *miR-146b*, *miR-150*, *miR-155*, and *miR-486*.<sup>130,131</sup> Long noncoding RNAs (lncRNAs) such as AS-RBM15 have also been demonstrated to influence megakaryopoiesis, in this case via regulation of transcription and translation of *RBM15*.<sup>132,133</sup> Furthermore, extensive de novo methylation is thought to be an important component of the epigenetic regulation of megakaryopoiesis.<sup>134</sup>

### Control of megakaryopoiesis: biophysical niche forces

The hematopoietic niche encompasses the various autocrine, paracrine, juxtacrine, and endocrine signals to which megakaryocytes and their progenitors are exposed. Neighboring cell types, cellular density, ECM composition, and diffusibility further influence these dynamics. Recent work has been carried out to dissect the contribution that ECM components and associated biophysical cues (e.g., stiffness) of the microenvironment have upon megakaryopoiesis.

Marrow is among the softest tissues of the body, with a Young's modulus ranging from approximately 0.3 kPa in medullary regions<sup>7,135</sup> to approximately 27 kPa in osteoblastic endosteal regions.<sup>7,136</sup> Stiffer type I collagen fibrils have been found to promote HSC differentiation through the megakaryocytic lineage. However, collagen I inhibits proplatelet formation via integrin  $\alpha 2\beta 1$  activation and subsequent Rho-ROCK axis signaling, while less stiff type III and IV collagens promote proplatelet formation through PI3K/Akt signaling.<sup>7,137</sup> Other ECM components including fibronectin, vitronectin, fibrinogen, plasmin, PAI-1, and thrombospondin-2 have also been shown to influence megakaryopoiesis.<sup>137</sup> Furthermore, murine platelet production has been increased by

limiting marrow stiffness via the inhibition of lysyl-oxydase (LOX)-mediated collagen crosslinking, further suggesting the importance of niche biophysical cues for megakaryopoiesis.<sup>7</sup>

Additional work has been carried out in evaluating the effects of microenvironmental stiffness upon *in vitro* megakaryopoiesis using various methylcellulose substrates as well as two- and three-dimensional substrates.<sup>138</sup> Cytoskeletal characteristics are modulated by microenvironment mechanical properties, as megakaryocytes confined within soft hydrogels have been shown to influence MYH9 distribution via promoting activation of the mechanosensitive transcription factor MKL1.<sup>7</sup> Potential mechano-sensing pathways proposed include initiation of calcium influx leading to subsequent PI3K/Akt signaling via a TRPV4-dependent (transient receptor potential cation channel subfamily V member 4) mechanism.<sup>7,137</sup>

As mentioned previously, vascular niche shear forces facilitate the extension and subsequent release of proplatelets. High shear stress is known to enhance MK fragmentation and promote higher proplatelet formation via cytoskeletal remodeling.<sup>53</sup> It is possible that shear forces act physiologically since hemodynamic stress in humans (e.g., exercise) has been shown to elevate platelet counts.<sup>139,140</sup> Interestingly, DNA synthesis in immature MKs can also be enhanced via exposure to shear stress.<sup>141</sup>

Exact mechanisms by which megakaryocytes sense various biophysical cues are still largely unknown;<sup>7</sup> dissection of the roles of ECM composition and mechano-sensing may have implications for the study of mechano-altering disease processes such as myelofibrosis, as well as the *ex vivo* production of platelets.

## Platelet kinetics

### Platelet production as a function of platelet circulatory survival

The kinetics of normal platelet production have been measured indirectly by determining the turnover rate of circulating platelets (platelet count divided by platelet survival corrected for recovery). The median overall rate of platelet production under steady-state conditions (platelet removal is equivalent to platelet production when the platelet count is constant) in healthy humans ranges from 35,000 to 44,000 platelets/ $\mu\text{L}/\text{day}$ .<sup>142–145</sup> The reliability of platelet turnover estimates depends on the accuracy with which each of the three variables used in calculating platelet turnover can be determined—mean platelet lifespan, recovery of platelets in the circulation, and blood platelet count. The summation error may be considerable, as occurs among patients with severely enhanced platelet destruction (e.g., ITP).<sup>145</sup>

### Platelet lifespan and its regulation

The human platelet lifespan is  $9.5 \pm 0.6$  days,<sup>142</sup> and healthy platelet disappearance is generally linear and thought to mostly reflect platelet senescence.<sup>144</sup> With consumptive thrombocytopenia, the platelet lifespan is shortened, with exponential, likely random, platelet removal from circulation.<sup>146</sup> Platelet survival time has also been shown to shorten progressively as the platelet count decreases to  $<100,000/\mu\text{L}$ .<sup>144,147</sup> Therefore, a shortened platelet survival time in patients with thrombocytopenia does not necessarily indicate a destructive process.

Hanson and Slichter proposed a model for platelet removal that predicted shortening of platelet lifespan in relation to the level of thrombocytopenia.<sup>144</sup> The analysis indicated that 82% of normal platelet turnover is caused by platelet senescence; only 18% of

platelet removal is due to the requirement of platelets to support vascular integrity. In this model, healthy hemostatic platelet loss represents about 7000 to 10,000 platelets/ $\mu\text{L}/\text{day}$ . Since there is evidence that clearance of platelets via hemostatic integrity is a fixed absolute requirement, thrombocytopenia caused by marrow hypoplasia causes the daily proportion of platelets removed by hemostatic consumption to rise significantly.<sup>148</sup> Hemostatic clearance in patients with megakaryocytic hypoplasia can actually be predicted by the platelet count (15.1–28.0% of overall platelet turnover).<sup>148</sup>

Kinetic modeling of platelet lifespan using labeling in murine populations suggests that, at steady state, circulating platelet senescence is internally programmed.<sup>149</sup> Since platelets contain the key components of a critical apoptotic pathway that regulates lifespan,<sup>150</sup> it may well be that platelet lifespan and the induction of senescent platelet death are regulated by internal, programmed functions rather than external injuries or “hits.” Antiapoptotic Bcl-2 family proteins restrain proapoptotic proteins Bak and Bax. Knockout and pharmacological inhibition studies suggest that Bcl-xL and Bak are likely the most important regulators of apoptotic-mediated platelet clearance, with induced deficiency of either’s activity producing thrombocytopenia or prolonged platelet lifespan, respectively.<sup>151,152</sup> Platelet-specific triggers that commence apoptosis have yet to be established. Of note, platelets seem to lack the Fas receptor central to the extrinsic apoptotic pathway. It remains to be determined how platelets integrate intrinsic and extrinsic cues that push them toward senescence.<sup>153</sup>

When platelets become senescent, the physiology of their removal is postulated to include (a) irreversible changes in membrane glycoproteins; (b) increased platelet-associated immunoglobulin with subsequent clearance of high-immunoglobulin-expressing platelets by the reticuloendothelial system; (c) increased exposure of the negatively charged procoagulant lipid, phosphatidylserine, on the external platelet membrane; and (d) decreased levels of surface sialic acid.<sup>154</sup> Mechanisms of platelet clearance have been examined with particular relevance to platelet storage; such studies may shed light on *in vivo* platelet circulation. Desialylation of platelet receptors occurs when platelets are warmed after cold exposure,<sup>155</sup> warming activates sialidases in plasma that target the sialic acid residues on platelet glycoproteins. Interestingly, oseltamivir phosphate, a sialidase inhibitor used clinically to treat influenza infection, has been shown to increase platelet counts in patients with ITP independent of influenza infection.<sup>156–158</sup> Cold exposure also primes matrix metalloproteinase (MMP) cleavage of GPIb $\alpha$ , and the end result of both pathways is increased platelet clearance by the liver.

The association between loss of sialic acid and platelet senescence has recently reinforced the possibility that platelets themselves act directly on TPO mRNA expression<sup>159–163</sup> rather than MPL uptake of TPO as the exclusive model for the regulation of hepatic production.<sup>101,164–167</sup> As platelets age in the circulation, they lose  $\alpha$ 2,3-linked sialic acid from surface glycoproteins; these desialylated platelets can then be cleared by binding to the hepatocyte Ashwell–Morell receptor (AMR), a heteromeric complex of asialoglycoprotein receptors 1 and 2.<sup>98</sup> Binding of platelets to the AMR induces hepatocyte TPO mRNA via JAK2-STAT3 signaling, and this may partly explain why TPO levels are higher than expected in essential thrombocythemia (ET) and lower than expected in ITP. In ET where platelet lifespan is unchanged, one would expect a higher daily number of senescent platelets to be cleared by the liver, thereby inducing more TPO; by contrast, since platelets in ITP are primarily cleared by macrophage Fc $\gamma$ R binding and would bypass the hepatocyte AMR, lower TPO production would be the result. In this

model, senescent platelet regulation of TPO production accounted for up to 50% of secretion, suggesting that this pathway may even be equivalent to constitutive TPO production for regulation of platelet mass (Figure 15.3). It is unclear if the apoptotic pathway intrinsic to platelets initiates these sialylation changes, but the apoptotic mechanism does affect platelet survival,<sup>150,168,169</sup> including proapoptotic platelet clearance via the liver.<sup>170</sup>

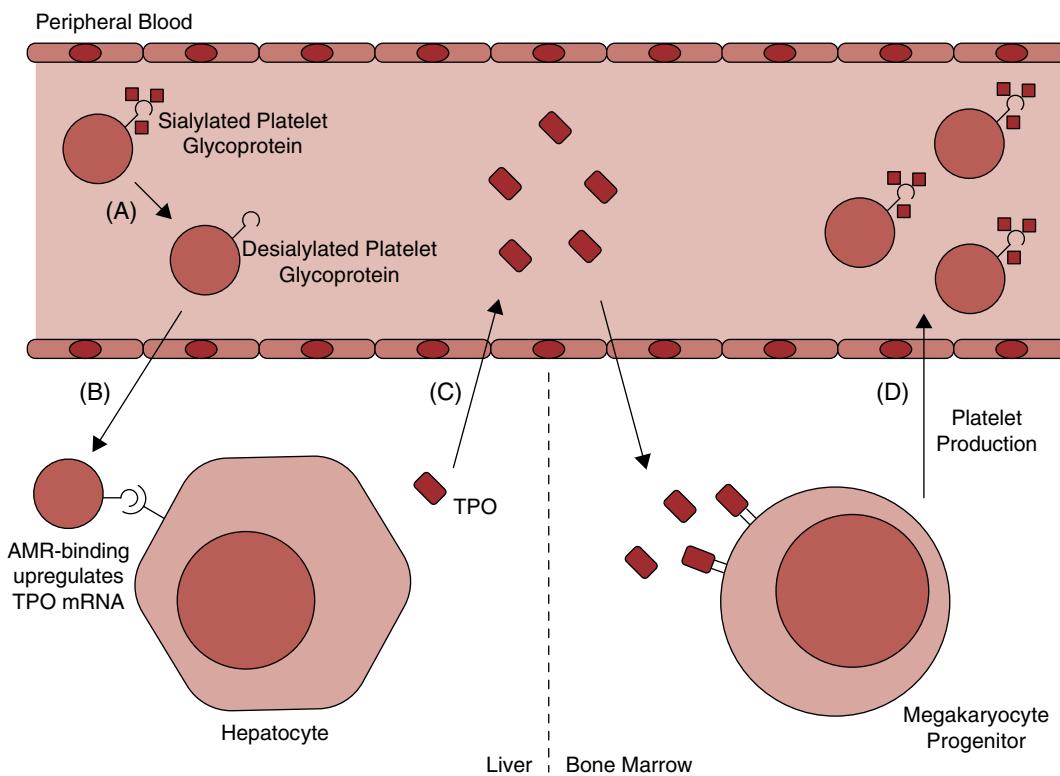

As noted in the “Platelet production” section, neonatal and adult MKs differ in their maturational abilities, and similarly, studies of neonatal platelets suggest kinetic differences from their adult counterparts. Murine studies suggest that platelets survive 1 day longer in neonatal mice when compared to platelets in the circulation of adult mice of the same genotype.<sup>171</sup> The antiapoptotic protein Bcl-2 was much higher in human neonatal platelets compared with adult platelets, suggesting relatively increased resistance to apoptosis.<sup>150,170</sup> These findings provide additional support for the concept of programmed cellular senescence via apoptosis, but they do not rule out additional processes governing nonhemostatic platelet clearance.

Newly released reticulated platelets (RPs) are identified by their increased RNA content;<sup>172</sup> murine studies have directly confirmed that RPs are the platelet subset most recently released from megakaryocytes into the blood.<sup>173,174</sup> The RP% in humans correlates with thrombopoietic activity.<sup>175</sup> Analogous to red cell reticulocytes, RPs increase in response to destructive thrombocytopenia and decrease when megakaryocyte hypoproliferation occurs with chemotherapy or intrinsic marrow aplasia.<sup>176</sup> The absolute RP count in humans

with normal platelet counts ranges from 15,000 to 48,000/ $\mu\text{L}$ ; this average platelet production agrees with isotopic labeling studies.

The RP% has proven valuable for detecting changes in overall platelet turnover. The RP% has been applied for predicting thrombopoietic recovery, transfusion independence, and thrombotic risk. An increase in the RP% was associated with subsequent graft-vs.-host disease after allogeneic hematopoietic stem cell transplantation.<sup>177</sup> Similarly, an asymptomatic increase in the RP%, with no change in platelet counts, from the first to second trimester in pregnancy was associated with subsequent preeclampsia.<sup>178</sup> Asymptomatic patients with steady-state thrombocytosis and an elevated RP% or absolute RP count were at increased risk for subsequent thrombosis, and their relative risk was higher than the risk associated with a high platelet count alone.<sup>179</sup> The RP% and absolute RP count in thrombocytosis decrease with either successful aspirin therapy or hydroxyurea.<sup>180,181</sup>

A compensatory increase in platelet production and the corresponding rise in circulating RP% are well established in patients with ITP.<sup>182,183</sup> Platelet lifespan in severe ITP can be shortened to hours. This increase in peripheral platelet destruction is so significant that platelet lifespans are shorter than predicted by Hanson and Slichter’s model. Hence, post-transfusion platelet counts are probably the only way to provide the clinician with the necessary platelet survival information for the management of such patients. ITP antibodies are commonly directed against the two most abundant platelet glycoprotein complexes, GPIIb-IIIa and GPIb-IX. While these antibodies are thought to facilitate platelet clearance

**Figure 15.3** The “platelet feedback” model of megakaryopoiesis. Liver secretion of thrombopoietin (TPO) into the blood is regulated by platelet-hepatocyte binding. Circulating platelets have  $\alpha 2,3$ -linked sialic acid on their surface glycoproteins. Over time in the circulation, platelet desialylation (A) occurs. When aged, desialylated platelets transit the liver (B) where the desialylated platelet glycoproteins bind to their receptor, the hepatocyte Ashwell-Morell receptor (AMR). This ligand-receptor binding event upregulates hepatocyte TPO mRNA levels and increases TPO production. TPO secreted from the liver into the blood (C) can either bind to platelet MPL or remain free in the circulation. Free TPO is then able to transit to the marrow where it is available to stimulate megakaryopoiesis (D); fully sialylated platelets are then released into circulation.

via Fc $\gamma$ R-mediated uptake by splenic macrophages, hepatic uptake is thought to be the predominant mechanism in cases associated with anti-GPIb $\alpha$  antibodies.<sup>158</sup> Mixed splenic and hepatic uptake patterns have also been observed.<sup>184</sup>

Although the marrow can increase megakaryocyte mass by 10-fold, this response is insufficient to maintain a normal platelet count with ITP; the increased RP% confirms the compensatory marrow production response.<sup>185</sup> The RP% is very sensitive to megakaryocyte production, and RP changes may precede changes in platelet counts; in fact, the RP% has been shown to decline about 24 hours before platelet count recovery in ITP<sup>59</sup> and to similarly rebound prior to marrow recovery from chemotherapy-induced hypoplasia.<sup>186</sup> The RP% in both situations will eventually normalize as the platelet count approaches the normal range, indicating that the restoration of a normal platelet lifespan rapidly downregulates MK platelet release.

Automated hematology analyzers have since incorporated methods for the measurement of young platelet subsets utilizing a combination of opening impedance, optical scattering, and fluorescence modalities. Immature platelet fraction (IPF) is one such parameter that correlates decently with reticulated platelet count as defined by flow cytometry in the settings of peripheral platelet destruction and nonimmune thrombocytopenia associated with hypersplenism, though not necessarily in the setting of defective platelet production or steady-state production.<sup>187</sup> IPF% has been shown to predict some etiologies of thrombocytopenia, but not others, e.g., myelodysplastic syndrome and *MYH9*-related congenital thrombocytopenia. Like RPs, the IPF% is sensitive to MK regulation and has been shown to increase in advance of platelet recovery after chemotherapy.<sup>188,189</sup> Higher IPF values may predict the preservation of a normal platelet count in patients with preeclampsia.<sup>189</sup> Prediction of thrombotic risk in thrombocytosis, sepsis development and severity, and outcomes in cardiovascular disease have also been explored with IPF.<sup>189</sup> One challenge that affects the utility of this particular platelet metric is the lack of method standardization among manufacturers, which consequently inhibits studies validating their use.<sup>189,190</sup>

### Platelet sequestration

Approximately two-thirds of human platelets circulate while the remaining are reversibly sequestered, primarily in the spleen.<sup>191</sup> Massive splenomegaly can cause severe thrombocytopenia (counts <50,000/ $\mu$ L) when as much as 90% of total-body platelet mass is sequestered in the spleen.<sup>145,191</sup>

Platelet accumulation in the spleen reaches 90% of maximum activity within 12.5 minutes after injection of labeled platelets.<sup>191</sup> Splenic pooling of platelets is reversible; intravenous epinephrine, which reduces blood flow to the spleen and causes the organ to empty passively into the circulation, will cause the blood platelet count to increase by 30–50%, and epinephrine does not affect platelet count in asplenic individuals.<sup>192</sup>

Splenectomy in humans may or may not affect platelet survival.<sup>193</sup> An animal model has demonstrated a significant (>40%) increase

in platelet lifespan after splenectomy.<sup>194</sup> Patients with moderate splenomegaly, such as seen with cirrhosis and portal hypertension, have platelet counts in the range of 60,000–100,000/ $\mu$ L. Hepatic pooling of platelets probably accounts for 10% of total-body platelets, but this fraction may increase after splenectomy.<sup>143,145</sup>

### Summary

Megakaryopoiesis is a complex biological process encompassing events from megakaryocyte differentiation and maturation to pro-platelet release and terminal platelet biogenesis. A milieu of cytokines, cellular interactions, and biophysical cues drives its progression and regulation on genetic, epigenetic, post-transcriptional, and post-translational levels. The resulting platelets carry out hemostatic functions and have lifespans that are normally dictated by their own varied processes that feed back to influence platelet production; an interconnected cycle of production and destruction ensues. Through the continued study of megakaryopoiesis and platelet kinetics, new insights regarding human physiology, pathophysiology, and improved clinical technologies can and will be elucidated.

## CHAPTER 16

# Platelet immunology and alloimmunization

Cheryl L. Maier<sup>1</sup>, Seema R. Patel<sup>2</sup>, & H. Clifford Sullivan<sup>1</sup>

<sup>1</sup> Center for Transfusion and Cellular Therapies, Department of Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, GA, USA

<sup>2</sup> Aflac Cancer and Blood Disorders Center, Children's Healthcare of Atlanta/Emory University School of Medicine, Atlanta, GA, USA

Platelets are critical mediators of hemostasis, and platelet transfusion remains an essential therapy for the treatment and prevention of bleeding. Platelets express a variety of immunogenic proteins, either unique to platelets themselves or shared with other cell types, and alloimmunization to platelet antigens can render patients refractory to transfusion, with important consequences on clinical outcomes.<sup>1,2</sup> Indeed, platelet refractoriness represents a major barrier to efficacious platelet transfusion and is associated with increased risk of bleeding, longer hospital stays, higher inpatient costs, and decreased overall survival.<sup>2–4</sup> This chapter reviews the antigens most relevant to platelet refractoriness, the impact of alloimmunization on transfusion responses, and finally the strategies employed to mitigate or prevent alloimmunization and immune-mediated platelet refractoriness.

### Platelet antigens and alloimmunization

Platelets express a number of antigens relevant to alloimmunization and platelet refractoriness, including human leukocyte antigens (HLA) and human platelet antigens (HPAs) (Figure 16.1). Platelet alloimmunization refers to the de novo development of alloantibodies capable of binding platelet antigens, which may or may not affect the survival of transfused platelets. In addition, in the context of efficacious platelet transfusion, it may be important to consider ABO blood group antigens expressed on platelets as patients may harbor naturally occurring alloantibodies against these antigens. Finally, it is important to note that drug-dependent antibodies can also contribute to platelet refractoriness (discussed below), though the mechanism by which these antibodies are generated is distinct from alloimmunization.

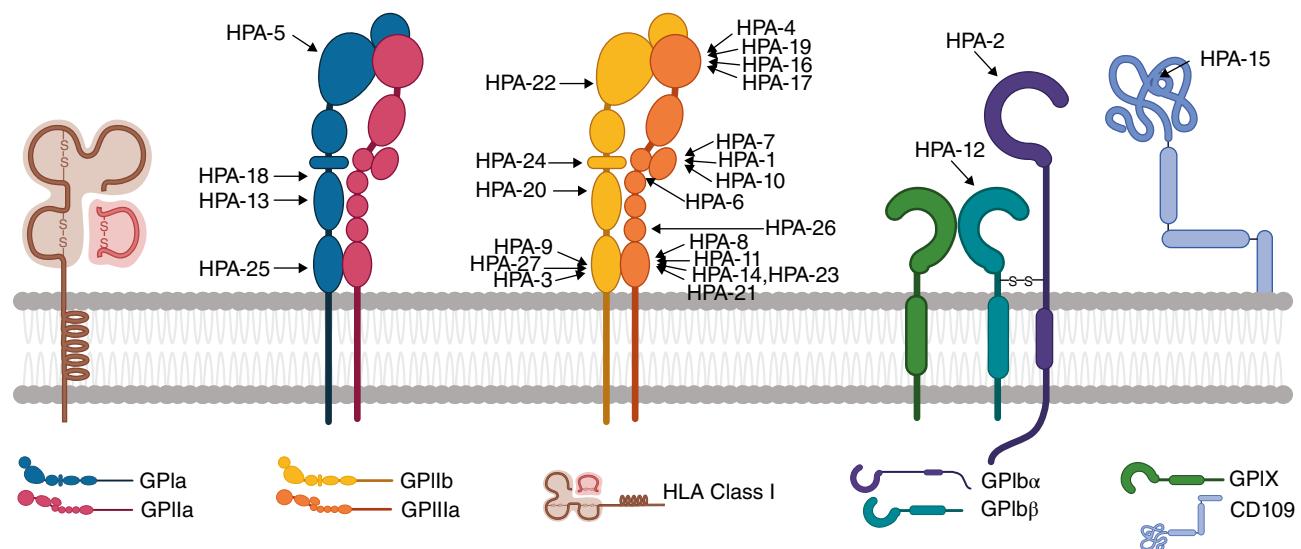

### Human leukocyte antigens

Human leukocyte antigens (HLAs) are highly polymorphic glycoproteins representing the major histocompatibility complexes (MHCs). As of December 2020, over 29,000 HLA allelic variants are reported in the IMGT/HLA database (<https://www.ebi.ac.uk/ipd/imgt/hla/intro.html>), making HLA one of the most significant immunological barriers for the management of patients requiring

life-long transfusion support. The majority of these allelic variants are found within the two major classes of HLA molecules: Class I (HLA-A, HLA-B, and HLA-C) and Class II (HLA-DR, HLA-DP, and HLA-DQ). HLA Class I molecules are expressed on platelets and the vast majority of nucleated cells in the body, whereas only a restricted group of specialized leukocytes involved in antigen presentation (e.g., macrophages, dendritic cells, and B cells) expresses HLA Class II molecules. It is worth noting that platelets from patients with idiopathic autoimmune thrombocytopenic purpura may transiently express HLA-DR.<sup>5,6</sup> Given the broad expression profile of HLA Class I, there is a significant risk of exposure to allogeneic HLA Class I during platelet transfusion, pregnancy, and solid-organ transplantation. HLA alloimmunization in these contexts can result in the formation of an immune response that renders subsequent transfusions ineffective, and patients may be classified as having platelet refractoriness as discussed below.

Platelets express approximately 50,000–120,000 HLA Class I molecules per cell.<sup>7</sup> Although all three types of HLA Class I molecules are detected on platelets, the degree of expression varies. HLA-A and HLA-B are predominantly found on the surface of platelet membranes and are the primary targets for alloantibodies implicated in platelet refractoriness.<sup>8</sup> The level of HLA-B8, HLAB44, HLA-B45 and HLA-B35 has been reported to vary between donors, with some expressing low to undetectable levels.<sup>9–12</sup> HLA-C are also present,<sup>13</sup> but with rare exception,<sup>14</sup> alloantibodies to HLA-C do not appear to significantly impact transfused platelets. Despite having less HLA Class I molecules on their surface compared to leukocytes, platelets represent a major source of circulating HLA Class I given their very large numbers present in the circulation.

HLA alloimmunization may result from pregnancy or prior transfusions, with exposure to leukocyte-containing blood components resulting in high rates of alloantibody formation in patients receiving multiple transfusions. In the context of prior platelet transfusions, passenger donor leukocytes are implicated as a major cause of HLA alloimmunization. Studies in humans show that when leukocyte-reduced platelet concentrates are transfused, primary alloimmunization to HLA is delayed or even absent,<sup>15–17</sup> whereas unmodified platelet concentrates are associated with a rate of HLA alloimmunization ranging from 19% to 71% (Table 16.1).<sup>18–20</sup>

\* Frequency of HLA alloantibody and platelet-specific alloantibody formation in studies of patients with hematologic and oncologic diagnoses requiring repeated platelet transfusion.

† HLA alloantibodies determined by lymphocytotoxicity testing.

‡ Platelet-specific alloantibodies (PSA) determined by a variety of methods.

The risk of HLA alloimmunization appears to be influenced by several patient and blood component factors. Transfused patients previously exposed to allogeneic HLA via transfusion or pregnancy develop HLA alloantibodies sooner—and, in many studies—more often than patients without a previous exposure.<sup>20,25,27,28</sup> In the Trial to Reduce Alloimmunization to Platelets (TRAP) study,<sup>20</sup> 62% of previously pregnant women with AML receiving untreated blood components (control product) developed alloantibodies compared to 33% of those who had not been pregnant or transfused previously. Furthermore, the underlying disease for which patients require platelet transfusion also appears to influence the rate of HLA alloimmunization. Studies have shown that patients undergoing induction chemotherapy for AML are more likely to become alloimmunized than patients being treated for acute lymphoblastic leukemia (ALL) (44 vs. 18%;  $p < 0.001$ ).<sup>29</sup> Others have corroborated this finding and noted that alloimmunization may occur sooner in patients with AML than in those with ALL.<sup>25,30</sup> In addition, a study of chronically transfused sickle cell disease patients determined that 85% of those with  $\geq 50$  past red cell transfusions had evidence of platelet-reactive alloantibodies, whereas 48% of those with  $< 50$  past exposures were sensitized and no HLA alloantibodies were detected in patients with no past transfusions.<sup>31</sup>

### Human platelet antigens (HPAs)

Human platelet antigens (HPAs) are platelet-specific antigens with single nucleotide polymorphisms (Figure 16.1). Although these amino acid substitutions do not appear to generate functional defects, exposure to these alloantigens during pregnancy or transfusion can result in the formation of alloantibodies and result in (1) fetal and neonatal alloimmune thrombocytopenia (FNAIT),<sup>32</sup> (2) post-transfusion purpura (PTP)<sup>33</sup> or (3) platelet refractoriness.<sup>34</sup> To date, 35 types of HPAs have been serologically identified either in women with infants affected by FNAIT or in patients refractory to platelet transfusion. Characteristics of these HPAs are listed in Table 16.2 (modified from the HPA Database, <https://www.versiti.org/hpa>).<sup>35</sup> The HPAs identified thus far are located on one of the seven glycoproteins, with the vast majority residing on GPIIIa (CD61). While 6 HPA systems are paired with either one or two other alleles, the remaining 29 HPAs do not appear to correspond with pairs of alleles and are designated with a “w” for workshop (e.g., HPA-8bw). Alloantigens that do not correspond with pairs of alleles occur at a low frequency (<1%) and have been discovered in mothers who have given birth to infants affected by FNAIT.<sup>36</sup> Of the multiallelic HPA systems, HPA-1 is the only alloantigen that is a triallelic,<sup>37</sup> while HPA-2, HPA-3, HPA-4, HPA-5, and HPA-15 are biallelic. As HPAs are inherited in a codominant autosomal manner, the most frequent allele is designated with an “a,”<sup>38,39</sup> while “b” identifies the less frequent allele.

HPA frequencies have been best studied in individuals of Caucasian descent, and it is important to note that the frequency varies significantly by racial and ethnic group. For example, approximately 15% of European descendants but <1% of individuals of Asian ancestry express HPA-1b. Alloimmunization to high-frequency platelet-specific antigens can thus present a major challenge in finding compatible platelets to support a patient requiring multiple platelet transfusions. Fortunately, these cases are extremely rare.<sup>40–42</sup> However, knowledge of HPA frequencies among different populations is essential to reduce antigenic differences and thereby diminish the risk of alloimmunization.

It is important to note that the majority of refractory patients with platelet-specific alloantibodies also have HLA alloantibodies.<sup>43</sup> Although platelet-specific antibodies against defined HPAs can

result in transfusion failure,<sup>44–46</sup> most platelet reactivity lacking specificity (e.g., nonspecific reactivity) does not seem to influence transfusion response.<sup>20,24,47</sup> Evidence implicating HPA or platelet-specific antibodies in the destruction of transfused platelets comes from the failure of some HLA-matched platelet transfusions given to patients who are refractory to random whole-blood-derived platelets.<sup>15</sup> The poor responses to these platelet transfusions, despite HLA matching, suggests that other antigens may be involved. Assays detecting platelet glycoprotein-specific reactions allow for the identification of platelet-specific non-HLA antibodies. Using one such method, the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) assay, a group documented that among 252 patients with hematologic-oncologic diagnoses receiving platelet transfusions, 20 (8%) developed platelet-specific alloantibodies with clear-cut specificity. The most common specificity in these patients was for HPA-5b in 10 of the 20; followed by HPA-1b

in 4; HPA-5a in 2; and 1 each with HPA-2b, HPA-1a, HPA-1b plus HPA-5b, and HPA-1b plus HPA-2b.<sup>48</sup> This study confirmed earlier findings in the TRAP study where 8% of the 530 patients in the trial formed platelet-specific alloantibodies, the most common being anti-HPA-1b.<sup>20</sup>

### ABO blood group antigens

Platelets express low levels of blood group antigens I,<sup>49</sup> P,<sup>49,50</sup> and ABO.<sup>51</sup> While antibodies against blood group antigens I and P do not appear to impact the survival of transfused platelets, antibodies against ABO can contribute to accelerated platelet clearance<sup>52–54</sup> and are associated with an increased incidence of HLA alloimmunization.<sup>55,56</sup> Notably, platelets derived from individuals with an A<sub>2</sub> blood group subtype do not express detectable A antigens.<sup>57,58</sup> As the ABO blood group antigens are terminal carbohydrate determinants, these antigens are expressed by a variety of glycosphingolipids and

glycoproteins on platelets.<sup>59–63</sup> Of the glycoproteins, GPIb, GPIIb, and GPIIa account for the highest degree of ABO motifs per molecule.<sup>59,64</sup> However, ABO expression levels have been reported to vary on platelets within a given individual.<sup>49,51,58,65,66</sup> While not all groups have found this difference to be significant,<sup>52</sup> to the extent that intra-platelet variability exist, these data may provide insight into why early studies demonstrate a rapid destruction of a subset of transfused ABO-incompatible platelets, followed by near to normal survival of the remaining cells.<sup>53,67</sup>

Platelet destruction in ABO-incompatible platelet transfusions is thought to result from recipient anti-A or anti-B IgM and IgG. These naturally occurring isoagglutinins can interact with A and B motifs on transfused platelets, resulting in their destruction. Explanations offered for the aforementioned biphasic survival curves of ABO-incompatible platelets include (1) the elution of a portion of group A motifs from the platelet surface; (2) the nonhomogeneous distribution of group A motifs on donor platelets, with resultant rapid destruction of the subpopulation with the highest expression; and (3) secondary injury to a subset of transfused platelets caused by the reaction between anti-A isoagglutinins and A-positive red cells in the platelet concentrate.<sup>53,58</sup>

Interindividual variability in the level of blood group antigen A and B expression on platelets has also been reported in healthy individuals.<sup>52,58,66,68</sup> In particular, a study found that the level of group A on platelets from individuals with an A<sub>1</sub> blood group subtype can range from 2100 to 16,000 molecules per platelet.<sup>58</sup> This was attributed to the roughly 7% of group A individuals that demonstrate strong expression of blood group antigen A.<sup>58</sup> Similarly, 4–7% of group B donors present with up to 20 times greater group B expression than normal.<sup>51,58</sup> Healthy donors with platelets expressing these unexpectedly high levels of blood group antigens A and/or B are described as having a “high expresser phenotype” trait, termed *type II high expressers*.<sup>58</sup> It is worth noting that in addition to high and normal expressers, there is an additional group of individuals that illustrate a similar pattern of blood group antigen A expression on platelets from normal expressers but have an overall higher level of expression (termed *type I high expressers*). Although the high expresser trait was first identified in Japanese blood donors,<sup>51</sup> recent studies have observed a similar phenotype in other ethnic groups (e.g., Caucasians).<sup>58,66</sup> Despite the prevalence of “high expresser phenotype,” the mechanism(s) driving increased blood group antigen A and/or B expression on platelets remains poorly defined. However, the “high expresser phenotype” has been reported to correlate with increased glycosyltransferase activity and was found to be inherited as an autosomal dominant trait,<sup>51,58</sup> suggesting that inherited factors may contribute to its etiology. Nevertheless, the “high expresser phenotype” trait is of significant clinical relevance as the transfusion of high expresser platelets into ABO-incompatible recipients has been implicated in FNAIT<sup>69</sup> and platelet transfusion refractoriness.<sup>51</sup>

Several studies have documented the impact of ABO incompatibility on platelet recovery. One study demonstrated a reduced recovery of 23% in ABO-incompatible donor-recipient pairs, while another reported an increased frequency of refractoriness in patients receiving ABO-unmatched platelet transfusions (69% vs. 58%;  $p = 0.001$ ).<sup>56,70</sup> In addition, others have shown that as many as 20% of group O patients develop severe refractoriness to group A platelets.<sup>51,57,71</sup> Another study examined the impact of ABO in transfusion responses by randomly assigning forty patients with hematologic diseases to receive either ABO-identical or ABO-unmatched platelets.<sup>72</sup> The responses in the group of patients receiving

ABO-unmatched transfusions (i.e., when either the recipient would be expected to have isoagglutinins to the antigens on transfused platelets or the donor had such antibodies directed at the recipient's blood type) were significantly worse than those observed in patients receiving ABO-identical platelet transfusions. Analysis of the first 25 transfusions in each group showed a significantly better response in the ABO-identical arm (mean corrected count increment [CCI], 6600 vs. 5200;  $p < 0.01$ ). This effect was most important in the first 10 transfusion episodes and tended to predict subsequent alloimmunization and refractoriness to platelet transfusions.

It is important to note that adverse effects of ABO-incompatible platelet transfusion extend beyond platelet alloimmunization and refractoriness. For example, a retrospective cohort study of cardiac patients significantly demonstrated more red cell transfusions, longer hospital stays, more days of fever, and increased healthcare costs in patients who received ABO-mismatched platelets compared to those who received ABO-identical platelets.<sup>73</sup> Indeed, a later study failed to identify negative effects of ABO-mismatched platelet transfusions in a larger cohort of cardiac patients;<sup>74</sup> nevertheless, there remains the possibility that ABO-mismatched platelet transfusions may be associated with increased inflammation. Finally, ABO plasma-incompatible transfusions, such as the transfusion of products from group O donors into non-group O recipients, carry a risk of acute hemolytic transfusion reactions caused by high titer isoagglutinins. This risk has increased with the shift from pooled whole-blood-derived platelet concentrates to apheresis platelets as some donors have potent ABO isoagglutinins; therefore, many blood product providers have taken steps to alleviate this risk by reducing the volume of incompatible plasma or screening group O donors for high-titer isoagglutinins.<sup>75</sup>

## Transfusion refractoriness

*Alloimmunization* is an immune response in a recipient stimulated by foreign donor antigens. In the setting of platelet transfusion, these responses involve the production of alloantibodies against donor platelets. *Platelet refractoriness* describes the clinical condition in which patients do not achieve the anticipated platelet count increment following platelet transfusion. It is possible to be alloimmunized to platelet antigens without being refractory to platelet transfusions and also to be refractory to platelet transfusions without being alloimmunized. *Alloimmune or antibody-mediated platelet refractoriness* occurs when the level of alloimmunization, as measured by the breadth of antibody response to platelet antigens, is sufficient to affect the majority of randomly selected platelet products.

The detection of alloimmunization is performed using laboratory techniques to detect antibodies in the patient's serum that are reactive with allogeneic HLA or platelet-specific antigens. In contrast, the definition of the refractory state is less precise.<sup>8,76</sup> A standard dose of platelets (six units of pooled whole-blood-derived platelet concentrates or one apheresis platelet unit) generally results in a post-transfusion increment of about 30,000–40,000 platelets/ $\mu$ L one hour after platelet transfusion.<sup>76</sup> The TRAP study, mentioned previously, defined the refractory state as a corrected count increment (CCI; Table 16.3), which normalizes transfusion responses for the patient's blood volume estimated using body surface area and platelet dose, of <5000 after two sequential ABO-compatible platelet transfusions.<sup>20</sup> Clinically, some institutions use a CCI cutoff of <7500 to define platelet refractoriness.<sup>34,77</sup> The age of the transfused platelet unit should also be considered when

assessing CCI, which is expected to increase more when using platelets stored for less than 48 hours compared to longer storage times.<sup>78</sup> Post-transfusion platelet counts should be measured 10 minutes to 1 hour after completion of the platelet unit. Low CCI values observed at 1 hour are indicative of immune-mediated clearance, while low CCI observed at 24 hours following acceptable CCI values at 1 hour is more indicative of nonimmune-mediated platelet clearance,<sup>77,79,80</sup> although recent data do suggest a potential role for antibody-independent immune mediated refractoriness involving recipient T cells.<sup>81</sup> An additional measure of platelet transfusion response is the percent platelet recovery (PPR; Table 16.3). Similar to the CCI, the PPR uses platelet dose and patient blood volume; the latter is estimated using the patient's body weight in kilograms. Studies in normal autologous platelet donors show an average one-hour PPR of approximately 66%.<sup>77</sup> Recovery less than 20–30% at one-hour post-transfusion indicates a refractory response.<sup>82</sup>

It is important to recognize that refractoriness does not necessarily imply alloimmunization. Indeed, only about 30% of refractory responses to platelet transfusion are attributable to alloimmunization. The remainder are due to nonimmune factors that result in shortened platelet survival and/or markedly decreased platelet recoveries in patients who receive transfusions.<sup>77,83,84</sup> Table 16.4 provides a list of nonimmune causes of poor response to platelet transfusion that should be considered when evaluating a patient for

**Table 16.3** Calculations Determining Platelet Count Increment in the Evaluation of Platelet Refractory Patients

Methods to Calculate Response to Platelet Transfusion	Equation
Corrected count increment (CCI)	$= (\Delta \text{ platelet count} \times \text{BSA}) / \text{platelet count of unit(s)}$
Percentage platelet recovery (PPR)	$= (\Delta \text{ platelet count} \times \text{TBV}) / \text{platelet count of unit(s)}$

$\Delta$  platelet count = post-transfusion platelet count – pretransfusion platelet count;  
BSA: body surface area; TBV: total blood volume; platelet count of unit(s): generally  $3 \times 10^{11}$  is used per unit unless the exact count of unit is available.

• Low platelet count

platelet refractoriness. Indeed, prior to performing time-consuming and resource-rich antibody and molecular typing tests, nonimmune causes of platelet refractoriness should be ruled out. Individual patients may have significantly different responses to the same nonimmune causes of refractoriness, with some patients experiencing minimal impact and others having a markedly impaired response to platelet transfusions. Some patients, particularly those with multiple clinical complications (e.g., sepsis and fever), appear to respond particularly poorly to platelets approaching the end of the recommended storage interval (five days). Such patients may experience an improvement in their platelet response after receiving “fresh platelets”—platelets collected less than 48 hours earlier.<sup>76,85</sup>

### Treatment of the alloimmunized platelet-refractory patient

In the modern era, wherein universal leukocyte reduction of blood products for patients receiving multiple platelet transfusions has become standard practice, the rate of alloimmunization (primarily to HLA class I antigens) remains about 20%,<sup>20,84</sup> with the rate of refractoriness due to alloimmunization being about half of that. As such, not all patients who develop HLA alloantibodies will become platelet refractory.<sup>20</sup> The refractoriness, if related to HLA alloimmunization, can be transient or persistent. Generally, only sensitization to HLA-A and HLA-B is considered clinically significant as expression of HLA-C is low; however, sensitization to HLA-C has been implicated in some reports of platelet refractoriness.<sup>14</sup> Several approaches can be considered to provide such patients adequate platelet support: (1) HLA-matched platelets, (2) antigen specificity prediction (ASP, i.e., antigen negative platelets), (3) and cross-matched platelets.

As the majority of immune-mediated platelet refractoriness is due to HLA alloantibodies, the remainder of this section focuses on HLA alloimmunization-mediated platelet refractoriness with references to platelet-specific alloantibodies as appropriate. Clinically, it is also important to consider ABO antibodies, as discussed previously, which can lead to increased platelet clearance in the setting of ABO-incompatible platelet transfusion. A number of studies have demonstrated superior CCI with ABO-identical platelet transfusions compared to ABO-nonidentical transfusions.<sup>86</sup> Another immune-mediated cause of platelet refractoriness is drug-induced antibody, which are hypothesized to develop from drug and platelet surface glycoprotein interactions.<sup>34</sup> Implicated drugs include ceftriaxone, sulfamethoxazole/trimethoprim, quinine, piperacillin, and carbamazepine.

### HLA-matched platelet transfusions

Given that the primary cause of immune refractoriness to platelet transfusion is alloimmunization to HLA Class I, it is reasonable that the avoidance of incompatible HLA specificities should result in a more successful platelet transfusion response. This was first demonstrated in a study that showed that patients who were refractory to platelets from unselected donors could be successfully supported by the transfusion of platelet concentrates from an HLA-matched family member.<sup>87</sup>

Certain “private” HLA can be segregated into so-called cross-reactive groups (CREGs), defined by antibodies directed against shared “public” determinants.<sup>88</sup> These shared determinants are the basis for crossreactivity and are different from private determinants, which account for the highly polymorphic HLA system. Selection of platelet donors with antigens in the same CREGs as

the antigens in the patient, so-called crossreactive antigens, was demonstrated to be nearly as successful in supporting alloimmune platelet refractoriness in patients as that of HLA-identical transfusions.<sup>89</sup> This appeared to be due to the relative inability of the patient's immune system to recognize these crossreactive antigens as different, thereby greatly increasing the number of potentially compatible platelet donors in a given pool.<sup>90</sup> However, it is important to bear in mind that a patient can make antibody to more private determinants within a CREG group. Hence, just because a patient receives a crossreactive antigen platelet does not equate to compatibility, especially in highly sensitized patients.

In alloimmune refractory patients, the best increases in CCI occur with the subset of grade A and B1U or B2U HLA-matched platelets, but platelets mismatched for some antigens (e.g., B44 and B45) that are poorly expressed on platelets can also be successful.<sup>9</sup> Although alloimmunized patients with high percent reactive (HLA) antibody (PRA) values benefit only from platelet products that lack any incompatible HLA Class I (match grades A, B1U, B1X, B2U, and B2UX; Table 16.5), patients with lesser degrees of sensitization can sometimes benefit from less well-matched platelets.<sup>91,92</sup> However, in cases in which patients are highly sensitized (e.g., PRA > 90%), HLA-matched platelets may be a patient's best and only option.

Disadvantages of HLA-matched platelets include the need to HLA type patients and prospective donors. HLA typing is both time intensive and expensive. See Chapter 54 for details on HLA molecular typing methods. Depending on the method employed

and location of testing (in-house vs. reference laboratory), HLA typing can take anywhere from 24 to 72 hours. As such, providing HLA-matched platelets may delay the provision of compatible platelets. However, given that many platelet refractory patients are those who are being evaluated for or have already undergone hematopoietic stem cell transplantation, they may have already been HLA typed. In such cases, HLA matching would only entail an inventory search of HLA-typed donors. That being said, in order to find sufficient HLA-compatible matches to support a typical patient, it is estimated that a pool of 1000–3000 or more HLA-typed potential apheresis donors is generally needed.<sup>93</sup> Moreover, donor selection on the basis of HLA type can lead to the exclusion of donors whose HLA types, although different from that of the recipient, may still be effective. HLA-matched platelets can also be exceedingly difficult to procure for patients with rarer HLA haplotypes. In these cases, searching among family members for HLA identical/similar individuals may help identify appropriate donors.

Epitope-based matching, which is a current research focus in the HLA and solid organ transplant communities, has made its way into platelet matching. Epitopes can be short linear amino acid sequences or discontinuous amino acids that are spatially brought in proximity by the tertiary folding of the protein.<sup>94</sup> HLA molecules are composed of numerous epitopes, which can themselves be shared amongst numerous HLA molecules. Consequently, patients can be matched based on epitope profiles in lieu of antigen matching; and software has been developed to assist in epitope matching using recipient and donor HLA typing.<sup>95</sup> Epitope matching is well represented in solid organ transplantation literature. More recently, it has been employed in platelet matching. Studies have demonstrated that HLA epitope-based matching results in similar CCI increases when compared to traditional HLA matching.<sup>96,97</sup>

**Table 16.5** Classification of Donor/Recipient Pairs on the Basis of HLA Match

Match Grade	Definition	Example	
		Recipient	Donor
A	All four antigens* in donor are identical to those in recipient.	A*02, A*29 B*08, B*44	A*02, A*29 B*08, B*44
B1U**	Only three antigens are detected in donor; all are present and identical in recipient.	A*02, A*29 B*08, B*44	A*02, A*29 B*08, XX
B1X	Three donor antigens are identical to recipient; the fourth antigen is crossreactive with recipient.	A*02, A*29 B*08, B*44	A*02, A*29 B*08, B*45
B2U	Only two antigens are detected in donor; both are present and identical in recipient.	A*02, A*29 B*08, B*44	A*02, XX B*08, XX
B2UX	Only three antigens are detected in donor; two are identical with recipient, and the third is crossreactive.	A*02, A*29 B*08, B*44	A*02, A*30 B*08, XX
B2X	Two donor antigens are identical to recipient; the third and fourth antigens are crossreactive with recipient.	A*02, A*29 B*08, B*44	A*02, A*30 B*08, B*45
C	One antigen of donor is not present in recipient and non-crossreactive with recipient.	A*02, A*29 B*08, B*44	A*02, A*29 B*08, B*78
D	Two antigens of donor are not present in recipient and non-crossreactive with recipient.	A*02, A*29 B*08, B*44	A*02, A*29 B*7, B*78

\* Four antigens refer to both alleles at the HLA-A and HLA-B loci.

\*\* U: unknown/blank and is generally interpreted as homozygosity (designated XX) at one or both loci. However, the classification system was created when serology typing techniques were employed, which were not sensitive enough to detect all antigens, especially those within a CREG. As such, the assay might not identify antigens that were present, and thus the U designation.

NOTE: This classification scheme is included more for historical purposes and because some centers still use this terminology. However, HLA molecular typing has superseded the utility of matching grading.

### Antibody specificity prediction (ASP)

Despite best efforts, HLA-matched platelets are frequently unavailable for many refractory patients either due to rarity of recipient HLA type and/or insufficient pool of HLA-typed donors. In such cases, the use of the patient's HLA antibody specificity for the selection of platelet products has been demonstrated to widen the pool of compatible donors. Antibody specificity prediction (ASP) allows the procurement of platelet products from donors who lack HLA to which the patient has antibody. This approach is akin to supplying appropriate red blood cell (RBC) units to patients with blood group antibodies. One study compared ASP platelets to those selected by standard HLA matching criteria and by platelet crossmatching. All three methods were found to have similar platelet recoveries; however, the number of potential donors for each group was vastly different. For 29 alloimmunized patients, the mean number of potential donors found among 7247 HLA-typed donors was 6 for grade A HLA matches, 39 for BU matches, but 1426 (20% of total) for the ASP method. Hence, careful HLA antibody specificity identification could greatly enhance the number of potential donors by identifying nonmatched products that lack the corresponding HLA antigens.<sup>98</sup>

Current sensitive techniques for detecting and identifying HLA Class I alloantibodies using flow cytometry or Luminex (see Chapter 54 for HLA specificity testing methods) provide a precise way of determining the relative strength of multiple HLA alloantibodies that may be present in patient sera.<sup>99–101</sup> Though these test allow for the identification of HLA alloantibody specificities, their sensitivity can also detect low levels of alloantibodies that may not

induce platelet destruction but could limit the donor pool if they are considered in donor selection. Running antibody specificity assays in parallel with platelet crossmatches can help determine levels of HLA alloantibodies that correspond to positive crossmatches.<sup>102</sup> Such correlation studies may help set thresholds for risk stratifying HLA alloantibody specificities. Also, HLA alloantibody testing should be obtained periodically (e.g., weekly and monthly), given that the ASP method may lead to additional sensitization while a patient is transfused using platelet concentrates from nonmatched HLA donors.

In a small number of patients who fail to respond to HLA-matched or ASP-selected platelets and for whom no other nonimmune explanation can be found for refractoriness, platelet-specific alloantibodies may be responsible. Though there are many platelet-specific antigens (see Table 16.2), only a few, as discussed above, are commonly associated with platelet refractoriness.<sup>103</sup> Approximately 8% of multitransfused patients develop platelet-specific alloantibodies.<sup>20</sup> Many of these patients are also alloimmunized against HLA.<sup>104</sup> Patients with platelet specific alloantibodies can be successfully supported with platelets that are HPA typed and matched or selected by platelet crossmatching.

### Platelet crossmatching

Platelet crossmatching provides yet another modality to supply immune refractory patients with compatible platelet products. Many platelet and leukocyte antibody detection methods have been assessed as platelet crossmatch compatibility tests. One method that has gained wide acceptance is the commercially available solid-phase red cell adherence (SPRCA) assay. In this assay, patient serum is added to microwell plates with wells that have been coated in platelets from donor units.<sup>105</sup> Indicator RBCs coated in antihuman globulin are then added. In the presence of recipient antibodies, the indicator cells will adhere to the side of the wells; whereas in the absence of recipient antibody, indicator cells will aggregate at the bottom of the well. The test is rapid and sensitive, particularly for the detection of HLA alloantibodies, and is therefore suitable for routine platelet crossmatching.<sup>106,107</sup> Good correlation between test results and post-transfusion platelet counts has been achieved with the SPRCA assay.<sup>107,108</sup> Other methods for platelet crossmatching include a modified capture ELISA (MACE) and flow cytometry.

Platelet crossmatching has been shown to be efficacious in increasing the platelet count in immune refractory patients.<sup>109,110</sup> When compared to HLA-matched and ASP-selected platelets, crossmatch platelets also demonstrate comparable clinical efficacy.<sup>109,111,112</sup> However, some studies suggest that HLA selected platelets may be more long lived in vivo than crossmatched platelets.<sup>109</sup> Moreover, platelet crossmatching permits large numbers of platelet concentrates to be routinely tested and identification of compatible pools of platelets for refractory patients. The speed at which crossmatching can be performed can shorten the time to identify compatible platelets for immune refractory patients. One caveat is the delay incurred by institutions that are reliant on blood centers to perform platelet crossmatches. In addition to quick turnaround time, crossmatching offers the benefit of identifying compatibility in the face of platelet specific alloantibodies to platelet glycoproteins. If a patient is not responding to HLA-matched or ASP-selected platelets and the patient is found to have platelet-specific alloantibodies, crossmatching serves as an alternative to HPA-matched platelets. However, there are some drawbacks to platelet crossmatching. The degree to which a patient is

alloimmunized has an impact on the success of platelet transfusions selected by crossmatching assays. For patients who are highly HLA sensitized, numerous platelets may have to be crossmatched before finding a single compatible platelet. Indeed, if a patient has a PRA of 99%, all platelet crossmatches may yield incompatible results. In these cases, HLA-matched or ASP-selected platelets may be better alternatives. Another disadvantage of platelet crossmatching is the need to perform the assay every time transfusion is required.<sup>113</sup>

### Platelet refractory evaluation

The considerable effort and expense entailed in their procurement, HLA- or crossmatch-selected platelet products should be reserved for those refractory patients who (1) have had nonimmune refractory etiologies ruled out and (2) have definite evidence of alloimmunization by either HLA or platelet alloantibody testing. For those unfamiliar HLA alloantibody and antigen testing, selecting the appropriate tests at the right time opens up the possibilities of inappropriate test utilization and test misinterpretation. Complicating the evaluation is the possibility of platelet specific antibodies. Although the incidence of platelet-specific alloantibodies causing patients to be refractory to most or all attempted platelet transfusions is small, this possibility should be investigated when most of the attempted crossmatches are positive or when HLA-matched transfusions fail. If platelet-specific alloantibodies are present, donors of known platelet antigen phenotype or family members, who may be more likely to share the patient's phenotype, should be tested. In the event that testing fails to document alloimmunity (i.e., no HLA- or platelet-specific alloantibodies are identified), then support with randomly selected or ABO compatible platelet products should resume.

Given the complicated clinical workup, selecting the most appropriate method of platelet selection (HLA matching vs. ASP vs. crossmatching) can be difficult. The method selected should be made by weighing the pros and cons of each method (Table 16.6) in the context of the clinical picture and laboratory test results. To assist in both the workup of platelet refractoriness and product selection method, many have proposed diagnostic and management algorithms (Figure 16.2).<sup>102,113,114</sup> Employing diagnostic management team models, in which laboratorians assist in proper test utilization and interpretation, some have developed full platelet refractory consults, which have taken the onus off the clinical providers and can provide the appropriate products in timely fashion.<sup>115</sup> However, it is worth noting that despite the effort and expense involved in procuring compatible platelets, a positive impact on morbidity and mortality related to bleeding has not been demonstrated by using methods such as platelet crossmatching.<sup>116</sup> Furthermore, procuring serologically compatible platelets does not guarantee increased platelet count increments as there may be nonimmune mediated factors contributing to poor response. Indeed, up to 20% of refractory cases have been reported to have immune and nonimmune etiologies contributing to the overall clinical picture.<sup>117</sup>

### Overcoming established alloimmunization

Strategies attempting to reverse established alloimmunity to HLA have been met with limited success to date. Attempted methods include (1) methods to neutralize recipient alloantibody by absorption or removal, (2) temporal blockade of immune mediated

**Table 16.6** Advantages and Disadvantages of the Different Methods for Compatible Platelet Allocation

	Advantages	Disadvantages
HLA-matched	<ul style="list-style-type: none"> <li>• Useful for highly sensitized patients</li> <li>• Limits further sensitization</li> </ul>	<ul style="list-style-type: none"> <li>• Requires donor and recipient HLA typing</li> <li>• Restricts donor pool</li> <li>• Requires recruitment of HLA-typed donors</li> <li>• Does not help when platelet-specific alloantibodies are responsible for refractoriness</li> </ul>
ASP	<ul style="list-style-type: none"> <li>• Widens donor pool</li> <li>• Does not require recipient HLA typing</li> </ul>	<ul style="list-style-type: none"> <li>• Does not help when platelet-specific alloantibodies are responsible for refractoriness</li> <li>• Requires donor HLA typing</li> <li>• Requires repeat HLA antibody specificity testing to monitor HLA alloantibody profile and ensure continued provision of HLA compatible platelets</li> <li>• Risk of further sensitization to unmatched antigens</li> </ul>

Table modified from Forest and Hod.<sup>118</sup>

destruction of platelets, (3) suppression of the immune response to decrease the production of relevant alloantibodies, and (4) provision of modified platelets or alternative (nonplatelet) hemostatic compounds.

In thrombocytopenic immune refractory patients who are bleeding or who are at risk of bleeding, there is a theory that alloantibodies can be absorbed by large platelet dose transfusions. Some experts explain that they implement such strategies by repeat transfusions of platelets expressing antigen(s) to which the recipient has alloantibodies.<sup>34</sup> After antibody depletion, platelets expressing the same antigen(s) as those in the “in vivo adsorption” will hopefully yield better increment count responses as the corresponding alloantibody should no longer be present. Though similar anecdotal protocols exist, this method has not been heavily studied and/or published.<sup>119</sup>

Several studies investigated the utility of high-dose intravenous immunoglobulin (IVIG) to increase the platelet count in association with transfusion in refractory patients. The results of these studies have been highly variable.<sup>120–122</sup> To date the literature does not appear to support the use of IVIG in lieu of HLA-matched platelet transfusions.<sup>121</sup> Hence, IVIG is not commonly utilized in the treatment of immune refractory patients. Rh immune globulin (RhIG) infusions have also been studied in preventing refractory responses; however, patients treated with weekly intravenous RhIG infusions have similar rates of refractoriness to those treated with placebo, indicating that this form of reticuloendothelial system blockade is not helpful in preventing refractory responses.<sup>123</sup> Other strategies evaluated to overcome the platelet refractory state include the use of vinblastine-loaded platelet transfusions,<sup>124</sup> treatment with cyclosporin A,<sup>125</sup> immunoabsorption using staphylococcal protein

\* Crossmatch platelets may be ordered concurrently to the platelet-specific antibody test and HLA antibody screen if clinical need warrants quick provision of compatible platelets, or could be ordered depending on the results of the platelet-specific antibody test and HLA antibody screen if time is not a limiting factor.

**Figure 16.2** Algorithm to evaluate for platelet refractoriness.

A columns,<sup>126,127</sup> and plasmapheresis. A more recent report describes the coincident improvement in platelet response in a patient treated with bortezomib for multiple myeloma.<sup>128</sup> In addition, eculizumab, a complement inhibitor, has also been evaluated and indicated a potential to overcome platelet refractoriness in some patients.<sup>129</sup> Each strategy has had some limited success, but none can be recommended for routine use in this situation.

One approach that has been developed involves the transfusion of platelets that have undergone acid treatment, which modifies HLA Class I, making them less recognizable to the immune system.<sup>130,131</sup> Several potential platelet substitutes are also being investigated including lyophilized platelets, infusible platelet membranes, thromboerythrocytes, and thrombospheres. Whether any of these methods will have clinical relevancy remains uncertain.<sup>132,133</sup> The role of platelet growth factors such as interleukin-11 (IL-11)<sup>134</sup> and recombinant human thrombopoietin has also been studied, and shown to not only shorten the duration but also blunt the severity of thrombocytopenia after chemotherapy; however, toxicity and the development of thrombopoietin-neutralizing antibodies render these agents less effective.<sup>135</sup> These drugs may play more of a role in preventing rather than managing platelet refractoriness because responsive patients would require fewer platelet transfusions. There have been only limited studies of the newer thrombopoietin mimetic agents romiplostim or eltrombopag for refractory patients.<sup>136</sup> Finally, studies suggest an adjunct role of antifibrinolytics and recombinant coagulation factors in the prevention and management of bleeding in platelet refractory patients.<sup>137,138</sup>

### **Prevention of alloimmunization**

Supporting effective hemostasis in patients with immune-mediated platelet refractoriness is challenging once alloimmunization has occurred. Strategies to overcome immune mediated refractoriness are expensive and primarily consist of additional matched or cross-matched transfusions.<sup>2</sup> Thus, as a more practical modality to ensure continued successful platelet transfusion support, attention has turned to developing approaches to prevent alloimmunization from occurring.

One method to decrease the risk of forming an immune response to alloantigens on transfused platelet concentrates is the use of apheresis platelet units. Apheresis allows for the collection of platelet units that are from a single donor rather than a pool of whole blood derived platelet concentrates that typically consist of 5–8 different donors.<sup>139</sup> Thus, the major advantage of using apheresis platelet concentrates is that it limits antigenic exposure within a given transfusion as well as overtime. Both animal studies and clinical trials have shown that alloimmunization to HLA Class I molecules can be delayed, if not reduced by the provision of apheresis platelet units. Accordingly, the majority of platelet transfusions in the United States are now collected from apheresis.<sup>140</sup>

As an early murine study demonstrated that the removal of leukocytes from platelet concentrates could eliminate alloimmunity,<sup>141</sup> it is hypothesized that residual leukocytes are the immunogen responsible for alloimmunization to HLA following platelet transfusion. Due to this, strategies to reduce the number of residual leukocytes in platelet concentrates have been developed. Indeed, differential centrifugation of blood products reduces leukocyte numbers by separating distinct cellular populations. However, it does not sufficiently reduce alloimmunization to HLA following platelet transfusions. As a result, the removal of leukocytes is most often accomplished by passing blood components through third-generation leukocyte reduction filters that use a combination of adhesion and pore size to remove leukocytes. These filters result

in a 3–4 log reduction of leukocytes in platelet concentrates, meeting the US Food and Drug Administration's requirement of  $<5 \times 10^6$  total leukocytes per platelet concentrate. While these filters can be used at the bedside, the preferred method is to leukocyte reduce platelet concentrates prior to storage. Doing this allows for platelet concentrates to be generated according to good manufacturing practice regulations with well-defined quality control. Moreover, leukocyte reduction of platelet concentrates prior to storage prevents the formation of leukocyte fragments that can pass through filters and consequently sensitize recipients.<sup>142</sup> Leukocyte reduction of platelet concentrates can be accomplished through the use of a leukocyte reduction filter prior to storage.

The majority of clinical trials to date support the use of leukocyte reduction to decrease the risk of forming an alloimmune response to HLA in blood products. In 1998, 18 clinical trials (some randomized controlled and some nonrandomized) using leukocyte-reduced RBCs and platelet concentrates to prevent alloimmunization were reviewed.<sup>143</sup> Fourteen of these trials demonstrated a positive trend, if not a statistically significant reduction in alloimmunization to HLA and platelet refractoriness following the transfusion of leukocyte-reduced platelet concentrates, while three other trials<sup>27,144,145</sup> illustrated no statistically significant benefit from leukocyte reduction. However, a subsequent meta-analysis of eight randomized controlled trials demonstrated a clear protective effect of leukocyte reduction in decreasing the risk of alloimmunization to HLA and platelet refractoriness.<sup>146</sup>

The most definitive and landmark clinical trial demonstrating the importance of leukocyte reduction in decreasing the incidence of alloimmunization to HLA and refractoriness to platelet transfusion was the TRAP study.<sup>20</sup> This multi-institutional, randomized clinical trial compared de novo formation of alloantibodies and refractoriness in AML patients transfused with (1) unmodified, pooled platelet concentrates from random donors (control), (2) leukocyte-reduced pooled platelet concentrates from random donors, (3) ultraviolet B (UVB) irradiated pooled platelet concentrates from random donors, and (4) filtered platelet concentrates obtained by apheresis from single random donors. Of the 530 patients with no detectable alloantibodies at baseline, lymphocytotoxic alloantibodies were observed in approximately 45% of the control group compared with 17–21% of treated groups ( $p \leq 0.0001$  for each treated group compared with control). Moreover, roughly 13% of patients in the control group developed refractoriness in association with alloimmunization to HLA compared to only 3–5% of those in the treated groups ( $p \leq 0.03$  for each treated group compared to control). No statistical difference in alloantibody formation or platelet refractoriness was observed among the treated groups.

A second large, single institute study that found leukocyte reduction of platelet concentrates to be effective in reducing the rate of alloimmunization and refractoriness to subsequent platelet transfusions was a retrospective study from Canada, where universal leukocyte reduction of blood components was instituted between 1997 and 1999.<sup>21</sup> In this study, the rate of alloimmunization and refractoriness before and after the introduction of universal leukocyte reduction was examined in patients with acute leukemia or those undergoing stem cell transplantation. Patients transfused with universal leukocyte-reduced platelet concentrates were found to demonstrate a significantly decreased rate of alloimmunization to HLA, immune-mediated refractoriness, and a need for HLA-matched platelets. Indeed, the trigger for platelet transfusions was changed during the period of this study from 20,000 to 10,000 platelets/ $\mu\text{L}$ , resulting in considerably lower number of platelet transfusions for patients administered universal

leukocyte-reduced platelet transfusions. However, the trial found that leukocyte-reduced transfusions were a significant independent variable driving the lower rates of alloimmunization and refractoriness in these patient populations.

An alternative strategy that has been explored in parallel with leukocyte reduction technology to prevent alloimmunization following platelet transfusion is to treat platelet concentrates with ultraviolet irradiation.<sup>147</sup> Ultraviolet irradiation inactivates HLA Class I and II bearing cells (e.g., antigen presenting cells), thereby preventing the activation of recipient T cells even upon recognition of cognate HLA molecules. With the inability to activate, donor antigen presenting cells cannot upregulate costimulatory molecules and secrete cytokines, both of which are essential for optimal activation of recipient T cells. Instead, studies suggest that inactivated antigen presenting cells in ultraviolet B (UVB) irradiated blood products may possess the ability to induce immune tolerance.<sup>148–153</sup> However, murine studies demonstrate that ultraviolet irradiation of allogeneic platelet concentrates only diminishes the risk of developing alloantibodies to MHC Class I.<sup>150,151,154</sup> Similarly, clinical data from the TRAP study found that the transfusion of UVB-irradiated platelet concentrates associated with a decreased incidence (5%) of alloimmunization to HLA and platelet refractoriness in patients with acute myeloid leukemia compared to those individuals transfused with unmodified platelet concentrates (13%).<sup>20</sup> This rate of alloimmunization was found to be comparable to individuals that were transfused with leukocyte-reduced pooled or apheresis platelet concentrates. Nevertheless, despite being a promising and effective strategy to reduce the risk of forming alloimmune responses to HLA, UVB irradiation of platelet concentrates is not approved for use in the United States.

Pathogen reduction technology, initially developed to improve the safety of blood products by inactivating pathogens, has been explored as a means to reduce alloimmunization to platelet transfusions. Pathogen reduction technology essentially combines the therapeutic benefits of ultraviolet irradiation with a photosensitizer (e.g., riboflavin or psoralen) to kill or inactivate residual leukocytes that may also carry intracellular pathogens. Using this technology, several animal studies have demonstrated that pathogen-reduced platelet concentrates, whether in the presence or absence of leukocyte reduction or ultraviolet irradiation, generated a weak to undetectable alloimmune response to MHC.<sup>155–159</sup> As both ultraviolet irradiation and photosensitizer treatments damage DNA, the inability of pathogen-reduced platelet concentrates to induce an alloantibody response is likely due to reduced immunogenicity of residual leukocytes. Several preclinical studies have demonstrated that pathogen reduction induces tolerance through a variety of mechanisms.<sup>159–161</sup> However, several clinical studies evaluating the efficacy of various pathogen-reduced technologies (e.g., riboflavin + ultraviolet irradiation or psoralen + ultraviolet irradiation) unexpectedly demonstrated that alloimmunization and refractoriness appear to be increased in patients receiving pathogen-reduced platelet concentrates.<sup>162–166</sup> It is worth noting that the interpretation of these studies may be complicated by known confounding factors that could in general increase the risk of alloimmunization, and others have concluded that pathogen reduction is not associated with higher rates of alloimmunization.<sup>167</sup> For instance, trials to date have used stored pathogen-reduced platelet concentrates and pathogen reduction is known to enhance the development of platelet lesions as well as increase phosphatidylserine on platelets and downstream phagocytosis.<sup>168–171</sup> Thus, the disparate observations made in preclinical and clinical studies may be due to differences in the utilization of fresh or stored pathogen-reduced platelet

concentrates. In addition, the trials differed in whether concurrent gamma irradiation was used and exposure to other untreated allogeneic blood products, all of which could increase alloimmunization risk independent of pathogen reduction.

Several future directions are being explored as strategies to prevent alloimmunization. One such method is to strip platelet concentrates of HLA using chloroquine diphosphate or a citrate buffer. The rationale behind this approach is that lower antigen expression may render cells in platelet concentrates less susceptible to recognition; low antigen expression on RBCs has been shown to induce antigen-specific tolerance compared to RBCs expressing the antigen at normal levels.<sup>172</sup> Early studies indicated that HLA could be eluted from the surface of platelets following treatment with chloroquine or a low pH buffer.<sup>130,131,173–175</sup> However, subsequent studies found that citric acid treatment actually dissociates  $\beta_2$ -microglobulin from the heavy chain of HLA Class I molecules, resulting in a denatured HLA molecule on the surface of platelets.<sup>176</sup> Although not decreasing the expression level of HLA, the denatured HLA on citric-acid-treated platelets may possess the ability to modulate the immune response to HLA; a recent study demonstrated that acid treatment prevented the binding of alloantibodies against HLA, activation of the classical complement pathway, and antibody-mediated endocytosis of platelets.<sup>177</sup> Unfortunately, treatment with chloroquine or citric acid impacts the long-term functionality and viability of platelets.<sup>130,177,178</sup> Moreover, the clinical application of transfusing acid-treated platelets remains unclear, with some studies demonstrating a benefit but others not.<sup>179–181</sup> Thus, though there is potential for a therapeutic benefit of acid-treated platelets, additional studies investigating the impact of acid treatment on platelet function and the possibility of reassembling<sup>182</sup> HLA molecules or de novo synthesis<sup>183</sup> of HLA are still needed. Finally, over recent years, significant progress has been in the use of human-induced pluripotent stem cells (iPSCs) as a source for producing autologous, HLA-matched or HLA-universal donor platelets ex vivo.<sup>184–186</sup> iPSCs can be produced without donor dependency and possess the potential to not only eliminate alloimmunization to HLA but supply shortages of platelets. However, the clinical application of iPSC-derived platelets is still extremely premature, as this strategy still necessitates major optimization and characterization of the functionality as well as longevity of these platelets.

## Summary

Platelet transfusion remains an essential therapy for the maintenance of hemostasis in patients with thrombocytopenia or bleeding. Alloantibodies directed at platelet antigens, most notably HLA or HPA, may negatively impact transfusion responses, rendering patients platelet refractory and necessitating specific approaches to mitigate their effects and allow for efficacious transfusion. Ongoing efforts focused on both the prevention of alloimmunization and the development of new treatment strategies for patients with existing alloantibodies will aid in overcoming this significant clinical hurdle.

## CHAPTER 17

# Preparation, preservation, and storage of platelet concentrates

Moritz Stolla<sup>1,2</sup>, Valery J. Li<sup>1,2</sup>, & Johnathan P. Mack<sup>3</sup>

Platelet concentrates used for transfusions can be obtained from either pooling 4–6 whole-blood-derived units or be selectively collected from a single donor by various apheresis instruments. While the method may differ, the total number of platelets in each transfusable unit must contain at least  $3 \times 10^{11}$  platelets. In both methods, platelets are suspended in autologous plasma or a mixture of plasma and a saline-based additive solution.

### Preparation of platelets from whole blood: platelet-rich plasma method

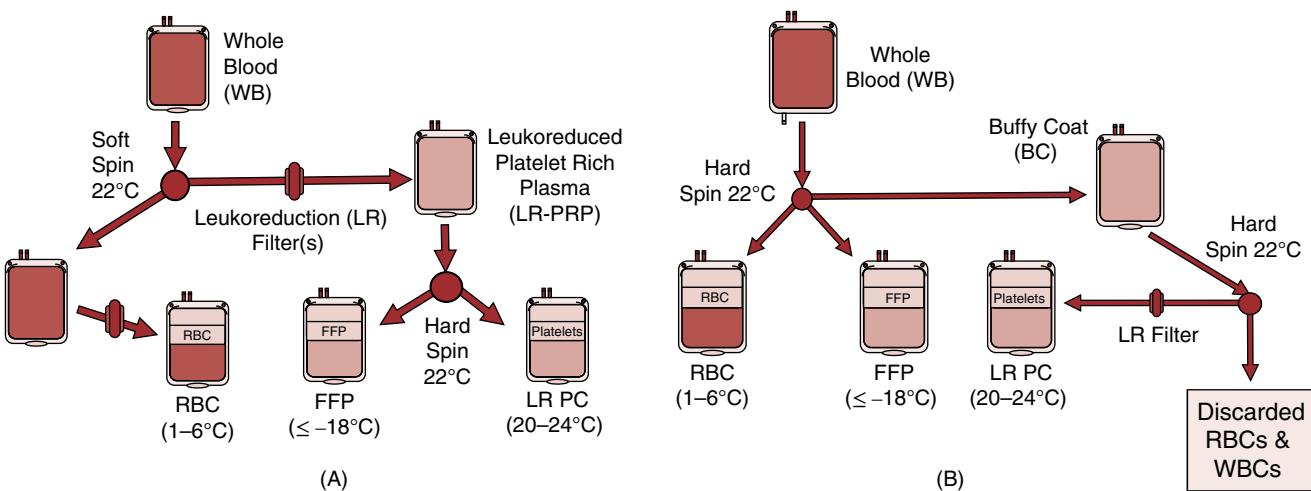

Platelet component therapy was facilitated by the advent of plastic storage containers in the late 1960s, enabling the direct transfusion of platelet-rich plasma to thrombocytopenic patients after a one-step “soft” centrifugation of collected whole blood.<sup>1</sup> At this time, blood was processed under refrigeration to prevent bacterial growth. The effort to increase the concentration of platelets in each unit by an additional “hard” centrifugation step was complicated by irreversible clumping at the bottom of the refrigerated bag. Mourad discovered that by allowing the centrifuged platelets to rest for 30 minutes at room temperature, they can be manually resuspended in residual plasma without major clumps.<sup>2</sup> A landmark finding by Murphy *et al.* demonstrated that platelet viability was best maintained by storage at ambient room temperature (20–24 °C).<sup>3</sup> Building upon this knowledge, Slichter and Harker introduced a preparation method that increased both the platelet yield and viability.<sup>4</sup> They discovered that a stepwise centrifugation process can recover 86% of the platelets from a unit of whole blood at room temperature: A soft spin to procure platelet-rich plasma (PRP) followed by a hard spin to concentrate the platelets (Figure 17.1A).

Following whole blood collection (WB), the product is held between 20 and 24 °C in storage. During transport from the collection center to the processing facility, the temperature is kept as close to 20–24 °C as possible. In the early 1970s, United States Food and Drug Administration (FDA) guidelines stipulated that platelet components be prepared within four hours of WB collection. However, Kahn *et al.* showed that platelet yield and recovery

in vivo were comparable with hold times of four, six, and eight hours. As a consequence, WB holding time was extended to six hours in the late 1970s.<sup>5</sup> In the 1980s, with the introduction of more gas-permeable storage containers, FDA guidelines were modified to allow component separation within eight hours of collection.<sup>6</sup> Many changes have been implemented over the years to optimize the production process. For example, companies have introduced new anticoagulants, improved bag materials, and integrated leukocyte reduction filters into collection sets. Blood centers have improved centrifugation protocols. Nevertheless, PRP remains the only FDA-licensed method of producing whole-blood-derived platelets in the United States at this time.

Whole-blood-derived platelets are formally known as *Platelets* per FDA nomenclature (colloquially, random-donor platelets [RDPs]). AABB and the FDA mandate that a unit of *Platelets* contains at least  $0.55 \times 10^{11}$  platelets suspended in 40–70 mL of plasma.<sup>7,8</sup> Modern concentrates usually contain an average of  $0.9 \times 10^{11}$  platelets with a relatively wide ( $\sim 0.27 \times 10^{11}$ ) standard deviation. This requires a pool of at least five concentrates to ensure 99% of pools contain at least  $3 \times 10^{11}$  platelets, the minimum dose as stipulated by AABB/FDA for apheresis platelets.<sup>9</sup> An integrated filter between the primary blood container and the platelet bag facilitates leukoreduction. PRP is expressed off of the RBC product through the filter after the initial centrifugation.<sup>10</sup> While filtration can cause ~4–5% loss of platelet content, leukocyte reduction results in a  $\geq 3$  log reduction in white blood cell (WBC) content, satisfying the FDA’s requirement for residual WBC count  $<0.83 \times 10^6$  per unpooled unit and  $<5 \times 10^6$  per pooled unit.<sup>11</sup>

Individual units of *Platelets* or *Platelets Leukocytes Reduced* can be pooled either pre- or poststorage. Prestorage pools are more convenient as they can be placed in licensed and validated containers, and thus have a five-day outdate compared to the four-hour outdate for poststorage pools performed in an open system. *Platelets* or *Platelets Leukocytes Reduced* are primarily used for neonatal transfusion, for which one or two units constitute a therapeutic dose.

**Figure 17.1** Platelet production methods. RBC: red blood cell; FFP: fresh frozen plasma; LR: leukocyte reduced; PC: platelet concentrate.

### Preparation of platelets from whole blood: buffy-coat method

In contrast to the United States, the buffy-coat (BC) pooling method is widely used in Europe. Europeans noted the substantial number of residual WBCs  $>10^9$  in RBC products after the initial “soft spin” and the formation of microaggregates between WBCs and platelets.<sup>12</sup> Thus, Prins and colleagues in the Netherlands began using the buffy-coat method to produce blood components in the 1970s.<sup>13</sup> Whole blood donations undergo a “hard spin” initially to separate plasma and RBCs from the buffy-coat layer, containing platelets and WBCs. Four to six buffy coats of the same ABO blood group are pooled, resuspended in plasma from a male donor (in the United Kingdom and Canada) or in a platelet additive solution (PAS; most of continental Europe) and a second centrifugation step “soft spin” to separate the WBCs and residual RBCs from the platelets (Figure 17.1B).<sup>14</sup> The resultant product is passed through a leukocyte reduction filter to produce a prestorage pool with  $<1 \times 10^6$  residual WBCs per unit per European leukocyte reduction standards.<sup>15</sup> Compared to the PRP method, the BC method yields an average platelet product with nearly equivalent platelet content and 10% fewer contaminating white cells before leukoreduction. In addition, the RBC component has about 20 mL fewer red cells and one log fewer white cells. There is also about 30–75 mL more recovered plasma.<sup>16</sup> In 2005, Canadian Blood Services switched from PRP method to BC method to alleviate the chronic strain to platelet inventory and improve logistic hurdles. The BC method used butanediol plates within transport containers to rapidly cool and hold WB at 20–24 °C for up to 24 hours before manufacturing. The overnight hold at room temperature permits exclusive day-shift manufacture and eliminates multiple trips from collection sites to the processing lab. A more theoretical advantage of BC-method production may be less early activation that contributes to platelet loss during storage as platelets are centrifuged against a cushion of RBCs rather than the nonphysiologic plastic container of the PRP method.<sup>17</sup>

Recently, there have been calls by US blood centers to transition from the PRP method to the BC method to optimize the use of all donated products.<sup>18</sup> Automated expression technology contributes to process control, making the BC method potentially even more economical while improving product

standardization.<sup>19</sup> Currently, ~70% of platelet units are prepared from whole blood in Canada, while >85% of platelets are prepared from WB in Denmark, Spain, and the Netherlands.<sup>20</sup> These countries demonstrate that a national platelet supply can be derived predominantly from WB instead of from apheresis. Between 2008 and 2017, the proportion of BC platelet distributions from 11 centers outside the United States increased from approximately 35–60%.<sup>21</sup>

### Preparation of platelets from plateletpheresis

Platelets produced by apheresis are called *Platelets, pheresis* by the FDA (informally, single donor platelets [SDPs]). Recognition by Yankee *et al.* that poor platelet increment in recipients was associated with human leukocyte antigen (HLA) alloimmunization in 1970s led to increased single-donor utilization apheresis platelets. This was implemented not only for platelet-refractory patients but also to minimize donor exposure for the general patient population.<sup>22</sup> It is estimated that apheresis platelets account for ~90–95% of all platelet usage in the United States.<sup>23</sup>

Automated apheresis instruments have evolved over the years to obtain multiple platelet doses from a single collection. In-process leukocyte reduction became possible with better separation controls, so *Platelets, pheresis Leukocytes Reduced* now contain  $<5 \times 10^6$  WBCs. Unlike WBD platelets, red cell content in apheresis platelets is very low and often (but not always) below the dose of red cells associated with RhD alloimmunization.<sup>24,25</sup> There are several licensed apheresis instruments that separate platelets in different ways (see Chapter 22 for more detail). Some devices employ a disposable plastic centrifuge chamber from which a layer of PRP is siphoned into a collection bag. Others use a spinning channel with two-stage plastic inlays to initially separate the RBCs from the PRP and then remove plasma from the platelet product. Yet another device uses an elutriation mechanism. This device moves platelets away from the RBC layer, separates the PRP, and then hyperconcentrates platelets along a collection bag wall before plasma resuspension in a storage container. This heterogeneity of collection technologies leads to apheresis products that are not necessarily similar and may not always produce equal platelet increments in a given recipient.<sup>26</sup>

## Alternative sources of platelets

An entirely different approach to collecting platelets from peripheral blood is the generation of platelets from stem cells ex vivo. Possible advantages are preparing and storing patient-specific precursor cells and an inventory-independent, donor-independent reservoir of platelets. Different groups reported the differentiation of CD34+ hematopoietic precursor cells from peripheral blood, cord blood, bone marrow, stromal cells, and fetal liver cells.<sup>27–36</sup> However, the low proliferation capacity of these cells leads to a dependence on donors and thereby eliminates some of the postulated advantages of in vitro generation. The utilization of embryonic stem cells and induced pluripotent stem cells (iPS) represents a source with unlimited proliferation capacity.<sup>37–42</sup> While utilizing embryonic stem cells raises ethical concerns limiting their application to research questions, this reservation does not apply to iPS cells. Another advantage of iPS-derived platelets is using patient-specific, reprogrammed cells to generate a personalized product for alloimmunized patients. In vitro generated megakaryocytes and platelets have similar characteristic features as cultured, native megakaryocytes.<sup>43</sup> Platelets from iPS and embryonic cells are hypo-reactive compared to adult platelets.<sup>44–47</sup> Whether this is beneficial or detrimental for transfusion outcomes remains to be investigated. Age-mismatched transfusions have recently been problematic when higher transfusion triggers of adult platelets worsened premature infants' outcomes.<sup>48</sup> High costs and low platelet yields per megakaryocyte still represent major bottlenecks for the routine clinical application of these cells. Another more manageable challenge is the application of good manufacturing practices. Transfusion of in vitro generated megakaryocytes could represent an alternative. Using this approach, the lung could represent a natural bioreactor for platelet generation in vivo. At least in mice, the lung appears to be involved in platelet biogenesis at a steady state.<sup>49</sup> Furthermore, human data, including radiolabeling studies with megakaryocytes or platelets in humans, are largely missing.<sup>50</sup>

## Storage conditions

Once the circulatory survival benefit of room temperature processing and storage was appreciated, platelets were kept for up to three days in the first generation of plastic containers. As improvements were made in platelet storage technology, shelf life was first increased to five days and then to seven days. In 1986, the FDA mandated a return to a five-day shelf life because of increasing reports of bacterial sepsis associated with prolonged 20–24 °C storage.<sup>51</sup> Detection methods for bacterial contamination were required in 2004 (discussed in detail in Chapter 53), but the re-extension of storage duration was delayed because of concerns about the poor sensitivity of standard testing (29–40%).<sup>52–54</sup> However, improvements in bacterial testing and pathogen reduction technologies have led to the extension of platelet storage life to seven days in several countries, including Canada, the Netherlands, Switzerland, and the United Kingdom. Draft guidance from the FDA permitted the extension of platelet storage up to seven days with rapid bacterial testing or up to five days following pathogen reduction.<sup>55</sup> A new FDA guidance published in 2019 will bring widespread changes in bacterial testing by blood centers and hospitals in the United States.<sup>56</sup>

When released into circulation from the bone marrow, platelets survive for approximately 9–10 days and are removed by senescence, consumption during maintenance of vascular integrity (normally,  $\sim 7.1 \times 10^9/\text{L/day}$ )<sup>57</sup>, or clot formation to control pathologic bleeding. Room temperature storage appears to slow platelet

metabolic activity by almost 60% compared with in vivo activity at 37 °C.<sup>58</sup> This suggests that seven days of storage may lead to only three days' worth of in vivo senescent loss. Efficacy-wise, it is well known that platelet recovery and survival continuously decline over storage time.<sup>59</sup> Progressive loss of recovery can be observed over the first five days of storage<sup>60</sup> and further decline by seven days.<sup>61,62</sup> Some storage lesion features, such as pH, differ significantly between five-day stored and seven-day stored platelets.<sup>63</sup> Three systematic studies examined the effect of storage time on clinical outcomes.<sup>64–66</sup> The freshest units (<2–3 days of storage) consistently resulted in the highest corrected count increments (CCIs). In stable hematology patients, six- or seven-day stored platelets resulted in similar corrected count increments, bleeding events, and time to next platelet transfusion compared with 2–5-day stored platelets, supporting extended room temperature storage.<sup>67</sup>

Storage conditions that minimize platelet loss by inhibiting platelet activation, senescence (apoptosis), or metabolic exhaustion might, in theory, permit the extension of PC shelf life well beyond seven days. Certain experimental conditions appear to allow for extended storage at room temperature with remarkable in vivo characteristics. The investigators collected platelets with an elutriation apheresis device and replaced most plasma with an additive solution.<sup>68</sup>

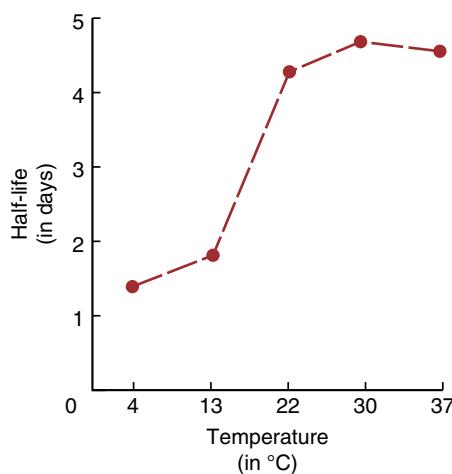

The critical variables affecting stored platelet health are (1) temperature, (2) metabolic fuel availability, and (3) respiratory capacity. The last variable is dependent on platelet content, gas diffusion through the plastic container, and agitation. Activation occurring during collection and processing appears to be somewhat reversible, but excessive activation may also lead to platelet loss.

## Metabolic concerns during storage: temperature

When platelets are exposed to the cold, their plasma membranes undergo phase transitions that result in the coalescence of lipid rafts. This leads to shape change and activation priming, clustering of neopeptope-expressing glycoprotein (GP)-I $\beta$  $\alpha$  domains with enhanced von Willebrand factor (vWF) binding capacity, and acceleration of platelet apoptosis.<sup>69–73</sup> The in vivo platelet cold sensitivity presumably facilitates activation at wound sites on the cooler body surface while removing repetitively primed platelets to prevent core thrombosis.<sup>74,75</sup>

Membrane phase transitions begin at temperatures below 30 °C, bringing phosphoinositide-rich lipid rafts together.<sup>74,76</sup> Resultant phosphoinositide release results in an increase in intracellular calcium, which is associated with activation priming. Indeed, the in vitro function of cold stored platelets exceeds that of room temperature stored platelets, prompting a call for the re-evaluation of the role of cold stored platelets when immediate hemostasis is paramount (e.g., after trauma).<sup>77</sup> Hypothermic membrane changes also result in a clustering of the principal vWF receptor, GP-Ib/IX/V.<sup>74</sup> The function of the receptor appears to be enhanced by clustering. However, lectin-binding domains of hepatic macrophages and hepatocyte receptors recognize sugar changes on clustered GP-I $\beta$  $\alpha$  subunits and rapidly remove these platelets. Hence, the circulation time of these potentially more hemostatically active chilled platelets is shortened.<sup>77</sup>

The reversibility of cold-induced platelet membrane changes is both time- and temperature-dependent. Figure 17.2 shows the effect of 18 hours of storage at various temperatures upon the half-life of radiolabeled autologous platelets after reinfusion into healthy volunteers. Temperatures above 20 °C resulted in normal platelet survival.<sup>3</sup> Holme *et al.*<sup>78</sup> reported that significant loss of platelet circulatory capacity occurred after 24 hours at 18 °C, 16 hours at

**Figure 17.2** *in vivo* survival of radiolabeled autologous platelets stored at various temperatures for 18 hours.<sup>3</sup> Source: Reproduced from Dr. Ralph Vassallo.

16 °C, 10 hours at 12 °C, and 6 hours at 4 °C. Storage above the 20–24 °C temperature described as optimal by Murphy and Gardner did not result in measurable damage but was accompanied by increased metabolism compared with room temperature storage. The salutary metabolic effects of room temperature storage include decreased in vitro aging and slower accumulation of toxic metabolites within the platelet container. There is, however, a reversible loss of function that recovers only after a variable period of time in circulation.<sup>77</sup> The ability of room temperature stored platelets to circulate for longer periods of time, despite transiently decreased activation capacity, is desirable in preventing spontaneous hemorrhage in chronically thrombocytopenic transfusion recipients.

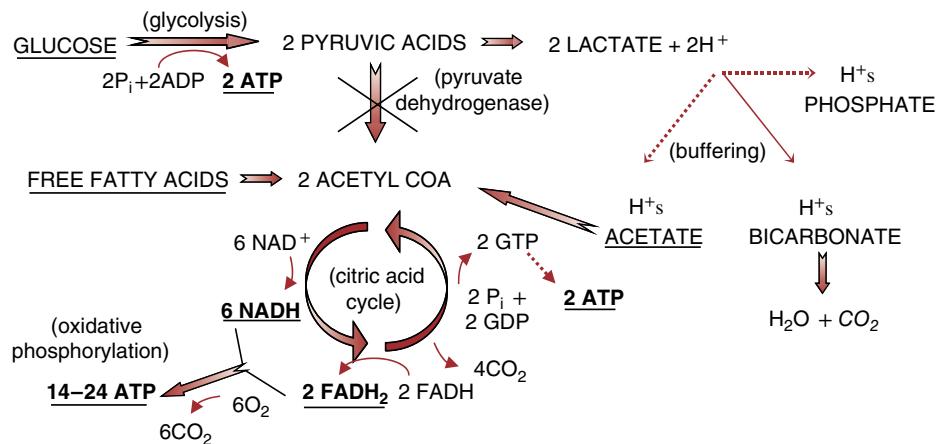

### Metabolic concerns during storage: metabolic fuel availability

Stored platelets must catabolize substances within their suspension medium to regenerate adenosine triphosphate (ATP), the cell's principal "energy currency." Figure 17.3 shows the pathways for ATP regeneration.

Seminal studies of glucose consumption and lactate production in PRP-PCs revealed an approximately 1:2 ratio consistent with predominantly anaerobic glucose metabolism. Pyruvate dehydrogenase, which produces acetic acid for the aerobic citric acid cycle, appears to be downregulated in stored platelets. Glucose metabolism in platelets ends with only 2 moles of ATP per mole of glucose consumed. Lactic acid is buffered primarily by plasma bicarbonate, which results in the production of CO<sub>2</sub>.<sup>79</sup> This CO<sub>2</sub>, a volatile acid, diffuses through the storage container wall. Progressive depletion of bicarbonate thus occurs through lactic acid buffering and slow spontaneous dissociation to CO<sub>2</sub> and water. Once bicarbonate is consumed, continued lactic acid production ultimately results in a deleterious decrease in product pH.

Aerobic metabolism through the citric acid cycle and oxidative phosphorylation is a far more efficient energy source, yielding up to 13 moles of ATP per mole of acetic acid entering the cycle. Comparison of platelet oxygen consumption (approximately 6 moles of ATP produced per mole of O<sub>2</sub> consumed) with lactate production (1 mole of ATP per mole of lactate) suggests that approximately 85% of platelet energy is derived from aerobic metabolism in continuously agitated PCs.<sup>80</sup> Studies using radiolabeled palmitate identify free fatty acids derived from plasma triglycerides as the predominant metabolic fuel for platelets stored in plasma.<sup>73</sup> A small, rather insignificant component results from the metabolism of the amino acid glutamine.<sup>72</sup> Efforts to identify plasma-sparing PAs led to the discovery that acetate could serve as an effective alternative fuel to plasma free fatty acids.<sup>71</sup> As described below, acetate also provides a valuable lactate-buffering function by consuming a hydrogen ion during its metabolism.

Under low oxygen conditions, glycolysis is upregulated six- to sevenfold, the so-called Pasteur effect.<sup>70</sup> Although this satisfies energy requirements in the absence of aerobic metabolism, it results in a considerable increase in lactic acid production, which can exacerbate plasma buffer exhaustion and produce deleterious declines in pH. Mechanical factors also affect platelet oxygenation. Mitochondrial oxygen starvation can occur with interruption of agitation during shipping, accompanied by an expected increase in lactate generation and pH decrements.<sup>69</sup> Studies have shown that platelets begin to suffer deleterious effects below a pH of 6.5–6.8 at room temperature (22 °C) and are irreversibly damaged in the face

**Figure 17.3** Pathways of platelet adenosine triphosphate (ATP) regeneration from inorganic phosphate (P<sub>i</sub>) and adenosine diphosphate (ADP). Metabolic fuels are underlined. Energetic intermediates are underlined. Carbon dioxide (CO<sub>2</sub>) is produced from hydrogen ion (H<sup>+</sup>) buffering and oxidative metabolism of acetyl CoA. AMP: adenosine monophosphate; PPi: pyrophosphate; GDP/GTP: guanosine di/triphosphate; NAD/NADH: nicotinamide adenine dinucleotide/reduced NAD; FADH/FADH<sub>2</sub>: reduced flavin adenine dinucleotide forms. Source: Reproduced from Dr. Ralph Vassallo.

of a sustained pH below 6.2 at 22 °C.<sup>79,81</sup> Efforts to extend platelet storage have been limited by the constitutive glycolytic production of lactate, even with maintenance of adequate oxygenation. Glycolysis can also be transiently upregulated by activation associated with platelet separation.<sup>82</sup> Attempts to develop glucose-free additive solutions to minimize the production of lactate have not been successful. Despite the presence of sufficient amounts of alternate fuels (e.g., acetate), once PCs exhaust their supply of glucose, they deplete their adenine nucleotides and a host of other metabolic intermediates, leading to cell death.<sup>71,83</sup> The reasons for this are poorly understood but may be related to substrate depletion of the antioxidant pentose phosphate shunt and an as-yet-unexplained link between glucose metabolism and mitochondrial function. Adenine nucleotide depletion during storage has been characterized in PRP-PCs.<sup>84</sup> After seven days of storage, adenine nucleotide levels in PCs (in both metabolic and storage granular pools) decline to 70% of those initially present.<sup>85</sup> Although platelet ATP levels are not predictive of platelet quality except at extremely low levels, energy depletion is responsible for a host of deleterious effects that ultimately culminate in platelet senescence or necrosis.

Proteomic and metabolomic studies have shed additional light on platelet storage metabolism.<sup>82,86,87</sup> Regardless of the separation method, there appears to be a transition from active aerobic and glycolytic metabolism to a state of metabolic decay characterized by progressive depletion of intermediates. This is posited to occur due to mounting activation stimuli, both outside-in and inside-out, which reach an irreversible tipping point after three days of storage under current conditions. In vitro suppression of signaling proteins appears to delay the metabolic shift from maintenance to activation, but this laboratory approach has not resulted in an inhibitor suitable for clinical use.<sup>82</sup>

### **Metabolic concerns during storage: respiratory capacity**

Maintenance of aerobic metabolism requires a PO<sub>2</sub> above 5–10 mmHg.<sup>80</sup> Because oxygen consumption is relatively constant per platelet, the presence of a high total platelet bag content stresses the storage container's oxygen permeability. When PC consumption exceeds the ability of the container to transport oxygen, the PO<sub>2</sub> will decline to hypoxic levels over several days, leading to the upregulation of glycolysis, lactic acid accumulation, and a deleterious decrease in pH. Gases diffuse across storage container walls driven by their gradients once the plastic is saturated. Each manufacturer's container has a different gas permeability related to the wall thickness and the plastic's unique gas transport capacity. Oxygen delivery also depends upon the container's ratio of the volume-to-surface area and continuous agitation, which promotes gas diffusion and helps maintain normal platelet oxygen consumption.

Kilkson *et al.*<sup>80</sup> demonstrated that across the CO<sub>2</sub> concentrations seen in PCs stored in the least permeable containers (10–100 mmHg), little pH change is attributable to the carbonic acid formation from aqueous CO<sub>2</sub> and H<sub>2</sub>O. Lactate concentration was shown to be the principal determinant of pH. Thus, high CO<sub>2</sub> permeability is not as critical as adequate oxygen permeability. High CO<sub>2</sub> permeability can lead to an early increase in pH as the PCO<sub>2</sub> falls from physiologic plasma levels, unbalanced by significant lactic acid accumulation. A pH >7.4 at 22 °C may result, which has been associated with cellular damage with earlier forms of agitation. Although European regulators have set 7.4 pH as the upper limit of acceptable end storage at 22 °C, a comprehensive study noted that

with modern forms of agitation, a pH >6.3 at 22 °C, had no predictive value for platelet viability (in PCs compliant with licensed maximum and minimum platelet contents and concentrations).<sup>88</sup>

From the foregoing discussion of metabolic fuel requirements, it is evident that high platelet content will increase constitutively produced levels of lactic acid and that high platelet concentrations also result in fewer plasma buffers per respiring platelet, both of which may lead to deleterious drops in pH. Less intuitive are the harmful effects of low platelet contents and concentrations. Adverse effects in these situations result from low CO<sub>2</sub> and lactate production, which initially increase PC pH. Why these products develop metabolic exhaustion and adenine nucleotide depletion is not entirely clear, but some forms of agitation further increase this effect at higher pH values.

The very first containers, made of polyvinyl chloride (PVC) plasticized with di-(2-ethylhexyl) phthalate (DEHP), were originally designed for freezing plasma. Serendipitously, they allowed enough oxygen and CO<sub>2</sub> diffusion across their walls to permit room temperature platelet storage of relatively lower content PCs for three days before the pH decreased to unacceptable levels. Containers were later specifically designed for improved gas permeability as trial and error revealed that PCs stored in more gas-permeable containers had lower pH failure rates (pH <6.2 at 22 °C).<sup>89</sup> The so-called second-generation containers appear to store PRP-PCs for at least seven days without deleterious pH decrements. Because apheresis PCs and prestorage pooled PRP-PCs have such heterogeneous contents, each unit must be assayed to ensure that total platelet content and concentration limits validated by the container manufacturer are not exceeded. The platelet concentration of donor blood limits individual WBD-PC content to values below those accommodated by newer storage containers. Second-generation containers currently in use are manufactured from polyolefin, ethylene-vinyl acetate (EVA), or PVC that is thinner or plasticized with different compounds such as triethyl hexyl trimellitate (TOTM) and butyryl-tri-hexyl citrate (BTHC).<sup>90</sup> These bags provide nearly twice the oxygen permeability of first-generation DEHP-plasticized PVC containers.<sup>91</sup>

The need for continuous agitation was also recognized as a means of facilitating oxygen utilization.<sup>89,92</sup> Several different types of platelet rotators have been used over the years. Ferris wheel and elliptical rotators have given way to face-over-face tumblers (3–6 rpm) and flatbed platform shakers (50–70 cpm) because of inefficient maintenance of pH or damage to platelets at pH >7.4 at 22 °C.<sup>79</sup> Initially thought to promote oxygen diffusion throughout the PC, agitation appears to exert a more complex effect on platelet metabolism. Several groups have shown that PO<sub>2</sub> was maintained in unagitated PCs and that mixing of products even once a day could prevent injurious pH decrements in relatively lower content platelet products.<sup>93,94</sup> Agitation, therefore, may also facilitate oxygen utilization by platelet mitochondria or prevent settling and a platelet contact-mediated switch from oxidative to glycolytic metabolism.<sup>95</sup> In any case, even with relatively higher content PCs, agitation may be safely interrupted for 24 hours (as during shipping) without undue lactate accumulation and subsequent development of injuriously low pH.<sup>95,96</sup>

### **The platelet storage lesion**

Stored platelets experience a progressive decline in function accompanied by characteristic morphologic changes. Studies document up to 20% loss of platelet recovery through five days of storage.<sup>60</sup> In apheresis containers currently licensed in the United States, Day 7

recovery is approximately 83% of Day 5 recovery.<sup>61,62</sup> This progressive damage has been termed the *platelet storage lesion*.<sup>97,98</sup> Well-characterized changes are seen in common tests assessing platelet morphology, activation, cell metabolism and function, and apoptosis. Some, but not all, of these changes are reversible upon platelet transfusion.<sup>99</sup>

The gold standard for evaluating product efficacy remains post-transfusion bleeding assessments. However, the large patient numbers required and related time and expense usually lead to the substitution of surrogate measurements such as patient-adjusted count increments assuming that a circulating platelet is a functional one. An even less costly alternative involves the reinfusion of healthy volunteers with autologous stored platelets radiolabeled with chromium-51 or indium-111. (Cell kinetics are described in greater detail in Chapters 7, 18, and 22.) Percent recovery and survival may be calculated by serial assay of postinjection blood radioactivity. Platelet recovery is significantly affected by individual differences in splenic sequestration (usually ~33%) and blood volume estimation errors during calculations. Murphy proposed that products be evaluated against concurrently injected fresh autologous platelets to establish a fixed, rather than floating, standard.<sup>100</sup> This facilitates the comparison of interventions designed to ameliorate the storage lesion. Although in vitro tests have attempted to rapidly and economically predict the ability of transfused platelets to circulate, only extreme values have documented any correlation with outcomes.<sup>101,102</sup> Accordingly, batteries of tests are often examined to ensure product equivalency after minor changes or as the first step in the assessment of more substantive changes in storage methods.

Alterations from normal discoid morphology are observed during platelet storage. Kunicki described a scoring system that assigned four points to discs, two to spheres, one to dendritic forms, and none to ballooned platelets.<sup>103</sup> Multiplied by the percentage of each form seen under phase contrast microscopy, scores decline from a maximum of 400 as changes associated with the storage lesion progress. Others have advocated simply reporting the percentage of discoid forms. The extent of shape change assay uses aggregometry to measure the decrease in light transmission after adenosine diphosphate stimulation of stirred PRP in the presence of EDTA to prevent aggregation.<sup>104</sup> Because only discoid platelets can change shape and block more light, the assay provides a more objective measure of the percentage of discoid platelets. All three approaches appear to correlate somewhat with *in vivo* recovery and survival at high or low assay values but predict less well for in-between values. The mean platelet volume decreases throughout storage when membrane loss from dendritic forms occurs or when activation or apoptosis results in microvesiculation.<sup>105</sup>

Platelet activation during processing and throughout storage is accompanied by surface expression of sequestered granular membrane proteins (P-selectin and CD63) and conformational changes of the fibrinogen receptor,  $\alpha$ IIb $\beta$ 3 (GP-IIb/IIIa). Release of specific granular contents into the supernatant ( $\beta$ -thromboglobulin, platelet factor 4, etc.) also occurs throughout platelet storage as a manifestation of activation. However, this may not be specific for activation because granular content release also occurs with platelet lysis. Similarly, platelet procoagulant activity (surface expression of membrane phosphatidylserine) appears not only with activation but also during cellular apoptosis. None of these indicators of platelet activation appear to correlate reliably with platelet recovery and survival. However, studies of storage medium supplementation with activation inhibitors suggest that activation contributes in part

to the platelet storage lesion.<sup>106</sup> As previously noted, the use of activation inhibitors in storage media has not gained widespread acceptance because of inconsistent results, toxicity, and the expense of licensing novel storage systems.

The ability of stored platelets to function normally has been assessed in several ways, and only one functional assay—hypotonic shock response—has proven to be of value in assessing platelet viability. Measurements of platelet ATP levels do not consistently provide reliable information.<sup>85</sup> Aggregation studies similarly fail to predict platelet viability. Responsiveness to single agonists rapidly declines during storage but can recover with plasma rescue or *in vivo* reinfusion.<sup>82</sup> Responses to agonist mixtures, although better preserved, are still not helpful in assessing viability.<sup>107</sup> The hypotonic shock response or osmotic reversal reaction exposes platelets to a hypotonic environment. Metabolically active platelets rapidly extrude water after initial swelling. Recovery of normal intracellular water content can be quantified using light transmittance. Significant changes in values for this assay have been shown to correlate with *in vivo* recovery and survival.

Markers associated with cellular apoptosis accumulate throughout platelet storage with evidence of caspase activation, structural protein degradation, and mitochondrial membrane potential changes.<sup>108,109</sup> Although apoptotic inhibitors can ameliorate some of these changes, they have not improved platelet viability, casting doubt upon cellular senescence as a significant contributor to the platelet storage lesion.

### **Platelet additive solutions (synthetic storage solutions)**

In Europe, synthetic storage solutions, also called PASs, have been used routinely for two decades.<sup>110</sup> In the United States, PASs were approved for use in 2010. The use of PASs allows<sup>1</sup> greater plasma recovery from whole blood donations for transfusion or fractionation;<sup>2</sup> minimization of the adverse effects mediated by plasma (e.g., allergic and febrile nonhemolytic transfusion reactions [FNHTRs] and possibly the reduction of ABO isoagglutinin-mediated hemolysis or antibody-mediated transfusion-related acute lung injury [TRALI]); and potential improvements in platelet storage through engineered manipulation of the storage medium.<sup>111,112</sup> Platelet collection with the Amicus collection system allows for the addition of PAS and thereby facilitates the use of photochemical pathogen reduction technology. In contrast, pathogen-reduced platelets from the Trima system are all in plasma as per FDA.

Early studies demonstrated the feasibility of suspending PRPPCs in a commercially available, neutral intravenous crystalloid solution, Plasmalyte A.<sup>113</sup> The 10–20% plasma carried over in the storage medium provided the sole source of glucose and bicarbonate. *In vitro* results were quite encouraging, and versions of this PAS containing additional glucose and citrate were shown to be promising *in vivo*. However, the solution was not successfully commercialized.<sup>114</sup> When Murphy tested another balanced salt solution, the *in vivo* results were disappointing.<sup>115</sup> In retrospect, the deletion of acetate from Murphy's so-called PSM-2 solution was likely responsible for the pH failures seen *in vitro*. Acetate can efficiently substitute in the citric acid cycle for free fatty acids, the primary *in vivo* substrate for oxidative metabolism (Figure 17.3), decreasing both the glycolytic rate and lactic acid generation.<sup>116</sup> Acetate must also be transformed to acetic acid to enter the cycle, removing hydrogen ions produced by the anaerobic metabolism of glucose. This bicarbonate-sparing buffering effect also helps preserve pH. From Murphy's experience and other studies, it appears likely that

some glucose must be available throughout storage. Holme and Gulliksson noted the association of glucose exhaustion (even in the presence of alternate fuels) with adenine nucleotide depletion and loss of platelet viability.<sup>71</sup> The addition of glucose to PAS is technically difficult because glucose caramelizes upon heat sterilization at the neutral or slightly basic PAS pHs best suited to maintain PC pH. Accordingly, most commercially available PASs do not contain additional glucose and require 20–40% plasma carryover. Two as-yet FDA-unapproved solutions have gotten around this problem by adding bicarbonate to a separately sterilized glucose-containing low-pH base solution.<sup>117,118</sup> Table 17.1 lists the components of various solutions, including those currently FDA-approved and under investigation in the United States.

In addition to sparing bicarbonate, PAS contents have been designed to modulate the glycolytic rate and downregulate platelet activation. Citrate, important in maintaining anticoagulation, upregulates glycolysis and renders platelets more susceptible to activating stimuli. Consequently, the use of the lowest possible concentrations of citrate in the medium appears desirable.<sup>71</sup> Phosphate similarly has both salutary and detrimental effects in PAS.<sup>119</sup> Phosphate serves as a buffer, and in apheresis platelets it is important in maintaining adenine nucleotide levels. The difference in anticoagulants can explain this: apheresis platelets are suspended in acid–citrate–dextrose (ACD), while PRP-PCs and BC-PCs use CPD/CP2D. Phosphate also upregulates glycolysis and consequently mandates more plasma carryover or addition of glucose to PAS. Magnesium and potassium both appear to decrease platelet activation and may downregulate glycolysis as well.<sup>119</sup> Studies with several platelet activation inhibitors (e.g., prostaglandin E1 and theophylline) suggest that these substances may enhance PAS efficacy, but safety concerns related to routine transfusion in various patient populations significantly hinder commercial applicability.<sup>120</sup>

Clinical studies comparing platelets stored in plasma with FDA-approved additive solutions have demonstrated that allergic reactions and FNHTRs were reduced by approximately two-thirds.<sup>121</sup> Dutch investigators reported a nonsignificant reduction from 11% to 9% in mostly mild reactions when PAS-C was used compared to 100% plasma.<sup>122</sup> PAS-C also proved efficacious in reducing the relative risk of all transfusion-related adverse rates (incidences of 1.37% vs. 0.55%).<sup>121</sup> A large retrospective study found that storage time was associated with allergic transfusion reactions in platelets stored in PAS-B and PAS-C. For PAS-B, storage time was also associated with FNHTRs. However, due to the lower overall incidence of reactions in the PAS-C group, the authors considered PAS-C the best choice to prevent transfusion reactions.<sup>123,124</sup> The effect of PAS on TRALI is

less clear, likely because of the lower incidence of TRALI. A large retrospective study from France reported a significant reduction of TRALI cases with PAS platelets compared to plasma platelets. However, this was only when buffy-coat-derived platelet (pooled) concentrates were used and not with apheresis platelets.<sup>125</sup> A possible explanation is that the amount of plasma from one individual donor is much smaller in pooled units, and further dilution may reduce concentrations below a disease-causing threshold.<sup>126</sup> Replacing plasma with PAS could also have negative effects. PAS may enhance bacterial growth by reducing the bactericidal properties of plasma.<sup>127</sup> Faster growth could allow for quicker detection and reduce false positives, but this remains to be investigated. Retrospective hemovigilance data from the Netherlands show that the relative risk is four-fold higher for transfusion-transmitted bacterial infections with PAS-B and PAS-C compared to 100% plasma.<sup>128</sup> An additional negative side effect is that the corrected count increments after transfusion are approximately 25% lower with PAS platelets. This effect may be less severe with PAS-E.<sup>129,130</sup> Nevertheless, when the conditions are optimized, platelets in PAS can be superior to platelets in 100% plasma, as shown by a recent radiolabeling study using PAS-F and the Haemonetics MCS+ elutriation collection system.<sup>68</sup> Additive solutions containing glucose and bicarbonate require 5% or less plasma carryover. Once commercialized, these “low plasma” PAS may further reduce transfusion reaction rates, including antibody-mediated reactions such as TRALI and ABO-mediated hemolysis. However, even with currently licensed PAS/plasma ratios, desirable ABO antibody titer thresholds can be achieved.<sup>131</sup>

With the re-emergence of cold stored platelets, platelet additive solutions have gained further attention since additive solutions prevent cold-induced micro- and macroaggregates associated with wastage.<sup>132,133</sup> Hemostatic in vitro properties of cold stored platelets appear to be preserved in additive solution, but in vivo recoveries were reduced compared to 100% plasma in a radiolabeling study.<sup>134</sup> Additive solutions appear to have beneficial effects beyond the prevention of aggregates and the preservation of hemostatic function. When treated with pathogen reduction techniques, cold stored platelets in PAS-C/plasma showed less plasma membrane damage than platelets stored in 100% plasma.<sup>135</sup> In other studies, PAS led to better preservation of mitochondria and reduced apoptosis during cold storage.<sup>136</sup> Whether PAS or 100% plasma is the better storage solution for cold stored platelets remains to be investigated.

### Component modification

Several PC modifications are occasionally required for various subsets of patients. Cellular products containing viable lympho-

cytes must be irradiated before transfusion to patients who are susceptible to graft-versus-host disease. An irradiation dose of 25 Gy (15–50 Gy) has no significant effect on common in vitro parameters even after seven days of storage following irradiation as early as Day 1.<sup>137</sup> Similarly, little or no effect of irradiation was seen on in vitro storage parameters or in vivo recovery and survival with five-day stored platelets irradiated with up to 30 Gy on Day 1 or 3.<sup>138,139</sup>

Patients with moderate to severe allergic reactions to plasma components or newborns with neonatal alloimmune thrombocytopenia receiving maternal platelets benefit from plasma removal by platelet washing. Some institutions also wash platelets to remove ABO-incompatible plasma.<sup>140</sup> However, washing leads to a significant loss of platelets and a decrement in platelet function while also reducing the product shelf life to four hours. A standard saline wash procedure using the COBE 2991 instrument (TerumoBCT, Lakewood, CO) has been described. Platelet losses range from 8% to 29%.<sup>141,142</sup> Functional impairment of saline-resuspended washed platelets resulted in a two-thirds loss of recovery versus an unwashed control in one study.<sup>143</sup> Other studies have reported better in vitro properties of washed platelets resuspended in additive solutions instead of the saline commonly used in the United States.<sup>144</sup> For IgA-deficient patients, saline alone may not remove as much IgA as citrate-buffered saline because of IgA's low isoelectric point and its coprecipitation with platelets in an acidic saline wash fluid.<sup>145</sup>

For transfusions in utero or for volume-sensitive neonates, the additional concentration of PCs can be achieved through volume reduction by centrifugation and plasma removal. This technique has also been used to minimize infusion of maternal antibodies or ABO-incompatible plasma, although washing is preferred when antibody removal is critical. Some have questioned the need for volume reduction for most neonates and have pointed out that nonmanipulated PCs are well tolerated in neonates not *in extremis*.<sup>146</sup> Procedures have been described for volume reduction, resulting in <15% loss of platelets and relatively preserved in vivo viability.<sup>147</sup> British standards call for a concentration over  $2000 \times 10^9/L$  for in utero transfusion.<sup>148</sup> Volume-reduced PCs maintain acceptable in vitro properties in plastic syringes at room temperature or in neonatal incubators (at 37 °C).<sup>149</sup> PCs should be transfused as soon as possible after volume reduction in a closed system, employing sterile connection devices, and must be used within four hours if prepared in an open system, such as via spike entry.

Most apheresis platelets are leukocyte reduced during the separation process. Leukocyte reduction of WBD-PCs is usually accomplished by prestorage leukofiltration during separation or at prestorage pooling. Prestorage leukocyte reduction has resulted in a 75–90% reduction in FNHTRs after platelet transfusion.<sup>150,151</sup> Leukocyte reduction also reduces cytomegalovirus transmission and platelet alloimmunization.<sup>152,153</sup>

### Novel storage techniques

Room temperature platelet storage addressed the problem of rapid clearance that occurs with cooler storage temperatures but is not without limitations. Bacterial proliferation occurs more easily, and platelet metabolism is increased compared with cold storage. Prolonged storage at cold temperature reduces platelet recovery and survival, but membrane integrity may be more effectively preserved.<sup>154</sup> Additionally, in vitro suggest cold stored platelets may have better hemostatic function.<sup>77</sup> Sustained survival following transfusion is important for prophylactic transfusions, but the

possibility of improved function with cold storage is appealing for transfusion in bleeding patients.

The in vivo significance of cold-related platelet activation is uncertain. Cold stored platelets are more effective in correcting prolonged bleeding time (BT) in healthy volunteers taking acetylsalicylic acid (ASA) but not both ASA and clopidogrel.<sup>155–159</sup> Both cold- and room-temperature stored platelets reversed ASA effects measured using the VerifyNOW assay. However, the duration of reversal was shorter with cold stored platelets.<sup>160</sup> In a pilot study, patients undergoing cardiac surgery were randomized to receive platelets stored at room temperature for up to seven days or at 2–6 °C for up to 14 days without agitation. The primary outcome of chest tube output was not significantly different between groups, supporting the feasibility of prolonged cold storage but not suggesting a hemostatic advantage to cold storage.<sup>161</sup> Attempts to mask clustered GP-Ib/IX/V receptors with sugar moieties, a successful manipulation in mice transfused with briefly cold stored platelets, have not reversed the rapid clearance of longer stored chilled platelets observed in humans.<sup>162</sup>

Cryopreserved platelets can be prepared and stored for up to 10 years, but cost, inconvenience, procedure-related platelet loss, and functional decrements remain barriers to wider implementation. There is, however, considerable military interest in frozen platelets because of their low volume, rapid availability, and less demanding transportation requirements. The most common freezing method employs 5–6% dimethylsulfoxide (DMSO) as a cryoprotectant and requires <65 °C storage, with DMSO removal possible before freezing.<sup>163,164</sup> The use of cryopreserved platelets results in corrected count increments that are approximately half of the increments seen with liquid apheresis platelets.<sup>163,165</sup> Contemporary autologous reinfusion studies with modern cryopreserved platelets have observed a recovery of 52% and survival of 89% of fresh platelets. Controlled rate freezing appears superior to uncontrolled temperature reduction.<sup>166,167</sup> Nonmilitary use is generally limited to broadly alloimmunized patients refractory to allogeneic transfusion. Collected between successive rounds of high-dose chemotherapy, these units can support patients through short periods of severe thrombocytopenia. Functionally, one unit of frozen platelets has been shown to correct the aspirin-prolonged bleeding time in healthy humans.<sup>168</sup> Results from several retrospective studies suggest safety and efficacy, but the usual limitations, including possible biases and confounders apply.<sup>169–171</sup> Only very few controlled trials with limited patient numbers are available. A multicenter trial included 28 thrombocytopenic hematology-oncology patients with WHO grade II–IV bleeding. Up to three cryopreserved platelet doses were administered, and no major adverse events were observed.<sup>172</sup> The majority of recipients showed improved bleeding scores after receiving cryopreserved platelets.<sup>172</sup> In a randomized, controlled trial in trauma patients, cryopreserved platelets resulted in comparable clinical and laboratory outcomes, but the trial was underpowered to allow for any conclusive statements about efficacy.<sup>173</sup> Similarly, the CLIP-I trial showed comparable outcomes and safety in a cardiac surgery population comprising 23 patients receiving cryopreserved platelets and 18 receiving liquid stored platelets.<sup>174</sup> The group receiving cryopreserved platelets received more FFP than the control group making a definitive interpretation difficult.<sup>174</sup>

Lyophilized platelets have been studied without great success in a resulting product. Animal studies in the 1950s showed no hemostatic effect of early preparations.<sup>175,176</sup> Bode and Read described a

new technique using 1.8% paraformaldehyde to fix washed platelets, followed by freezing in 5% bovine albumin and lyophilization.<sup>177</sup> This preparation has been stored at -80 °C but may be stable at room temperature for shorter periods. Paraformaldehyde treatment appears to confer an additional benefit by killing bacteria and many viral pathogens. Although morphologically normal and able to support adhesion and thrombin generative functions, these platelets do not activate or aggregate. Observation of thrombosis, splenic accumulation, and short circulatory time in animal models has led to limited enthusiasm for the product.<sup>178</sup> A trehalose-based formulation of freeze-dried platelets (thrombosomes) underwent a Phase I dose-escalation study in 10 healthy humans. While no serious adverse events were observed, three out of four subjects in the group with the highest dose had treatment-related adverse events, including EKG abnormalities, elevated D-Dimers, and a platelet autoantibody.<sup>179</sup> In vitro, thrombosomes were able to adhere to collagen, expressed phosphatidyl-serine and promoted thrombin generation. Similar to previous products, minimal aggregation was observed.<sup>180</sup> The role of platelet substitutes, including platelet microvesicles, liposome-based hemostatic agents, fibrinogen-coated albumin microspheres, and red cells coated with fibrinogen or RGD peptides, is beyond the scope of this chapter, and readers are referred to published reviews for additional information.<sup>181-185</sup>

## Acknowledgments

Figures 17.1, 17.2, and 17.3 and Table 17.1 were reproduced from the chapter by Dr. Ralph Vassallo in the previous edition of this book. The authors of the current chapter appreciate the strong foundation provided in the earlier work.

## CHAPTER 18

# Neutrophil production and kinetics: neutropenia and neutrophilia

Lawrence Rice<sup>1</sup> & Eric Salazar<sup>2</sup>

<sup>1</sup>Department of Medicine and Cancer Center, Houston Methodist Hospital and Weill Cornell Medical College, Houston, TX, USA

<sup>2</sup>Department of Pathology and Laboratory Medicine, UT Health San Antonio, San Antonio, TX, USA

## Introduction

Changes in neutrophil count are frequently encountered in clinical medicine in that increased or decreased neutrophil counts are often seen with infections and other disorders. Neutrophils are the body's primary defense against invading pathogens, particularly bacteria and fungi. Thus, neutrophil changes most often represent a response to an underlying disorder, and they may be the first clue to its presence. At other times, high or low neutrophil counts can be a crucial indicator of a primary hematologic disorder. Increased neutrophils are characteristic of chronic myeloid leukemia and other myeloproliferative disorders, and decreased neutrophils can signal aplastic anemia, myelodysplastic syndrome, acute leukemia, or other disorders of bone marrow function. This chapter does not focus on primary hematologic disorders, but rather on normal neutrophil kinetics and common reasons for aberration, and briefly deals with esoteric disorders that primarily affect myeloid cells.<sup>1</sup>

## Normal neutrophil kinetics

### Production in marrow

Neutrophils are produced in the bone marrow, an extremely proliferative organ of the body. Neutrophils are among the most numerous cells being produced there with approximately  $10^{11}$  generated daily under baseline circumstances. There is a capacity to increase this several fold when stressed.<sup>2</sup> The production of neutrophils and other granulocytes (eosinophils; basophils) is termed *granulopoiesis* or *myelopoiesis*. This occurs in the extravascular space of the bone marrow. Mature cells are stored there until mobilized and released.

Neutrophils originate from multipotent myeloid progenitor cells. Once committed to the granulocyte line, precursor cells differentiate along morphologically distinct myeloblast, promyelocyte, myelocyte, metamyelocyte, band, and then segmented neutrophil stages. The stages of granulopoiesis can be defined not only morphologically, but also by cell surface markers (detected on flow cytometry) and by the mitotic capacity. The mitotic compartment includes myeloblast, promyelocyte, and myelocyte stages, with promyelocytes and myelocytes

comprising the neutrophil-committed mitotic bone marrow pool. The postmitotic pool includes metamyelocytes and band neutrophils. Mature neutrophils then participate in a state of exchange between the bone marrow, blood circulation, and other tissues.<sup>3</sup>

Granulopoiesis is regulated by hemopoietins, cytokines that can stimulate colony formation from progenitor cells in the bone marrow. Hematopoietins include stem cell factor, interleukin-3 (IL3), granulocyte macrophage colony-stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF). In addition to stimulating progenitor cells, GM-CSF and G-CSF directly enhance neutrophil function. G-CSF is the principal cytokine regulating granulopoiesis, providing a stimulus at several stages of differentiation.<sup>4</sup> G-CSF induces commitment of multipotential progenitor cells down the myeloid lineage and impacts the proliferation of granulocytic precursors. It also reduces the transit time through the differentiating granulocytic compartment and facilitates neutrophil release from the bone marrow. Thus, G-CSF both markedly expands the marrow neutrophil mitotic pool and it shortens the transit time of differentiating neutrophils through the postmitotic pool. The postmitotic transit time in healthy volunteers shortens from 6.4 days to 2.9 days after G-CSF administration.<sup>5</sup> Genetic expression related to granulocyte differentiation is regulated mainly by myeloid transcription factors PU.1, members of the CCAT enhancer binding protein family, and GFI-1.

The total transit time from myeloblast to mature neutrophil is 10–12 days *in vitro*.<sup>6</sup> Primary granules appear in the promyelocyte stage, containing myeloperoxidase and serine proteases, including neutrophil elastase. In myelocytes, secondary and tertiary granules appear. Secondary granules contain lactoferrin and collagenase; tertiary granules contain gelatinase. Secretory vesicles also appear near neutrophil maturity. Other changes during the maturation process include increases in adherence capabilities, deformability, responsiveness to chemoattractants, and the development of the characteristic segmented nucleus.

### Mobilization of neutrophils

Mature neutrophils remain in the bone marrow for 4–6 days as a storage pool, poised to respond to microbial invaders. These cells are estimated to number  $4.4 \times 10^9/L$  under basal conditions, with  $0.87 \times 10^9$  cells/kg

released daily into the circulation. Only about 2% of neutrophils circulate in the bloodstream at any given time, with about 90% retained in the bone marrow. The half-life of neutrophils in the circulation is 6–8 hours, and they then survive longer in tissues, up to one or two days.<sup>7</sup> The number of neutrophils produced and released from the bone marrow greatly increases in response to stimuli such as corticosteroids, exercise, cytokines such as G-CSF, chemokines, or bacterial products.<sup>5</sup>

The retention, mobilization, and homing of neutrophils to and from the bone marrow are regulated by molecular mechanisms involving CXCR4 (C-X-C motif receptor 4), CXCR2 (C-X-C motif receptor 2), and CXCL12 (C-X-C motif ligand 12). CXCR4 is a cytokine receptor essential for the homing of stem cells and more mature neutrophils to the bone marrow. When deleted in mice, it causes a shift in the pool of mature neutrophils from bone marrow to the circulation with no change in the lifespan of circulating neutrophils.<sup>8</sup> A mutation in CXCR4 causing enhanced responsiveness to CXCL12 underlies the WHIM syndrome (warts, hypogammaglobulinemia, infections, and myelokathexis) in which there is deficiency of neutrophils in the circulation with accumulation of mature neutrophils in the bone marrow. The CXCR4 antagonist plerixafor, FDA-approved to mobilize stem cells to the peripheral blood for collection and transplantation, can treat leukopenia in patients with WHIM syndrome. CXCR2 is a chemokine receptor expressed on myeloid cells that, when deleted, causes the retention of mature neutrophils in the bone marrow. Thus, CXCR4 seems to be necessary to maintain neutrophils in the bone marrow, whereas CXCR2 is necessary for their release. CXCL12, also known as stromal-cell-derived factor 1 $\alpha$ , is a ligand of CXCR4. Bone marrow stromal cells, including vascular endothelial cells and osteoblasts, express CXCL12.<sup>9</sup> CXCL12 expression is high in the bone marrow during normal steady state, acting to retain neutrophils in the bone marrow by binding the CXCR4 on the neutrophils.

Inflammation causes an increase in cytokine levels, including G-CSF, in the bloodstream. This decreases CXCL12 expression in the bone marrow, allowing egress of neutrophils toward circulation where there is a higher level of cytokine. G-CSF treatment decreases CXCL12 mRNA in the bone marrow, decreasing CXCL12 protein expression. G-CSF also decreases surface expression of CXCR4 on neutrophils over 5–18 hours. With less CXCR4 receptors on neutrophils and less CXCL12 expression in the bone marrow, more neutrophils are mobilized into circulation.

After release from the bone marrow, neutrophils become distributed between the circulating and marginal pools, freely exchangeable pools of approximately equal size.<sup>10</sup> Cells in the circulating pool are readily sampled by drawing blood. Cells in the marginal pool are loosely adherent to the endothelium of blood vessels, often slowly rolling along endothelial surfaces.<sup>11,12</sup> They are prepared for rapid egress into the tissues at times of need. Some studies suggest that the marginal pool is not diffusely distributed throughout the vasculature, but is largely localized to the liver, spleen, and lungs.<sup>7</sup> Stressors can influence allocation of neutrophils in each pool. Administration of prednisone increases the size of both the circulating and marginating pools, whereas exercise and administration of adrenaline cause a shift of cells from the marginal pool to the circulating pool.<sup>13</sup>

### Migration into tissues

Neutrophils must cross the vascular wall to get to sites of inflammation, a process referred to as diapedesis. P-selectin and E-selectin on endothelial cells capture neutrophils and mediate rolling by binding platelet sialoglycoprotein ligand-1 (PSGL1),

L-selectin, and CD44. This activates neutrophil integrins that interact with intracellular adhesion molecules (ICAMs) on endothelial cells. Migration through the endothelium is mostly paracellular, but 20% is thought to be transcellular.<sup>8</sup> In paracellular migration, neutrophils loosen the tight junctions by presenting alternative binding partners, platelet-endothelial cell adhesion molecule-1 (PCAM1), JAM-A, and  $\beta_2$  integrins (LFA1 and Mac1), facilitating the ability to squeeze through the tight junctions. Integrin  $\alpha 3\beta 1$  is upregulated and appears crucial to neutrophil diapedesis.<sup>14</sup> In transcellular migration, transmigratory cups expressing high ICAM-1 and VCAM-1 capture the crawling neutrophils, which allows neutrophils to go through the endothelial cells. Leukocyte adhesion deficiency (LAD) syndromes can result from the lack of adhesion molecules such as  $\beta_2$  integrins on the neutrophil surface, producing an inability to deliver neutrophils to sites of infection. Patients with LAD have neutrophilia and recurrent bacterial infections.

Once in the tissue, neutrophils initiate the generation of cytokines, including IL8 and Gro $\alpha$ , allowing recruitment of more inflammatory cells. Neutrophils then can phagocytose microorganisms and undergo apoptosis. Neutrophils in tissues are more actively phagocytic than neutrophils in the circulation.

### Neutrophil clearance

To prevent neutrophil-mediated tissue damage, a negative feedback mechanism controls the influx of neutrophils. Apoptotic neutrophils are phagocytosed by macrophages, which reduces proinflammatory chemokine production and stimulates the release of anti-inflammatory mediators such as prostaglandin E<sub>2</sub> and transforming growth factor- $\beta$ .<sup>1</sup>

The spleen, liver, and the bone marrow clear circulating neutrophils that have not migrated into the tissues. The CXCR4–CXCL12 chemokine pathway mediates the homing of neutrophils back to the bone marrow. Circulating neutrophils upregulate expression of CXCR4 and become “senescent” within a few hours of their release in blood. A chemotactic gradient of CXCL12 created by bone marrow stromal cells allows the neutrophils with upregulated CXCR4 to home back to the bone marrow. In the bone marrow, senescent neutrophils become apoptotic and are phagocytosed by macrophages.<sup>9</sup>

### NETosis

Neutrophils may extend their antimicrobial activity, beyond phagocytosis and degranulation, and beyond their lifespan, by forming neutrophil extracellular traps (NETs). During this process called NETosis, the nuclear and granule membranes dissolve, decondense chromatin, and extrude into the extracellular space along with proteins that were contained in the cytosol and granules.<sup>15</sup> NETs, therefore, are large, extracellular web-like structures consisting of neutrophil cytosolic and granule proteins on a scaffold of decondensed chromatin. NETs can trap pathogens, including bacteria, fungi, viruses, and parasites within the sticky meshwork of chromatin, and expose them to highly concentrated antimicrobial enzymes trapped within the chromatin. Numerous NETosis triggers have been identified, ranging from pathogens themselves to activated platelets and immune complexes. Microorganism size appears to influence whether phagocytosis or NETosis occurs.<sup>16</sup> Although NETs can help clear infections, NETs may also damage tissues. Excessive formation of NETs has been linked to various neutrophil-mediated pathologies, including vasculitis, vascular injury, and thrombosis. Excessive NETosis can

damage the epithelium in pulmonary fungal infections and the endothelium in transfusion-related acute lung injury. It is thought that NETs forming in the circulation can provide a scaffold for deep vein thrombosis formation. Thus, NETs may promote vaso-occlusion. Some have hypothesized that intravascular NETosis plays an important role in the vascular complications related to COVID-19.<sup>17</sup>

## Neutrophilia

Neutrophilia, defined as a neutrophil count greater than  $7.5 \times 10^9/\mu\text{L}$ , may be acute or chronic. (Much higher neutrophil counts are normal in infants less than one-month old (up to  $26 \times 10^9/\mu\text{L}$ ).) Table 18.1 summarizes causes and mechanisms of acute and chronic neutrophilia. Neutrophilias are acquired disorders, most commonly reactive phenomena with only a small minority representing a primary hematologic disorder.<sup>18</sup>

Faced with a symptomatic patient, primary care and emergency room physicians often equate neutrophilic leukocytosis with the presence of infection, and they may even base a decision on the need for hospital admission on its presence. While neutrophilic leukocytosis is the rule with most bacterial infections, it should be recognized that this is a very nonspecific finding that may occur with many causes of inflammation or stress. Mild chronic neutrophilia can even be due to smoking or obesity, where it has been associated with elevated leptin levels. Further, neutrophilic leukocytosis is certainly not sensitive for bacterial infections, and in fact many infections may occasionally or characteristically produce neutropenia.

The evaluation of neutrophilic leukocytosis begins with a history focused on potential causative factors, particularly infections. The history would include systemic symptoms such as fevers, night sweats, and weight loss. Questions are further directed to possible foci of infection such as cough, shortness of breath, dysuria, and abdominal symptoms. Medication history particularly assesses glucocorticoid use. Special attention on physical examination should be devoted to oropharyngeal and lung exams, lymph nodes, and spleen. As with any abnormality of blood cell counts, the review of the peripheral blood smear may be crucial to expeditiously pinpoint the problem. Eosinophils are generally decreased with bacte-

rial infection, so an increase in eosinophils and basophils may point to a primary hematologic disorder (or possibly a parasitic, allergic, or vasculitic disorder).

Pseudoneutrophilia may occur during exercise or time of stress because of epinephrine effects, shifting marginal pool cells to the circulating pool. The shift is rapid but short-lived, and should no more than double or triple the neutrophil count. Immature neutrophils should not be seen.

*Neutrophil left shift* refers to the presence in the circulation of relatively immature cells such as band neutrophils. With a marked left shift, myelocytes and metamyelocytes circulate. Left shift is nonspecific, occurring with infection or with any cause of neutrophilia.

Glucocorticoids cause neutrophilia by decreasing the uptake of neutrophils from the intravascular space. This is similar to the mechanism of neutrophilia in patients with leukocyte adhesion deficiency (CD11/CD18 deficiency). Other drugs known to cause neutrophilia include catecholamines, which affect demargination, and lithium, which may cause G-CSF release.

Leukemoid reaction is a nonclonal neutrophilic leukocytosis with white blood cells (WBCs)  $>50,000/\text{mm}^3$ . It is generally seen with an uncontrolled inflammatory state, cancer, asplenia, infection, recovery from neutropenia with or without the administration of colony stimulation factor, or some combination of these causes. In chronic infection and/or inflammation, the neutrophil production rate can increase threefold. G-CSF or GM-CSF administration can further increase neutrophil production, with a maximum response seen in 7–10 days. Overshoot in patients recovering from neutropenia is common, such as after myelosuppressive chemotherapy.

*Leukoerythroblastosis* is defined as the presence of immature myeloid cells (myelocytes) and nucleated RBCs in the peripheral blood, often with giant platelets as well. Leukocytosis is usually present. Two-thirds of patients with this finding have an underlying infiltrative disorder of the bone marrow, such as fibrosis, granuloma, necrosis, or metastatic tumor. Leukoerythroblastosis may also commonly accompany brisk hemolytic anemia. In about one-tenth of cases, it may result from hypoperfusion of the bone marrow (shock from sepsis, hemorrhage, anaphylaxis, or cardiac failure) causing disruption of the microenvironment. If an underlying cause of leukoerythroblastosis is not readily apparent, bone marrow biopsy is usually warranted. In the past, a major differential diagnosis was to distinguish reactive leukoerythroblastosis from chronic myelogenous leukemia (CML) or another myeloproliferative neoplasm. Helpful to differentiate these were the clinical situation, splenomegaly, eosinophilia, and basophilia. Leukocyte alkaline phosphatase, high with reactive neutrophilia but low with CML, was sometimes a final arbiter but is becoming obsolete with the availability of molecular tests for the Philadelphia chromosome t(9;22) (and for Jak2 mutations).

Chronic neutrophilic leukemia is a very rare myeloproliferative neoplasm characterized by sustained neutrophilia and splenomegaly. It mainly occurs in the elderly and carries a poor prognosis. Bone marrow biopsy shows neutrophilic hyperplasia without excess of myeloblasts.<sup>19</sup>

## Neutropenia

An absolute neutrophil count (ANC) of less than  $1500/\text{m}^3$  is considered to be neutropenia. ANC is the percentage of neutrophils multiplied by the WBC count. An ANC of  $1000\text{--}1500/\text{m}^3$  is considered mild neutropenia,  $500\text{--}1000/\text{m}^3$  moderate, and below

**Table 18.1** Causes and Mechanisms of Neutrophilia

	Cause	Mechanism
Acute	Stress	Decreased margination
	Epinephrine	Decreased margination
	Exercise	Mobilization from marrow
	Infection	Mobilization from marrow
	Inflammation	
	Stress	
	Corticosteroids	Mobilization from marrow
	Granulocyte colony-stimulating factor	Prolonged survival
Chronic	Rebound from neutropenia	Increased marrow proliferation
	Corticosteroids	Prolonged survival
	Leukocyte adhesion deficiency	Prolonged survival
	Myeloproliferative disorders	Increased marrow proliferation
	Infection	Increased marrow proliferation
	Inflammation	Increased marrow proliferation

500/m<sup>2</sup> severe neutropenia. The risk of infection is greatly increased with severe neutropenia, more so with ANC below 100/m<sup>2</sup>. Agranulocytosis is a condition of acute severe neutropenia with markedly diminished or absent white cell precursors in the bone marrow.

Neutropenia is commonly encountered in clinical practice. Like neutrophilic leukocytosis, the clinical significance of neutropenia varies greatly, starting with conditions that have no impact on overall health and longevity and that may require no evaluation beyond history, physical exam, and review of the blood smear. On the opposite end of the spectrum there are neutropenic disorders that can severely impact health and survival. Acute neutropenia with fever can be a life-threatening medical emergency. Other than the ANC, critical factors in determining the importance of neutropenia and the urgency of evaluation include whether it is an affected child or adult, if it can be determined to be congenital or acquired, if it is encountered in an inpatient or in the clinic, whether there have been infectious sequelae, what are the concordant symptoms and signs (e.g., arthritis, skin rash, and/or splenomegaly), and whether the patient is acutely ill. On physical exam, careful attention should be directed to the oropharynx, lymph nodes, and spleen.

Review of the peripheral blood smear is invaluable in the initial approach to neutropenia. Helpful findings may include neutrophil inclusions, such as Döhle bodies, and hypogranularity (pale cells due to a paucity of secondary granules). Most neutrophils have 3–4 lobes in their nucleus; 5% with five or more lobes indicates hypersegmentation. This is constantly found in megaloblastic processes and may also occur with antimetabolite drugs and with uremia. Changes in other cell lines may bear on the cause of neutropenia, such as large granular lymphocytes (LGLs) or other atypical lymphoid cells. Reactive lymphocytes can be a clue to viral infection. Blast cells may indicate leukemia.

Beyond the blood smear, tests commonly helpful in the evaluation of neutropenia include rheumatoid factor and antinuclear antibodies when there is reason to suspect an autoimmune problem. A direct Coombs test may also help to confirm an autoimmune diathesis. Flow cytometry may clarify the etiology of neutropenia in a number of disorders. This is particularly true when blood smear findings or splenomegaly creates suspicions for LGL syndrome/T-NK leukemia, hairy cell leukemia, or other clonal proliferations. Bone marrow exam is often valuable, particularly in more severe neutropenic disorders, although it should be realized that morphologic findings may be nonspecific. One example is that a hypercellular marrow with “maturation arrest” picture could be compatible with a stem cell maturation defect, antibodies to late precursors, early release in times of stress, or recovery from a toxic insult.

Conditions commonly resulting in neutropenia are listed in Table 18.2, and they are briefly discussed below.

### Congenital neutropenias

The molecular mechanisms underlying severe congenital neutropenias (SCNs) have been greatly clarified in recent years, and the prognosis for these patients has improved due to advances in supportive care, the use of granulocyte growth factors, and allogeneic bone marrow transplantation.<sup>20</sup> These patients have suffered from recurrent severe infections starting in infancy, and oral ulcerations and painful gingivitis by two years of age. As enumerated in Table 18.2, there are many defined conditions causing such neutropenia. Notable congenital neutropenias include the following:

**Table 18.2** Some Conditions Causing Neutropenia

#### Hereditary Neutropenias

- Severe congenital neutropenia (SCN)
  - SCN1: ELANE gene mutation
  - SCN2: GF11 gene mutation
  - SCN3 (Kostmann disease): HAX1 mutation
  - SCN 4: G6PC3 gene mutation
  - SCN 5: VPS45 gene mutation
  - X-linked SCN: WASP gene mutation
- Shwachman–Bodin–Diamond syndrome
- Cyclic neutropenia
- Duffy null red cell phenotype (previously “Benign Ethnic Neutropenia”)
- Myelokathexis (WHIM syndrome)
- Chediak–Higashi syndrome
- P14 deficiency syndrome
- Glycogen storage disease type 1 (von Gierke)
- Barth syndrome
- Cohen syndrome
- Charcot–Marie–Tooth disease
- Hermanski–Pudlak syndrome
- Gricelli syndrome
- GATA2 deficiency (MonoMAC syndrome)

#### Infections

- Overwhelming bacterial sepsis
- Particular pathogens (such as typhoid, ehrlichiosis, brucellosis, and rickettsia)
- Measles, rubella, and varicella
- HIV, EBV, CMV, hepatitis A, and hepatitis B
- Other viruses
- Granulomatous marrow infection (such as histoplasmosis and TB)

#### Drugs

(see Table 18.3)

- #### Autoimmune Conditions
- Systemic lupus erythematosus
  - Evan’s syndrome (ITP and AIHA)
  - Felty syndrome

#### Malignancies

- Acute leukemias
- LGL leukemia
- Hairy cell leukemia
- Myelodysplastic syndromes

#### Dietary

- Global caloric malnutrition
- Copper deficiency
- Alcoholism
- Vitamin B<sub>12</sub> and folate deficiency

#### Other Conditions

- Hypersplenism
- Hyperthyroidism

- SCN1 is an autosomal dominant disorder caused by mutation in the neutrophil elastase gene on the ELANE gene on chromosome 19p13.3.
- The same ELANE gene is mutated in cyclic neutropenia.<sup>21</sup>
- Kostmann syndrome is an autosomal recessive disorder linked to mutations in HAX1. It is associated with mental retardation.
- Myelokathexis is caused by a mutation in the CXCR4 chemokine receptor, part of the WHIM syndrome mentioned in this chapter. It consists of severe neutropenia in the setting of hypercellular marrow containing hypersegmented neutrophils.
- Shwachman–Bodin–Diamond syndrome (SBDS) is an autosomal recessive disorder usually with mutations in the SBDS gene, consisting of exocrine pancreatic insufficiency, bone marrow dysfunction, skeletal abnormalities, and short stature. There is a variable degree of neutropenia.
- Chediak–Higashi syndrome patients have cutaneous and ocular hypopigmentation, and mild neutropenia with large abnormal granules in the neutrophils. Neutrophil dysfunction leads to fre-

- quent pyogenic infections. Platelet granules are also affected resulting in a bleeding diathesis.
- Cyclic neutropenia is characterized by recurrent fevers, mouth ulcers, with infections due to regularly recurring severe neutropenia. G-CSF can be used to treat cyclic neutropenia.
  - MonoMAC syndrome is an autosomal dominant disorder due to mutations in the GATA2 transcription factor. It may be associated with mild chronic neutropenia and persistent severe monocytopenia, leading to opportunistic infections and a high risk of eventual leukemic progression.
  - The p14 deficiency syndrome, lacking an adaptor protein involved in mitogen-activated protein kinase signaling, is characterized by severe neutropenia, partial albinism, short stature, and recurrent infections.
  - Neonatal alloimmune neutropenia occurs when there is transplacental passage of IgG antibodies to neutrophil-specific antigens. The neutropenia can be moderate to severe.<sup>22</sup>

### Neutropenias in adults

In the hospital, the most common causes of neutropenia are medication reactions or sepsis, and these become especially suspect if the neutropenia has its initial onset during hospitalization. While almost any drug can rarely cause neutropenia, it is most closely associated with certain medications and classes. It is important to consider whether there is agranulocytosis (sudden- and severe-onset neutropenia) vs. a gradual decline in ANC, as the former is particularly characteristic of a few drugs. Table 18.3 reviews more common drug associations.<sup>23</sup>

Sepsis characteristically leads to increased neutrophil count, but neutropenia can also be seen relatively often, particularly in those with compromised marrow reserve such as an underlying hematologic disorder, chemotherapy, or malnutrition. Neutropenia in this context augurs a high mortality rate. Other infections that may be characterized by neutropenia include bacteria, such as typhoid fever and brucellosis, and nonbacterial infections, such as anaplasmosis, ehrlichiosis, and rickettsia. Neutropenia or pancytopenia is seen with granulomatous marrow involvement by histoplasmosis or mycobacteria. Transient neutropenia is very common with viral infection, so intensive evaluation of a low neutrophil count should ordinarily be delayed in those where an acute viral etiology seems likely. Viruses with a particular predilection to cause this include HIV, hepatitis A, hepatitis B, Epstein–Barr virus (EBV), cytomegalovirus (CMV), measles, rubella, and varicella.

Neutropenia is an expected and dose-limiting side effect of many cytotoxic and/or immunosuppressive drugs, such as those used for cancer chemotherapy or to prevent transplanted organ rejection.

Prophylaxis with growth factors and/or antibiotics is recommended if the risk of developing febrile neutropenia is greater than 20%. This risk can be calculated from age, extent of primary cancer, comorbidities, and the known myelotoxicity of the chemotherapy regimen (according to the National Comprehensive Cancer Network [NCCN], Multinational Association of Supportive Care of Cancer [MASCC] score, and Infectious Diseases Society of America [IDSA] risk assessment). With high risk, G-CSF or a long-acting analog should begin 24–72 hours after the completion of myelotoxic chemotherapy.

Other medications may cause neutropenia with variable frequency, severity, and mechanisms.<sup>24</sup> Neutropenia is sometimes sudden and severe. Dose- and duration-related myelosuppression may be seen with chlorpromazine, ticlopidine, and valganciclovir. Chloramphenicol can cause neutropenia by both dose-related and idiosyncratic mechanisms. Clozapine has been shown to induce apoptosis of myeloid precursors. Immune mechanisms have been implicated in neutropenia from antithyroid drugs and aminopyrine. An epidemic of severe neutropenia was first appreciated in 2007 in intravenous cocaine abusers and was linked to levamisole adulteration. Also, increasingly recognized in recent years is neutropenia related to rituximab. This is unusual for its late onset, typically three months after the last dose, and may be related to imbalanced recovery of B-lymphocyte subsets with resultant deficiency of stromal-derived factor 1.

Immune mechanisms may be implicated relatively commonly in neutropenia, sometimes in the context of autoimmune disorders such as systemic lupus erythematosus (SLE) or rheumatoid arthritis (RA). Immune neutropenia can vary from mild to severe. Antineutrophil antibodies are classically imputed, but autoreactive cytotoxic lymphocytes can also play a role. Bone marrow examination most often shows normal to increased cellularity with maturation arrest, but this picture is nonspecific (as discussed above). Available antineutrophil antibody tests are not clinically reliable, creating substantial challenges to validate the diagnosis. Sometimes, empiric immunosuppressive therapy (e.g., methotrexate) may enlighten in retrospect as to whether immune factors were at play. Felty syndrome is a complication of RA with splenomegaly and neutropenia that may be severe, and it is traditionally attributed to antineutrophil antibodies. This occurs in 1% of patients with RA and may be complicated by severe infections. Felty syndrome may be on a continuum with large granular lymphocyte proliferation (see below). The mainstay treatments for Felty syndrome are methotrexate, cyclosporine, or cyclophosphamide. G-CSF engenders a risk of exacerbating underlying inflammatory problems, so it should be used cautiously.

Splenomegaly can be a cause of leukopenia, anemia, thrombocytopenia, or any combination of these. The degree of cytopenia is

**Table 18.3** Drugs Commonly Causing Neutropenia and/or Agranulocytosis. Source: Based on Gibson and Berliner (2014).<sup>23</sup>

Antimicrobials	Vancomycin TMP-SMX Dapsone	Cephalosporins Semisynthetic Penicillins Ganciclovir Captopril Phenytoin	Chloramphenicol Flucytosine Linezolid Procainamide Ethosuximide
Cardiovascular Anticonvulsants	Ticlopidine Carbamazepine Valproate		
Psychotropic Agents Antithyroid Anti-inflammatory	Clozapine Methimazole Sulfasalazine Phenylbutazone	Phenothiazines Propylthiouracil	
Immunosuppressives Others	Mycophenolate mofetil Levamisole	Diclofenac Azathioprine Deferiprone	Indomethacin Methotrexate Rituximab

generally proportional to the degree of splenic enlargement. Additional factors such as drugs or autoimmune diseases should be considered if neutropenia is out of proportion to the splenomegaly and to the reduction in other cell lines.

T-cell LGL leukemia and other natural killer (NK) cell proliferations should be considered in adults with neutropenia. NK cell proliferations can vary from nonclonal reactive processes, to indolent clonal proliferations, to very aggressive neoplasms. Reactive LGLs can be idiopathic, or they can be seen in autoimmune disorders, after organ transplant or during therapy with dasatinib, a tyrosine kinase inhibitor.<sup>25</sup> Similarly, clonal T-NK-cell/LGL leukemia can be associated with RA or can be idiopathic. Felty syndrome can be associated with increases in T-NK cells. Peripheral blood smear shows large lymphocytes with mature chromatin, excess cytoplasm, and usually prominent cytoplasmic granules. Flow cytometry shows CD3 and CD57 positive cells, and molecular studies show T-cell receptor gene rearrangement and, in about half of cases, stat3 gain-of-function mutations. T-NK clonal disease most often responds to methotrexate, cyclosporine, or cyclophosphamide therapy. Pure NK cell proliferations are generally CD3 negative and CD56 positive.

A large majority of people of sub-Saharan African descent display a Duffy null [Fy(a-b-)] red blood cell phenotype, protective from malaria, and associated with a lower number of circulating neutrophils. Thus, African Americans have a lower mean ANC compared to Caucasians, with 5% falling below 1500, but there is not an increased risk of infection. This can also be seen in other ethnic groups, including those of Middle Eastern heritage. There is a current effort to no longer designate this as “Benign Ethnic Neutropenia” so as not to stigmatize people who have no clinical disease.<sup>26</sup>

Chronic idiopathic neutropenia is the default diagnosis in adults who have acquired the problem but do not meet diagnostic criteria

for established etiologies.<sup>21</sup> This usually runs a benign course, but some may require growth factor support at times of illness.

When treatment for neutropenia is indicated, one addresses the specific cause (e.g., withdraw suspicious medications), but additionally G-CSF may facilitate recovery. This may be required episodically or on a regular basis with chronic afflictions. This does not come without a price. After 10 years of G-CSF therapy, the risk of death from MDS and AML was reported as 21% in patients with SCN,<sup>27</sup> higher than 13% after eight years of G-CSF therapy reported by the Severe Chronic Neutropenia International Registry in 2003.<sup>28</sup> The later report did find a statistically significant association between the dose of G-CSF and the risk of MDS and AML in SCN. Prompt empiric initiation of appropriate antibiotics is an additional measure that may be life-saving in the situation of fever with severe neutropenia. As stressed in this chapter, changes in neutrophil counts are most often reactive phenomena, but occasionally they are manifestations of a primary hematologic process. Accelerated progress continues in our ability to understand and address these disorders.

Life-threatening infections with bacteria, yeast, and fungus continue to be a consequence of severe neutropenia, with an absolute neutrophil count less than 500/ $\mu$ L, and disorders of granulocyte (PMN) dysfunction. The most frequent situation is neutropenic fever and infection with yeast or fungus during either hematopoietic progenitor cell (HPC) transplantation or intense chemotherapy for hematologic malignant disease. Neutropenic infections cause considerable morbidity, occasionally are fatal, and add considerable cost to the treatment of these patients. One approach has been the use of granulocyte transfusions (GTXs).

Granulocytes can be collected by apheresis but because of the relatively low concentration of granulocytes in the circulation it is necessary to increase the level of circulating cells to collect an adequate dose for transfusion. Historically, the granulocyte count was elevated by the use of corticosteroids but even this did not yield a very meaningful dose of granulocytes. More recently, the hormone granulocyte-colony stimulating factor (G-CSF) has been used to mobilize the donors to produce high-dose granulocyte concentrates. This has led to renewed interest in granulocyte transfusions.

Therapeutic GTX to treat known or suspected infection has not gained broad acceptance despite many reports documenting benefits.<sup>1,2</sup> This lack of enthusiasm for GTX can be explained by the continuing development of effective antimicrobial drugs to prevent and manage infection, by the availability of recombinant hematopoietic growth factors to quicken granulocyte recovery, by preference for peripheral blood HPC over marrow-derived HPC transplantation to hasten patient recovery from myelotoxic therapy and to shorten the period of severe neutropenia, and by the lack of familiarity/experience by most physicians with the markedly improved PMN concentrates.

This chapter discusses the current technology of granulocyte collection and provides a critical assessment of the potential for the use of therapeutic and prophylactic GTX.

## Collection of granulocytes for transfusion

### Donor selection

Several factors must be taken into consideration beyond the standard allogeneic blood donor's eligibility screening criteria. These elements include the following: (1) ABO and Rh type, (2) CMV status,

(3) recent blood or apheresis donation, and (4) medical conditions that would contraindicate the use of corticosteroids and/or the hormone granulocyte-colony stimulating factor (G-CSF) as well as exposure to the erythrocyte sedimenting agent hydroxyethyl starch.

Donor granulocyte concentrates must be ABO and Rh compatible with the patient because of the red cell content found within the final GTX product. An in vivo study of indium labeled granulocytes shows that normal migration occurs in a chemotactic chamber containing ABO-incompatible granulocytes that are free of red cells.<sup>3</sup> This result confirms the lack of ABO antigens on the granulocytes cell.<sup>4,5</sup>

Pediatric and transplant patients should receive products from donors with CMV negative status as the virus is known to reside within leukocytes.<sup>6</sup> For the typical whole blood donation, this viral transmission risk would be significantly reduced by leukoreduction, but as this manufacturing step is not performed with granulocyte concentrates, it is best to consider providing a CMV negative donor if the patient's need requires it.

As the collected product will more than likely be distributed prior to having the infectious disease test results made available, consider scheduling donors who have undergone a blood donation in the past month. Another benefit for using platelet donors is that they are likely to have undergone anti-human leukocyte antigen (HLA) antibody screening to reduce the risk of a type of transfusion reaction called transfusion-related acute lung injury (TRALI).

Medical assessment must be performed to determine if the donor could tolerate the administration of drugs received for granulocyte stimulation and the exposure to the erythrocyte sedimenting agent, hydroxyethyl starch (HES). For example, contraindications for the use of corticosteroid include the following: diabetes, glaucoma, gastrointestinal ulcers, hypertension, and history of allergy to corticosteroid use. For G-CSF, it is required to determine if there was a prior exposure to the drug that resulted in an allergic reaction. HES requires a healthy donor who does not have a recent history for renal dysfunction, active heart disease, as well an allergic history to the reagent.<sup>7</sup>

### Histocompatibility matching

Granulocyte surfaces are coated with HLA and granulocyte-specific antigens<sup>8</sup> but probably not ABO.<sup>4,5</sup> Older studies of CML cells show that leukoagglutinating or lymphocytotoxic antibodies interfere

with the in vivo localization of granulocytes.<sup>9,10</sup> More specific studies of Indium labeled cells demonstrate the failure of granulocytes to localize at sites of inflammation<sup>9</sup> and also excess sequestration of granulocytes in the lungs,<sup>10</sup> indicating that incompatibility interferes with the clinical effect of the cells. One difficulty in developing a practical approach to this is that most of these patients' serum contains both HLA and granulocyte-specific antibodies, making it difficult to distinguish whether HLA is important. Clearly, granulocyte agglutinating antibodies interfere.<sup>9</sup> However, the practical application of this is difficult because granulocytes must be transfused within eight hours of collection. With such a short time frame, it is not feasible to collect and have available several granulocyte units to crossmatch and select a compatible unit for transfusion.

If the specificity of the granulocyte antibodies is identified, then consideration should be made to have family members tested to find compatible donors. It is unlikely that the general apheresis donor population is phenotyped on a routine basis for granulocyte-specific antigens; however, as a phenotype is more likely among familial relations due to genetic inheritance, a closer look at family members is of interest. Such testing is not only time consuming but is not always accessible as the technology for granulocyte antibody antigen workup is available only in a small number of research laboratories. Because of these factors, performing phenotype testing of donors would not be an option for acute needs.

### **Donor granulocyte stimulation**

A limitation of GTx has been the insufficient number of granulocytes collected to meet clinical need. Granulocyte concentrates collected from healthy donors who are not stimulated with corticosteroids or G-CSF will contain between 0.2 and  $1.0 \times 10^{10}$  PMNs—about 1% of a healthy marrow's output. To ensure adequate numbers and quality of PMNs for transfusion, granulocytes must be collected from optimally stimulated donors by automated leukapheresis using an erythrocyte-sedimenting agent, such as hydroxyethyl starch.

Donor stimulation with properly timed corticosteroids ( $\leq 12$  hours before leukapheresis) increases the number of circulating granulocytes by releasing those that were adhering to the vascular walls. In this manner, the granulocyte yield can expand two- to threefold higher from baseline for a healthy individual blood donor.<sup>11,12</sup>

The use of granulocyte colony-stimulating factor mobilizes PMNs directly from the marrow, will produce, especially in combination with corticosteroids, as much as 14-fold higher granulocyte yields when compared to unstimulated blood donors.<sup>13–17</sup> An example of a typical G-CSF stimulation protocol includes administering 300–480 µg of the drug subcutaneously and 8 mg dexamethasone orally, approximately 12 hours before beginning leukapheresis. Yields of  $4\text{--}8 \times 10^{10}$  PMNs are achieved regularly.

Adverse effects following G-CSF and dexamethasone are frequent but generally mild in nature.<sup>17</sup> Most donors experience minor discomfort including myalgia, headache, and generalized bone pain that is readily relieved with acetaminophen or ibuprofen. Donors given G-CSF for PMN collection have no reportable significant long-term adverse effects. One reassuring study found no cytogenetic abnormalities in individuals who had received G-CSF years earlier.<sup>18</sup> However, as a few reports suggest that the use of corticosteroids might cause posterior subcapsular cataracts in PMN donors<sup>19,20</sup> it seems logical to include cautionary information in the donor consent forms regarding the use of G-CSF and corticosteroids.

### **Apheresis collections and granulocyte concentrate manufacture**

Donation of granulocytes consists of utilizing an automated apheresis collection device such as the Spectra Optia (Terumo BCT) and the Trima Accel (Terumo BCT). The continuous flow separators typically processes 8–10 L of donor blood with the use of a sedimenting agent, such as hydroxyethyl starch (HES), for a minimum target volume of 250 mL ( $\pm 50$  mL). The final product consists of a minimum  $1 \times 10^{10}$  granulocytes per unit and approximately 20–50 mL red blood cells.<sup>21</sup>

Use of an erythrocyte-sedimenting agent, such as HES or pentastarch, during centrifugation leukapheresis is necessary to improve efficiency of cellular collection.<sup>11</sup> Although pentastarch was once advocated due to decreased impact on coagulopathy and increased removal from circulation,<sup>11</sup> HES is more widely used.<sup>22–24</sup> Hydroxyethyl starch is known to have a higher collection efficiency resulting in a larger PMN collection yield and has a sufficient safety profile that allows for its continued use with donors who undergo recurring collections.<sup>22,25,26</sup> Typical side effects of HES are mild in nature and include bone pain, headaches, generalized rash, and fatigue.<sup>17</sup> A decrease in the hematocrit is not surprising, due to the volume of red cells collected, which is a secondary effect of the sedimenting activity of HES.<sup>27</sup>

### **Function**

These granulocytes have normal bacterial killing, chemotaxis, and chemiluminescence superoxide production.<sup>28–31</sup> Thus, they should function normally in vitro. In vivo there is normal intravascular recovery and survival and particularly important normal migration to sites of inflammation.<sup>32–34</sup> The use of a G-CSF for donor stimulation does not alter these normal functions in vitro and in vivo.<sup>32</sup>

### **Granulocyte storage and distribution conditions**

As granulocytes have a short shelf life, it is best to transfuse the product as soon as possible after collection, preferably within 6–8 hours to ensure donor granulocyte function is retained.<sup>33</sup> The product is generally stored at room temperature, 20–24 °C, with little or no agitation for no more than 24 hours.<sup>21</sup> This was arrived at by in vivo studies of indium labeled granulocytes, where intravascular recovery, survival, and migration to sites of inflammation or in a skin window were used to assess in vivo function. Storage at 1–6 °C for 24 hours resulted in decreased intravascular circulation and reduction in migration to skin window reference,<sup>33</sup> but storage at room temperature for eight hours did not reduce the intravascular recovery or migration into the skin chamber. Storage at 1–6 °C for even eight hours reduced in vivo granulocyte function; thus, storage for up to eight hours at room temperature is recommended.

### **Granulocyte transfusion in clinical medicine**

#### **Historical overview of therapeutic granulocyte transfusion**

Granulocyte transfusions may be considered the oldest form of cell therapy with "leukocyte cream" reported to treat neutropenia in 1934. Subsequent studies in aplastic dogs showed that transfused granulocytes migrated to sites of infection. Initial studies were challenging due to difficulties obtaining enough granulocytes from healthy volunteers until the development of blood-flow separator in 1969. Case series suggested favorable outcomes and were followed

**Table 19.1** Historical Controlled Trials of Therapeutic Granulocyte Transfusions

Investigators	Success	Survival		Characteristics of Neutrophil Concentrates

by randomized controlled trials with conflicting results (Table 19.1). Three of the seven studies<sup>35–37</sup> reported a significant overall benefit for GTx while in two other studies<sup>38,39</sup> only certain groups of patients were found to benefit significantly. An analysis of these studies suggested that patients in the successful studies received relatively high doses of PMNs ( $>1.7 \times 10^{10}$  per day), and the donors were both erythrocytes and leukocytes compatible. Furthermore, two of the four studies with negative findings used PMNs collected by filtration leukapheresis for some patients<sup>38,39</sup> while it is now established that such PMNs have functional deficiencies.<sup>28</sup> Finally, control subjects responded particularly well to antibiotics alone in three of the four negative studies,<sup>38,40,41</sup> suggesting that these patients fared relatively well with conventional treatment alone, and it was not possible to document additional benefit by adding GTx. The results of the seven controlled GTx trials have been analyzed by formal meta-analysis,<sup>42</sup> and conclusions were that the low doses of PMNs transfused and the relatively high survival rate of the nontransfused control subjects were primarily responsible for the differing success rates of these studies.

### Contemporary experience with granulocyte transfusions

No satisfactorily designed and conducted randomized clinical trials of therapeutic GTx collected after G-CSF and dexamethasone donor stimulation have been reported to establish either the efficacy or the potential toxicity of modern GTx. Two randomized clinical trials<sup>43,44</sup> have been reported, but both have shortcomings and flaws that preclude firm conclusions or guidelines for clinical practice. Accordingly, practices must be based on an assessment of the overall literature.

Many case reports, which must be viewed with caution, suggest success for GTx. Most of them are reports of single patients responding favorably to GTx<sup>45,46</sup> reported patients with aplastic anemia, undergoing progenitor cell transplantation. Ozsahin et al.<sup>47</sup> and Bielorai et al.<sup>48</sup> reported single patients with chronic granulomatous disease and fungal infections. Bielorai et al.<sup>49</sup> reported a single patient with acute leukemia and sepsis with vancomycin-resistant *Enterococcus*. Lin et al.<sup>50</sup> or a single patient with multidrug-resistant *Pseudomonas* sepsis who underwent a successful HPC-A transplantation supported by GTx.

There are six studies of larger numbers of infected, neutropenic patients given GTx from G-CSF-stimulated donors (Table 19.2). However, even with investigation of larger numbers of patients, the benefits of GTx remain unclear because some lack concurrent control patients treated with antibiotics alone. In addition, in some studies<sup>51,52</sup> granulocytes were collected from donors stimulated only

with G-CSF and selected without regard for leukocyte compatibility. Although GTxs were successful in most patients, it was not possible to distinguish responses of fungus versus yeast infections. In three studies,<sup>52–54</sup> success was excellent for bacterial and stable fungus infections but was quite poor for progressive fungus infections with organ dysfunction.<sup>54</sup> Historical control patients ( $n = 74$ ) who did not receive GTx were included. Comparative success was similar between GTx recipients and nontransfused patients, and non-transfused controls had better success than PMN recipients for bacterial infections. The authors suggested that by including only patients with microbiologically documented infection they may have selected a group that was too advanced for the intervention to be of benefit. The study also indicated that allogeneic transplant recipients given GTx from unrelated donors experienced grade IV graft-versus-host disease more (GVHD) than controls who were not given GTx; however, relatively few patients were assessed for this end point. A recent retrospective review<sup>55</sup> showed that GTx did not affect the incidence of (GVHD).

Two additional studies reported results in ways that did not lend themselves to tabulation. Illerhaus et al.<sup>58</sup> transfused 42 neutropenic patients with GTx collected from donors stimulated with 5 µg/kg G-CSF. Eighteen of the patients had severe infections with a variety of organisms, and each received a median of three GTx each containing a median of  $2.6 \times 10^{10}$  leukocytes. Of these 18 patients, 8 (44%) improved, 4 (22%) stabilized, and 6 (33%) deteriorated—with 4 of these last 6 dying of pulmonary aspergillosis. Rutella et al.<sup>59</sup> transfused 20 patients with hematologic malignancies and neutropenic infections. Donors were HLA-identical siblings, and each received 5 µg/kg G-CSF. Favorable responses were seen in 54% of patients with bacterial and 57% of fungal infections. Underlying cancer status (i.e., complete or partial remission achieved) and recovery of blood PMN counts to 500/µL or more were significantly correlated with a favorable response to GTx.

No firm conclusions could be drawn from these larger reports of GTx for several reasons: (1) no concurrent control subjects were included (i.e., randomly assigned to receive antimicrobial drugs, but no GTx); (2) the number of patients reported, generally, was quite small; and (3) granulocyte collection methods were variable with a broad range of granulocyte doses transfused. Based on these preliminary findings, bacterial infections appeared to respond quite well to GTx, and relatively mild fungus and yeast infections responded modestly well. However, serious fungus infections with tissue invasion often resisted even the large doses of granulocytes<sup>51,53,57,58</sup>

There are two randomized, multicenter phase III trials, one from Europe<sup>43</sup> and the other from the United States.<sup>44</sup> The European

**Table 19.2** Neutropenic Patients Treated with GTx Collected from G-CSF-Stimulated Donors

Investigators	PMNs $\times 10^{10}$ per GTx	Stimulation	Leukapheresis	Outcomes
Hester et al. <sup>56</sup>	4.1	G-CSF 5 µg/kg	Pentastarch 7 L processed	60% (9 of 15) success with fungus (11 patients) and yeast (4 patients)
Grigg et al. <sup>53</sup>	5.9*	G-CSF 10 µg/kg	Dextran 10 L processed	100% (3 of 3) success with bacterial infection 0% (0 of 5) success with progressive fungus
Peters et al. <sup>51</sup>	3.5*	G-CSF 5 µg/kg or prednisolone	Hetastarch 6.4 L processed	67% (2 of 3) success with stable fungus 82% (14 of 17) success with bacterial infection
Price et al. <sup>52</sup>	8.2	G-CSF 600 µg/kg plus dexamethasone 8 mg	Hetastarch 10 L processed	54% (7 of 13) success with fungal infection 100% (4 of 4) success with bacterial infection 0% (0 of 8) success with invasive fungus
Hubel et al. <sup>54</sup>	4.6–8.1	G-CSF 600 µg/kg with or without dexamethasone 8 mg	Hetastarch or pentastarch 10 L processed	57% (4 of 7) success with yeast infection 55% (unrelated donor) success with bacterial infection 75% (family donor) success with bacterial infection 70% (unrelated donor) success with yeast infection 40% (family donor) success with yeast infection 15% (unrelated donor) success with fungal infection 25% (family donor) success with fungal infection
Lee et al. <sup>57</sup>	5.1–10.6	G-CSF 5 µg/kg and/or dexamethasone 3 mg/m <sup>2</sup>	Pentastarch 6–10 L processed	40% (10 of 25) success with multiple-organism infections

\* Assumptions made as PMN dose expressed  $\times 10^{10}$  unclear in these reports. PMN dose calculated using values for the total number and differential count of leukocytes collected, and the volume of units collected (Grigg et al.<sup>42</sup>). Dose calculated that would be given to a 70-kg recipient for Peters et al.<sup>44</sup> GTx, granulocyte transfusion; G-CSF, granulocyte colony-stimulating factor; PMNs, granulocytes.

multicenter randomized trial included 74 patients in five centers in Austria and Germany randomized between 1999 and 2005. Due to declining recruitment, the published study included less than 50% of the expected sample size. The patients did not have to have a microbiologically documented infection. Other limitations of the study included low number of transfusions (17 of 39 patients in the GTx arm received only one or two GTx before neutrophil recovery) and significant crossover between arms. Donors were stimulated only with G-CSF, and the doses of granulocytes per infusion were also lower than desired: 16% of the transfusions had less than the recommended by the study design neutrophil dose of  $3 \times 10^8$  per kg (which is still significantly less than the currently ideal  $4 \times 10^{10}$  dose). There was no subgroup identified that seemed to benefit more than the others. The RING (Resolving Infection in Neutropenia with Granulocytes) study was able to only partially overcome the limitations of prior trials. As in the previous trial, accrual was too slow and only 114 patients were randomized out of a target sample of 236. Originally, only patients with proven infection were recruited; however, as a result of the slow accrual, the inclusion criteria were changed to allow patients with presumed infection, and the time between meeting eligibility and randomization was extended from the original 24 hours after diagnosis to one week. The primary end point of clinical success was defined as survival to Day 42 plus clinical response of the infection. The adjudicating panel was blinded to the subject's study arm. Donors were stimulated with 480 mg of G-CSF and 8 mg of dexamethasone orally. Continuous flow apheresis with hydroxyethyl starch as a sedimenting agent was used, processing 7–10 L of blood. The goal was to collect  $4 \times 10^{10}$  granulocytes per transfusion ( $0.6 \times 10^9$ /kg); however, this was not always possible and approximately one-quarter of the subjects received a lower dose. The dose differences were site-specific and not due to dose or timing of G-CSF or dexamethasone, nor to amount of blood processed during the collection. There was no difference in the success rate

between the GTx and control groups, whether analyzed per protocol (PP: 49% vs. 41%) or by modified intention to treat (MITT: 42% vs. 43%). There was no discernible difference in the response rate based on the type of infection (bacterial vs. fungal), location of infection, or risk category. A model that adjusted for baseline prognostic factors like Zubrod score or mechanical ventilation did not find any difference either. In their discussion, the investigators pointed out the low power that did not allow to exclude with certainty a beneficial effect of GTx. In a post hoc analysis, they compared subjects who received high dose as intended with those who received low dose and found a significant difference in the success rate (high dose vs. low dose: 59% vs. 15%,  $P < 0.01$ ). Subjects in the control group did better than subjects in the low-dose group, and worse than subjects in the high-dose group, but these differences were not statistically significant. A retrospective review of patients with invasive Fusarium infections<sup>50</sup> also concluded that high-dose GTx may effectively control life-threatening infections to “bridge” periods of severe neutropenia until marrow function is restored, though another single-center, retrospective study from Italy found that recipients of both low-dose ( $<1.5 \times 10^8$  cells/kg) and high-dose ( $>3 \times 10^8$  cells/kg) GTx had higher infection-related mortality than recipients of “standard doses” ( $1.5\text{--}3 \times 10^8$  cells/kg).<sup>60</sup>

Thus, despite attempts<sup>43,44</sup> to perform a properly designed and conducted randomized clinical trial to test the efficacy of high-dose GTx collected from donors stimulated with G-CSF + dexamethasone, the definitive/proven role of GTx in the management of infected, neutropenic, oncology/transplant patients awaits definition by a successfully completed randomized clinical trial—something that seems elusive to date. A Cochrane review of therapeutic granulocyte transfusion<sup>61</sup> included 10 trials with a total of 587 participants conducted between 1975 and 2015. Overall, the quality of the evidence was very low to low across different outcomes. There may be no difference in all-cause mortality over

30 days between participants receiving therapeutic granulocyte transfusions and those that did not (six studies; 321 participants; RR 0.75, 95% CI 0.54–1.04). There were no differences between the granulocyte dose subgroups ( $<1 \times 10^{10}$  per day vs.  $\geq 1 \times 10^{10}$  per day) (test for subgroup differences  $P = 0.39$ ). There was a difference (reduction) in all-cause mortality between the studies based on the age of the study (published before 2000 vs. published 2000 or later) (test for subgroup differences  $P = 0.03$ ). There was no difference in clinical reversal of concurrent infection between participants receiving therapeutic granulocyte transfusions and those that did not (five studies; 286 participants; RR 0.98, 95% CI 0.81–1.19). There was insufficient evidence to determine whether there is a difference in pulmonary serious adverse events (one study; 24 participants; RR 0.85, 95% CI 0.38–1.88). None of the studies reported number of days on therapeutic antibiotics, number of adverse events requiring discontinuation of treatment, or quality of life. The authors concluded that in people who are neutropenic due to myelosuppressive chemotherapy or a hematopoietic stem cell transplant, there is insufficient evidence to determine whether granulocyte transfusions affect all-cause mortality. To be able to detect a decrease in all-cause mortality from 35% to 30% would require a study containing at least 2748 participants (80% power, 5% significance).

### Prophylactic granulocyte transfusions

Another approach is the use of granulocyte transfusions as prophylaxis to prevent infection. There are 12 such studies. Based on historical reports, prophylactic GTxs were of marginal value. Some measure of success was found in 7 of 12 studies.<sup>62–68</sup> Five studies failed to show a benefit for prophylactic GTxs.<sup>69–73</sup> In none of these five negative studies, there were large numbers of granulocytes obtained from matched donors and transfused daily. In a situation analogous to that for the negative therapeutic GTX trials, the failure of prophylactic GTX might be explained, as least in part, by inadequate dose of granulocytes.

In 1997, data from 8 of the 12 controlled trials of prophylactic GTX were analyzed quantitatively by means of formal meta-analysis.<sup>74</sup> The findings of the meta-analysis confirmed that variability in the dose of PMNs transfused, inconsistent attempts to provide leukocyte-compatible GTX, and the varying durations of severe neutropenia in different patient groups were primarily responsible for the differing success rates in the reported controlled trials. It was recommended that high doses of compatible PMNs should be transfused, if future trials are conducted.<sup>74</sup>

The role of high-dose prophylactic GTX (i.e., from G-CSF-stimulated donors) has not been established by definitive clinical

trials. Table 19.3 summarizes the few published studies. In a Cochrane database systematic review,<sup>61</sup> the authors concluded that in patients who are neutropenic due to chemotherapy or HSCT, there is low-grade evidence that prophylactic granulocyte transfusions decrease the risk of bacteraemia or fungemia. Prophylactic GTxs appear promising, but their efficacy, potential adverse effects, and economic analysis await definition by randomized clinical trials of sufficient numbers of patients.

### Pediatric granulocyte transfusion

There are few publications on the use of GTX in pediatric patients, and no randomized controlled trials have been performed. Table 19.4 offers a summary of some the published data. GTX was determined to be beneficial in retrospective analyses<sup>78–81</sup> and prospective uncontrolled studies.<sup>82</sup> In an open, single-center, prospective phase II clinical trial of early-onset G-CSF-mobilized GTX in neutropenic children with severe refractory infections,<sup>83</sup> GTX was well tolerated, with 93% clearance of initial infection and no other series.<sup>84</sup> There is a possible role for GTX in preventing infections or progression of infections in children with anticipated prolonged neutropenia after HSCT or chemotherapy<sup>85</sup> or in children with chronic granulomatous disease.<sup>86–88</sup> There is also a possible role for GTX in preventing infections or progression of infections in children with anticipated prolonged neutropenia after HSCT or chemotherapy.<sup>85</sup>

Most patients with congenital disorders of PMN dysfunction have adequate numbers of blood PMNs, but they are susceptible to serious infections because their PMNs fail to kill pathogenic microorganisms.<sup>92</sup> Patients with severe forms of PMN dysfunction are relatively rare, and no randomized clinical trials have been reported to establish the efficacy of therapeutic GTX in their management. Several studies have suggested that children with chronic granulomatous disease could benefit for GTX,<sup>93–97</sup> however, because of lifetime problems with infections, prophylactic GTxs are impractical.

Neonates (infants within the first month of life) are another group of patients who may suffer life-threatening bacterial infections caused, at least in part, by PMN dysfunction and neutropenia. A Cochrane review<sup>98</sup> included four trials and showed that there was no significant difference in all-cause mortality (RR 0.89, 95% CI 0.43–1.86; typical RD -0.05, 95% CI -0.31 to 0.21) when GTX was compared with placebo or no transfusion. The study concluded that there is inconclusive evidence to support or refute the routine use of granulocyte transfusions in neutropenic, septic neonates.

**Table 19.3** Prophylactic GTX Using PMNs from G-CSF-Stimulated Donors in Hematopoietic Progenitor Cell Recipients

Investigator	PMNs $\times 10^{10}$ per GTX	Stimulation	Leukapheresis	Outcomes
Bensinger et al. <sup>16</sup>	4.2	G-CSF 3.5–6 µg/kg	Variable	Not reported
Adkins et al. <sup>75</sup>	4.1 (Day 1)	G-CSF 5 µg/kg $\times$ 5 days after transplantation	Hetastarch	60% (6 of 10) Afebrile
Adkins et al. <sup>76</sup>	5.1 (Day 3) 6.1 (Day 5) 5.6 (Day 2)	G-CSF 10 µg/kg	7 L processed Days 1, 3, and 5 Hetastarch	40% (4 of 10) Febrile Three culture positive Reduction of fever and antibiotics if no leukocyte antibodies
Oza et al. <sup>77</sup>	7.0 (Day 4) 8.5 (Day 6) 9.9 (Day 8) 5.9 (Days 3 and 5) 5.2 (Days 6 and 7)	GCSF 10 µg/kg	7 L processed Days 2, 4, 6, and 8 Hetastarch 7 L processed Days 3 and 6 or Days 5 and 7	Less fever and antibiotics when GTX given; no effect on hospital Stay or survival

GTX: granulocyte transfusion; PMNs: granulocytes; F-CSF: granulocyte colony-stimulating factor.

**Table 19.4** Pediatric Patients Treated with Granulocyte Transfusions

Investigator	No. of Patients	Study Design	Stimulation	Outcomes
Grigull et al. <sup>89</sup>	3	Case series	G-CSF	All children survived
Kikuta et al. <sup>82</sup>	13	Phase I/II	G-CSF	Infection resolved in nine patients
Sachs et al. <sup>83</sup>	27	Phase II	G-CSF	92.6% cleared the infection, and 81.5% were alive and without signs or symptoms of their infection one month later.
Drewniak et al. <sup>78</sup>	16	Prospective	G-CSF + dexamethasone	All six children with aspergillosis cleared their infection.
Seidel et al. <sup>90</sup>	49	Prospective	G-CSF or prednisolone	70% showed clinical recovery 28-day survival probability of the total patient cohort was $0.72 \pm 0.06$ 100-day survival was $0.52 \pm 0.07$
Graham et al. <sup>84</sup>	13	Retrospective	prednisolone	50% of children with fungal infection and 100% with bacterial survived to discharge
Atay et al. <sup>80</sup>	35	Retrospective	G-CSF + dexamethasone	Infection-related survival rate was 82.4% and the overall survival rate was 77.1% at Day 30
Ozturkmen et al. <sup>79</sup>	10	Retrospective	G-CSF + dexamethasone	clinical response rate of 69.2% infection-related mortality 30.8%
Diaz et al. <sup>81</sup>	18	Retrospective	G-CSF + dexamethasone	92% of the episodes of acute infection had complete or partial resolution
Nikolajeva et al. <sup>91</sup>	28	Retrospective	G-CSF + dexamethasone	64% of patients survived

## Summary and recommendations for clinical practice

The use of G-CSF + dexamethasone to stimulate granulocyte donors has brought GTx therapy into a new era. It is now possible to collect relatively large numbers of granulocytes ( $>4 \times 10^{10}$ ). To determine whether a local need exists for therapeutic GTx, physicians should survey the outcome of neutropenic infections at their own institutions. If these infections respond promptly to antibiotics alone and the survival rate approaches 100%, therapeutic GTxs are unnecessary and should not be used because possible benefits are too small to outweigh the risks and expense. In contrast, if patients with infection and neutropenia (<500 PMN/ $\mu$ L) do not respond quickly and completely to antibiotics alone, the addition of therapeutic GTx should be considered along with other modifications of therapy, such as selection of different antibiotics, closer monitoring of antibiotic blood levels, intravenous  $\gamma$ -globulin therapy, and treatment with recombinant myeloid growth factors.

Once the decision has been made to provide either therapeutic or prophylactic GTx, granulocytes should be collected and transfused optimally as follows.

Collect granulocytes from allogeneic donors with a goal to transfuse  $6-8 \times 10^{10}$  granulocytes per GTx with an absolute lower limit of  $4 \times 10^{10}$ . Develop and refine methods to consistently ensure desired yields. The need to select donors who are leukocyte compatible with recipients has not been established for high-dose granulocyte transfusions despite the historical importance of doing so when lower doses of PMNs were transfused although this has been established for lower dose transfusions.<sup>9</sup> In studies of high-dose GTx, Price et al.<sup>52</sup> found no apparent adverse effects of several leukocyte antibodies (granulocyte agglutinating, granulocyte immunofluorescent, lymphocytotoxic, and lymphocyte immunofluorescent) that became detectable in the recipient's blood during GTx therapy (i.e., not preexisting antibodies). Adkins et al.,<sup>76</sup> however, found the presence of lymphocytotoxic antibodies to be a poor prognostic factor, in general, although actual donor-recipient incompatibility for individual GTx was rare. Until more data are available, it seems prudent to select donors who are leukocyte compatible (e.g., as done to select platelet donors by HLA matching or leukocyte crossmatching) whenever easily feasible, but never to delay or deny GTx therapy if selecting donors is not readily accomplished.

Stimulate donor neutrophilia by giving 300–600  $\mu$ g G-CSF subcutaneously plus dexamethasone orally 12 hours before beginning leukapheresis. A regimen reported to produce high granulocyte yields with reasonable adverse effects on the donor is one 480  $\mu$ g

vial G-CSF given subcutaneously plus 8 mg dexamethasone given orally 12 hours before leukapheresis.

Process 8–10 L of donor blood using a continuous-flow, centrifugation blood separator with citrated HES (hetastarch preferred) solution infused throughout the entire collection at a starch–donor blood ratio of 1:13.

Transfuse the granulocyte unit as soon as possible after collection to minimize storage damage. Granulocyte function begins to deteriorate within a few hours of storage. Until the efficacy of stored granulocytes from G-CSF-stimulated leukapheresis donors is documented, it seems wise to transfuse preferably within eight hours or so of collection. This timing may require agreement by the patient's physician to perform infectious disease testing on the donor before actual granulocyte collection (e.g., at the time G-CSF is administered before leukapheresis) or accept a donor who has been tested recently for a previous donation (e.g., within the preceding 10–30 days), but has not been tested for the PMN collection in question.

Give GTx daily until resolution of infection—as evidenced by clearing of tissue lesions, negative cultures, or resolution of fever—or until marrow function recovers to produce adequate numbers of endogenous PMNs. Determining marrow recovery may be difficult because PMNs collected from G-CSF-stimulated and dexamethasone-stimulated donors and transfused at doses of  $6-8 \times 10^{10}$  PMNs may elevate the recipient's blood PMN count to more than 1000/ $\mu$ L for more than 24 hours. Accurate differentiation of transfused PMNs from those produced endogenously is challenging, and marrow recovery must be based on a sustained increase in blood PMN count after GTx is discontinued.

## CHAPTER 20

# Composition of plasma

---

**Peter Hellstern**

Center of Hemostasis and Thrombosis Zurich, Zurich, Switzerland

The first part of this chapter describes the composition of plasma, focusing on those protein components that are important for treatment with plasma or its derivatives. The second part addresses individual factors influencing plasma levels of therapeutic plasma proteins. The regulation of blood coagulation and fibrinolysis and clinically useful blood coagulation and fibrinolysis screening tests are then discussed.

### Plasma composition

Plasma is the cell-free part of blood composed of water, proteins, electrolytes, lipids, and carbohydrates. It is the transportation medium through which nutrients, hormones, waste products, and drugs are transported through the body. *In vivo*, the fluidity of plasma is maintained through complex interactions between its procoagulant and anticoagulant proteins and between these proteins, circulating blood cells, and the endothelium. Coagulation activation in plasma is prevented and its fluidity maintained *in vitro* by the addition of anticoagulants. Citrate is presently the only anticoagulant used for collecting therapeutic plasma and plasma for fractionation, the starting material for the manufacture of plasma protein concentrates. Although proteomics based on two-dimensional gel electrophoresis and mass spectrometry has revealed about 10,000 different human plasma proteins,<sup>1,2</sup> the number of constituents important for transfusion medicine is small, comprising albumin, immunoglobulins G (IgG) and M (IgM), alpha-1-antitrypsin, C1 inhibitor, von Willebrand factor (vWF), vWF-cleaving protease, blood coagulation factors, and the blood coagulation inhibitors antithrombin (AT) and protein C. The plasma levels and biological half-lives of these plasma proteins are subject to large interindividual variation. Plasma is either prepared from citrate-phosphate-dextrose-anticoagulated whole blood units or collected by automated plasmapheresis. Because of lower final citrate concentrations and lower dilution due to lower anticoagulant-to-blood ratios, apheresis plasma contains higher concentrations of clotting factors V, VIII, IX, and XI than plasma from whole blood.<sup>3,4</sup> A dilution of 1:7 to 1:9 for plasma from whole blood and 1:16 for apheresis plasma has to be considered when plasma protein concentrations are given which are related to circu-

lating undiluted plasma. IgG levels in plasma from whole blood are significantly greater than in apheresis plasma because of a decrease in IgG when individuals donate apheresis plasma repeatedly at short intervals.<sup>4,5</sup>

### Albumin

Albumin is a 66.4-kD protein synthesized in the liver. Considering a total plasma volume of 3 L, about 120–140 g or 40% of the total body content of albumin circulates in the plasma at concentrations between 35 and 50 g/L (Table 20.1), which is more than 50% of the total plasma protein concentration, ranging from 64 to 88 g/L. The albumin concentration in the interstitial space of 10–12 L is about 14 g/L. The intravascular albumin compartment is responsible for 80% of plasma oncotic pressure, thus mainly contributing to maintaining blood volume. An intact liver synthesizes 12 g of albumin per day. In a steady state, the same amount of albumin is eliminated per day. The biological half-life of albumin in plasma is 17–20 days. Compensatory reduction of albumin metabolism occurs when plasma levels decrease because of reduced synthesis in the liver or capillary leakage.<sup>6</sup> A marked acquired hypoalbuminemia is a non-specific marker of severe illness and strongly indicates poor prognosis.<sup>7,8</sup>

The functions of albumin are as follows:

- Maintenance of the intravascular oncotic pressure.
- Binding and transportation of drugs, vitamins, minerals, bilirubin, uric acid, hormones, amino acids, and fatty acids.
- Binding of toxic metabolites, among them free fatty acids, and radical scavenging.

Despite all these important functions of albumin, it is remarkable that congenital analbuminemia causes only mild clinical symptoms (e.g., hypotension or discrete pretibial edema at all ages) or no symptoms at all.<sup>9</sup>

Commercially available albumin preparations are obtained from plasma fractionation, according to Cohn and Oncley<sup>10</sup> or Kistler and Nitschmann,<sup>11</sup> as fraction V and are subsequently pasteurized for virus inactivation.<sup>12</sup> These solutions contain either 3.5–5% or 20–25% (w/v) albumin at a purity of 95–98%. Albumin is also added to many drugs and plasma protein concentrates to stabilize the respective active ingredients.

**Table 20.1** Therapeutic Plasma Proteins: Albumin, Immunoglobulins, Alpha-1-Antitrypsin, and C1 Inhibitor

Plasma Protein	Plasma Concentration (g/L)	Biological Half-Life	Main Functions
Albumin	35–50	17–20 days	Maintenance of intravascular oncotic pressure, transportation protein, radical scavenger
Immunoglobulin G	6–17	23 days	Humoral immunity
Immunoglobulin M	0.5–2.5	5 days	Humoral immunity
Alpha-1-antitrypsin	1.5–3.0	4–7 days	Inhibits neutrophil elastase
C1 inhibitor	0.2–0.3	30–60 hours	Inhibits complement C1 activation

Plasma concentrations represent the 5th and 95th percentiles; biological half-lives represent the means or the 5th and 95th percentiles of elimination half-lives.

### Immunoglobulins G and M

IgG and IgM are glycoproteins synthesized in plasma cells and circulating in plasma at concentrations between 6 and 17 g/L and between 0.5 and 2.5 g/L, respectively. The molecular weights are 150 kD for IgG and 971 kD for IgM, and the half-lives are about 23 and 5 days, respectively.

Polyvalent intravenous immunoglobulin (IVIG) preparations can also be administered subcutaneously and are prepared from fraction II during plasma fractionation.<sup>12</sup> Current virus inactivation and elimination procedures are low pH incubation, pasteurization, solvent–detergent treatment, caprylic acid treatment, and nanofiltration. Although most IVIG preparations are primarily IgG with only trace amounts of other immunoglobulin isotypes, some IgM-enriched IVIGs contain up to 15% IgM and have been used for the treatment of severe sepsis and septic shock.<sup>13</sup>

Hyperimmune immunoglobulin preparations are obtained from the plasma of actively immunized donors using ethanol fractionation or chromatography.<sup>12</sup> They can be administered intravenously or intramuscularly and are used to prevent postexposure infections, intoxication by tetanus toxoid, and immunization to Rh-positive red cells. For more details, see Chapter 23. Convalescent plasma passively transfers antibodies capable of neutralizing viruses including COVID-19 with the goal of reducing the severity of illness, especially respiratory diseases.<sup>14,15</sup>

### Alpha-1-antitrypsin

Alpha-1-antitrypsin synthesized in the liver is the most abundant serine protease inhibitor (serpin) in plasma. It inhibits a variety of serine proteases of which neutrophil elastase is the most important target. The molecular weight is 52 kD, the plasma concentration is 1.5–3 g/L, and the half-life is 4–7 days.<sup>16,17</sup> Hereditary alpha-1-antitrypsin deficiency resulting in plasma levels lower than 0.8 g/L occurs at a prevalence between 1 in 1600 and 1 in 5000.<sup>18</sup> It is associated with lung emphysema and liver disease in childhood. Plasma-derived alpha-1-antitrypsin concentrates are indicated for the treatment of patients with emphysema secondary to congenital deficiency.<sup>19</sup>

### C1 inhibitor

C1 inhibitor is a 105-kD serpin synthesized in the liver. The plasma concentration is 0.24 g/L, and the half-life ranges from 30 to 60 hours.<sup>20,21</sup> C1 inhibitor affects early activation of the classical complement pathway by blocking activated C1 and subsequent C2,4 complex formations.<sup>22</sup> It also inhibits activated factors XI and XII and plasmin, and the formation of factor XIa, kallikrein, and bradykinin.

An inherited or acquired deficiency of C1 inhibitor may cause angioedema, which is characterized by subcutaneous or mucosal swelling in any part of the skin or the respiratory and gastrointesti-

nal tracts.<sup>22</sup> The prevalence of hereditary angioedema is from 1 in 10,000 to 1 in 50,000. C1 inhibitor concentrates purified by chromatography from the cryoprecipitate-reduced plasma produced during plasma fractionation are used successfully for the treatment of acute attacks of angioedema or for prophylaxis including before surgery.<sup>20,23</sup>

### von Willebrand factor–cleaving protease

The vWF-cleaving protease (a disintegrin and metalloprotease with a thrombospondin type 1 motif, member 13, ADAMTS13) is a 70-kD protein<sup>24</sup> expressed in the liver, platelets, and other tissues,<sup>25,26</sup> and circulates in plasma at concentrations between 0.7 and 1.3 mg/L.<sup>27</sup> The elimination half-life is 2–3 days.<sup>28</sup> The plasma enzyme cleaves the A2-domain of vWF. A defective cleaving protease results in unusually large vWF multimers, which are associated with thrombotic thrombocytopenic purpura (TTP). Therapeutic plasma contains normal vWF-cleaving protease activities and is effective for the treatment of TTP through therapeutic plasma exchange.<sup>29,30</sup>

### Clotting factors, coagulation factor inhibitors, and von Willebrand factor

The coagulation proteins discussed here are responsible for normal hemostasis (Table 20.2). Except for factor V, virus-inactivated plasma-derived concentrates have been developed for preventing or treating bleeding caused by hereditary or acquired vWF or any clotting factor deficiency states.<sup>12</sup> Antithrombin and protein C concentrates are also available and are used mainly for prophylaxis or treatment of thromboembolic complications in patients with hereditary deficiency of the respective blood coagulation inhibitor.<sup>12</sup> Because not all clotting factor and inhibitor concentrates are available in all developed countries, factor V deficiency, for which a concentrate has not yet been produced, and other clotting factor deficiency states (e.g., factor XI deficiency) are alternatively treated with plasma.<sup>31</sup>

Fibrinogen is the precursor of fibrin. Thrombin converts fibrinogen into fibrin monomers by cleaving fibrinopeptides A and B. Fibrin monomers polymerize to form an unstable fibrin clot, which is stabilized by factor-XIIIa-induced crosslinkage. Fibrinogen is also necessary for supporting platelet function. Prothrombin (factor II); clotting factors VII, IX, X, and XI; and protein C are proenzymes of respective serine proteases. After activation by thrombin, factor V accelerates the activation of prothrombin, factor VIII, and factor X. Factor XIII is activated by thrombin to form a transglutaminase, which stabilizes fibrin clots by crosslinkage. vWF is essential for platelet–subendothelium adhesion and platelet aggregation, and for the transportation of factor VIII in plasma. vWF protects factor VIII from early proteolysis. Antithrombin is a stoichiometric serpin that strongly inhibits thrombin and factors IXa,

**Table 20.2** Clotting Factors, Von Willebrand Factor, Antithrombin, and Protein C

Plasma Protein	MW (kD)	Plasma Concentration (mg/L)	Plasma Activity (U/dL)	Half-Life (Hours)	Main Functions	Replacement by Plasma-Derived Concentrates <sup>12</sup> or Plasma
Fibrinogen	340	2.5 g/L	1.5–4 g/L <sup>31</sup>	96 <sup>31</sup>	Clot formation, precursor of fibrin; supports platelet function	Fibrinogen concentrate, cryoprecipitate, plasma; locally, fibrin sealant <sup>32</sup>
Factor II	72	150 <sup>33</sup>	70–130	60 <sup>34,35</sup>	Proenzyme of thrombin	Prothrombin complex concentrates (PCCs) and plasma <sup>31,34</sup>
Factor V	330	7 <sup>36,37</sup>	70–125	12 <sup>38</sup>	Cofactor of prothrombin activation by factor Xa	Plasma <sup>31</sup>
Factor VII	50	1 <sup>39</sup>	70–150	5 <sup>34,30</sup>	Proenzyme of factor VIIa, which activates factor IX and factor X	Factor VII concentrates <sup>40</sup> and factor VII containing PCC
Factor VIII	330	0.15 <sup>41</sup>	60–200	14 <sup>42</sup>	Cofactor of factor X activation by factor IXa	Factor VIII concentrates and factor VIII/vWF concentrates
vWF	600–2 × 10 <sup>4</sup>	8 <sup>43</sup>	50–180	12 <sup>44,45</sup>	Platelet–subendothelium adhesion; platelet aggregation; transports factor VIII and protects it from proteolysis	Factor VIII/vWF concentrates and vWF concentrates
Factor IX	57	5 <sup>43</sup>	60–140	30 <sup>42</sup>	Proenzyme of factor IXa, which activates factor X	Factor IX concentrates
Factor X	59	10 <sup>43</sup>	70–130	30 <sup>34</sup>	Proenzyme of factor Xa, which activates prothrombin	PCC, factor X concentrates, <sup>46</sup> and plasma <sup>31</sup>
Factor XI	143	5 <sup>47</sup>	65–130	50 <sup>48,49</sup>	Proenzyme of factor XI, which activates factor IX	Plasma, factor XI concentrates <sup>31,47</sup>
Factor XIII	320	20 <sup>50</sup>	60–220	170 <sup>31</sup>	Proenzyme of factor XIIIa, which stabilizes fibrin by crosslinkage	Factor XIII concentrates <sup>51</sup>
Antithrombin	58	150 <sup>52</sup>	75–120	72 <sup>52</sup>	Stoichiometric serpin, inactivates thrombin, factor IXa, factor Xa, and factor Xla	Antithrombin concentrates <sup>53</sup>
Protein C	62	44 <sup>43</sup>	70–170	9 <sup>54</sup>	Proenzyme of activated protein C, which inactivates factor Va and factor VIIIa	Protein C concentrates <sup>55</sup>

Plasma concentrations represent the means or medians; plasma activities represent the 5th and 95th percentiles; half-lives represent the mean or median elimination half-lives; PCC: prothrombin complex concentrate; vWF: von Willebrand factor.

Xa, and Xla. Once activated by thrombin–thrombomodulin, activated protein C inhibits factors Va and VIIIa.

Most clotting factors, AT, and protein C are synthesized in the liver. Other sites of protein expression are megakaryocytes and endothelial cells for factor V and the  $\alpha$ -chain of factor XIII. vWF is synthesized in megakaryocytes and endothelial cells.

The synthesis of functionally active prothrombin complex factors II, VII, IX, and X and protein C in the liver requires vitamin-K-mediated gamma-glutamyl carboxylation. Impairment of carboxylation occurs in vitamin K deficiency, in the presence of vitamin K antagonists, and in some cases of liver dysfunction. This results in the synthesis of functionally impaired or inactive prothrombin complex factors, called *proteins induced in vitamin K absence or antagonism* (PIVKA).

## Factors influencing individual plasma composition

### Age and gender

The physiologic aging process is accompanied by an increase in plasma levels of fibrinogen; factors V, VII, VIII, IX, XI, and XIII; protein C; and protein S in both genders.<sup>56</sup> A significant decrease of prothrombin activity levels with increasing age has been found in men but not in women.<sup>57</sup> Young women have significantly lower AT plasma levels than males of similar age. Because of a marked increase after menopause, AT levels in older women exceed levels in male contemporaries.<sup>58</sup> Gradually declining AT plasma levels have been observed in males older than 45 years.<sup>58</sup> Pregnancy is associ-

ated with marked increases in levels of fibrinogen, prothrombin, factors VII and VIII, vWF, and factor X, whereas factor V, factor IX, AT, and protein C levels are largely unchanged.<sup>59</sup>

### ABO blood group

Individuals with blood groups O, A<sub>1</sub>O, and A<sub>2</sub>A<sub>2</sub> have on average about 20–25% lower factor VIII and vWF plasma levels when compared with other ABO blood group constellations.<sup>60–62</sup>

### Acute phase reaction

An acute phase response caused by any trigger of inflammation results in an increase in plasma levels of alpha-1-antitrypsin, C1 inhibitor, fibrinogen, prothrombin, factor VIII, and vWF and a decrease in albumin levels.<sup>63</sup> Smoking causes a low-grade systemic inflammatory response and concomitant increases in plasma fibrinogen.<sup>64–66</sup>

### Physical exercise and mental stress

Both acute severe physical exercise and acute mental stress cause increases in fibrinogen, factor VII, factor VIII, and vWF levels.<sup>67–71</sup> In contrast, prolonged severe physical exercise results in a decrease in factor VII levels, whereas fibrinogen levels continue to be increased during observation.<sup>72</sup>

### Hormones

Danazol, a weak androgen, improves the synthesis of C1 inhibitor, factor VIII, AT, and protein C.<sup>73</sup> Combined oral contraceptives induce increases in plasma fibrinogen; prothrombin; factors VII, VIII, IX, X, and XI; alpha-1-antitrypsin; and protein C, whereas AT

and protein S levels decrease.<sup>74–76</sup> Progestogen-only preparations lead to a decrease in factor VIII and an increase in protein S.<sup>77</sup>

### **Desmopressin (DDAVD)**

DDAVP has been used successfully to increase factor VIII and vWF levels in plasma donors.<sup>78,79</sup> The yields of these plasma proteins were markedly improved when cryoprecipitate or factor VIII concentrates were produced from plasma collected after pretreatment of donors with DDAVP.

### **The influence of storage and freezing on plasma composition**

Prolonged storage reduces factor VIII levels regardless of hold at 4 °C or at room temperature.<sup>80,81</sup> Storage at room temperature does, however, affect protein S activity, which is substantially less when compared to hold at 4 °C. Slow freezing at 20 °C reduces factor VIII and protein S activities markedly in comparison to rapid freezing to a core temperature of below 30 °C within one hour.<sup>80</sup> Factor VIII levels decline by 24% even when fresh plasma samples are frozen in liquid nitrogen, stored at 70 °C, and thawed at 37 °C for 10 min.<sup>82</sup>

### **Regulation of blood coagulation and fibrinolysis**

Hemostasis encompasses all processes of clot formation, clot lysis, and wound healing with the aim of maintaining vessel wall integrity. The mechanisms of hemostasis incorporate the vascular endothelium and subendothelium, platelets, leukocytes, red cells, pro- and anticoagulant, and pro- and antifibrinolytic proteins. Primary hemostasis is characterized by the formation of a platelet plug at the site of vessel wall injury. vWF forms a bridge between platelets and vascular subendothelial structures and promotes platelet aggregation. Secondary hemostasis is achieved by the formation of a stable fibrin clot, followed by fibrinolysis and tissue repair. Abnormal bleeding can result from impaired thrombin generation, clot formation, and clot stabilization, or hyperfibrinolysis. Conversely, increased coagulation and diminished fibrinolysis may provoke thrombosis.

Previous models have suggested two independent pathways of coagulation activation via the intrinsic and extrinsic cascades. However, it is now recognized that the generation or exposure of tissue factor (TF) at the site of vessel injury is the first physiologic step in initiating blood coagulation.<sup>83</sup> There are three closely linked phases of coagulation, comprising the initiation, amplification, and propagation processes (Figure 20.1). Clotting is mainly controlled by several circulating inhibitors. Activation of fibrinolysis results in fibrin cleavage by plasmin and subsequent restoration of vessel patency. The central role of thrombin in hemostasis by exerting both procoagulant and anticoagulant effects is illustrated in Figure 20.2.<sup>84</sup>

### **Initiation and amplification of coagulation**

Clotting is initiated by TF-factor VIIa complexes after TF is exposed to the circulating blood by smooth muscle cells, fibroblasts, disrupted or activated endothelial cells, or activated monocytes (Figure 20.1). Circulating factor VIIa represents approximately 1% of total factor VII and can be generated from the inactive zymogen by an autocatalytic mechanism. Factor VIIa does not express its full procoagulant activity until it is bound to TF.<sup>85</sup> TF-factor VIIa activates factors IX and X, and factor Xa generates thrombin by activating prothrombin (*initiation phase*). These small amounts of thrombin ensure that coagulation activa-

tion and further thrombin formation are maintained (*amplification phase*). Thrombin activates factors V, VIII, and XI, and platelets that provide the surface on which the *propagation phase* of coagulation occurs.

### **Propagation of thrombin generation, fibrin clot formation, and fibrin stabilization**

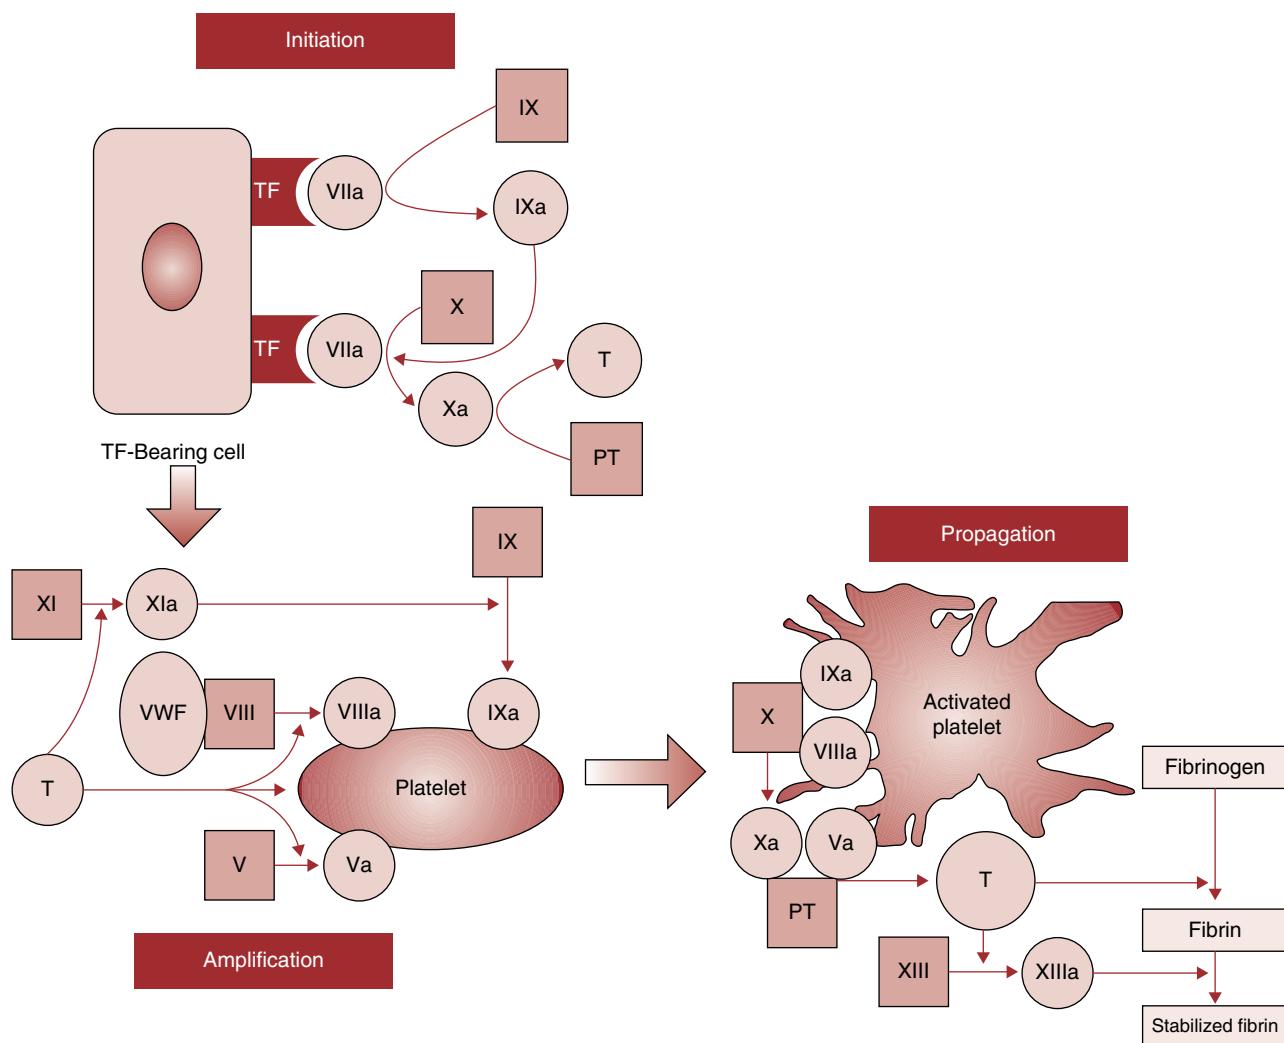

The *tenase complex* consisting of platelet membrane-bound factor IXa, factor VIIIa, and ionized calcium cleaves factor X much more effectively than TF-factor VIIa or factor IXa alone. Factor Xa binds to platelet surfaces and complexes with factor Va and calcium to form the *prothrombinase complex*, which rapidly generates large amounts of thrombin. Fibrin monomers resulting from thrombin-induced splitting of fibrinopeptides A and B from fibrinogen polymerize spontaneously to an unstable fibrin clot. Thrombin also activates factor XIII to the transglutaminase factor XIIIa, which stabilizes fibrin polymers by crosslinkage.<sup>86</sup>

### **Inhibition of blood coagulation and termination of clotting**

Several circulating inhibitors terminate the coagulation process (Table 20.3). The stoichiometric-heparin-binding serpin AT mainly inhibits thrombin and factor Xa and, less strongly, factors IXa and XIa.<sup>52</sup> Thrombin binds to endothelial thrombomodulin, and this complex activates protein C to the serine protease, activated protein C (APC).<sup>87</sup> Endothelial cell protein C receptor augments protein C activation by the thrombin-thrombomodulin complex. Together with its vitamin-K-dependent cofactor protein S, APC inactivates factors Va and VIIIa. Tissue factor pathway inhibitor (TFPI) downregulates blood coagulation by forming a quaternary complex with TF-factor VIIa/factor Xa. Heparin cofactor II is a specific inhibitor of thrombin in the presence of dermatan sulfate or heparin.<sup>52</sup> The protein-Z-dependent protease inhibitor is a serpin inhibiting factor Xa in the presence of the vitamin-K-dependent protein Z, phospholipids, and calcium.<sup>52</sup> Protein C inhibitor, a heparin-binding serpin, predominantly inhibits APC and thrombin.<sup>52</sup>

### **Fibrinolysis and its inhibition**

The role of the fibrinolytic system is to restore vessel patency once wound healing has maintained vessel wall integrity (Figure 20.3). The serine protease plasmin cleaves fibrin (and fibrinogen) at multiple sites, resulting in fibrin and fibrinogen degradation products (FDP), among them D-dimers (DD). Tissue plasminogen activator (tPA) released by endothelial cells is able to activate plasminogen to plasmin. Urokinase plasminogen activator (urokinase, UK) synthesized in endothelial and kidney cells also activates plasminogen to plasmin.<sup>88</sup> Plasmin cleaves not only fibrin but also fibrinogen and other plasma proteins. Fibrin specificity of plasmin is achieved by binding of plasminogen and tPA to the lysine binding sites of fibrin. Both plasminogen activators are mainly inhibited by plasminogen activator inhibitor type 1 (PAI-1) released from endothelial cells and platelets. Plasmin is predominantly inhibited by the very fast-acting plasmin inhibitor (alpha<sub>2</sub>-antiplasmin) and to a lesser extent by alpha<sub>2</sub>-macroglobulin. Plasmin inhibitor crosslinked to fibrin by factor XIIIa inhibits plasmin binding to fibrin. The thrombin-activatable fibrinolysis inhibitor (TAFI) is activated by thrombin-thrombomodulin complexes and protects clots from plasmin-induced degradation by removing lysine residues from fibrin.<sup>89,90</sup>

**Figure 20.1** Cell-based model of coagulation activation. Inactive clotting factors are in squares and active factors are in circles. The coagulation cascade is initiated by tissue factor (TF) release at the sites of cell injury. During the initiation phase, TF complexes with factor VIIa (FVIIa) at the site of cell injury. TF-factor VIIa activates factor IX and factor X. Factor Xa generates small amounts of thrombin, which activates platelets, factor XI, and cofactors V and VIII, allowing multiple positive feedback loops during the amplification phase. The tenase complex (factor VIIIa–factor IXa) generates large amounts of factor Xa on the surface of activated platelets. The prothrombinase complex (factor Va–factor Xa) converts prothrombin to thrombin, which forms fibrin from fibrinogen and activates factor XIII. PT: prothrombin; T: thrombin; TF: tissue factor.

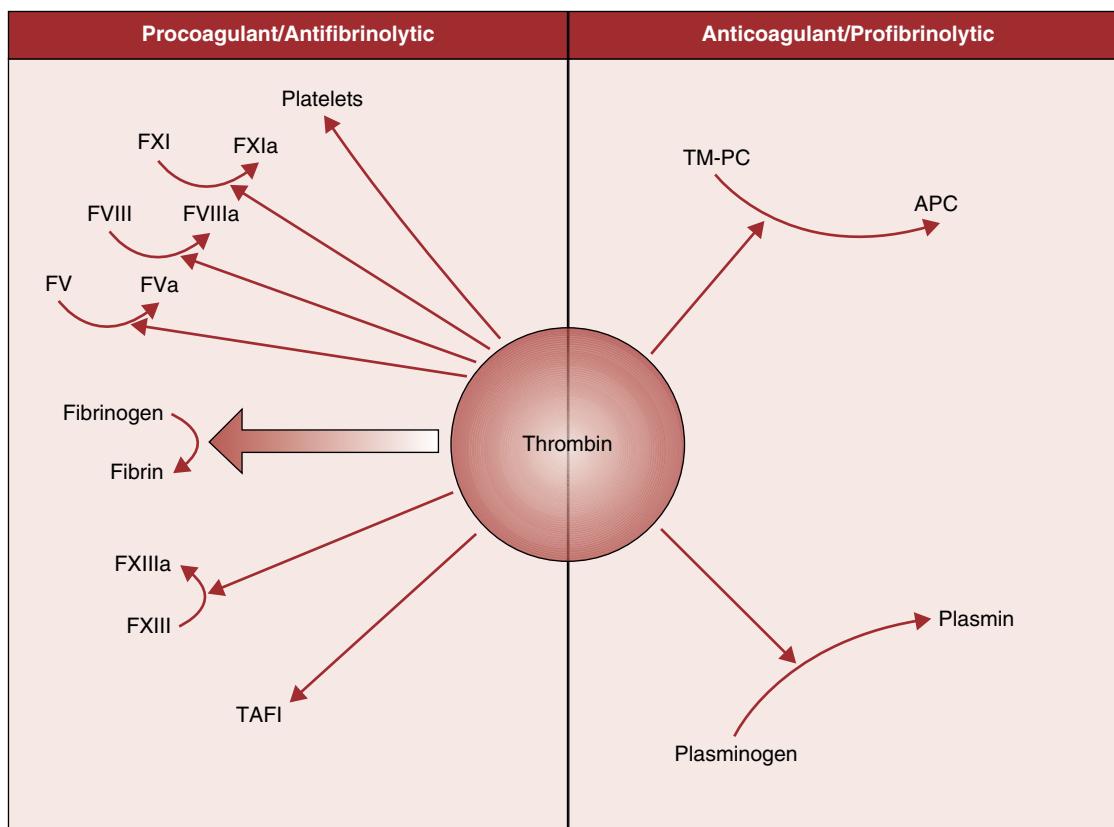

### Clinically useful coagulation and fibrinolysis screening tests

Coagulation and fibrinolysis screening tests are used for detecting disorders of secondary hemostasis caused by coagulation factor deficiencies, dysfunctional coagulation factors, inhibitors against coagulation factors, anticoagulants, or hyperfibrinolysis. In addition to a detailed clinical history and examination and laboratory investigation of disorders of primary hemostasis, coagulation and fibrinolysis screening tests are included in approaches to bleeding patients and to exclusion of bleeding disorders before operations or other invasive procedures.<sup>91</sup> Further applications of these tests are as follows:

- Monitoring of anticoagulant therapy.
- Monitoring of treatment with fresh frozen plasma or clotting factor concentrates.,
- Detection of lupus anticoagulants.
- Detection of hypercoagulable states.

The historical division of coagulation activation and subsequent fibrin formation into an *intrinsic pathway* comprising surface-contact factors and an *extrinsic pathway* (TF-factor VIIa) can be used for a better understanding of blood coagulation screening tests (Figure 20.4). The intrinsic pathway begins with the activation of factor XII and prekallikrein at negatively charged artificial surfaces as found on activated platelets and endothelial cells and at subendothelial collagen. Factor XIIa activates factor XIa and further prekallikrein to kallikrein. Factor XIa and kallikrein accelerate factor XII activation through a positive feedback mechanism. Factor XII and factor XI activation is amplified by high-molecular-weight (HMW) kininogen. Factor XIa activates factor IX, and factor IXa activates factor X. The extrinsic pathway starts with the formation of the TF-factor VIIa complex, also resulting in production of factor Xa.

The common pathway begins with factor X activation, where the intrinsic and extrinsic pathways converge. Factor Xa converts pro-

**Figure 20.2** The central role of thrombin in hemostasis. Procoagulant effects include platelet activation; the activation of clotting factors V, VIII, XI, and XIII; and subsequent formation of a stable fibrin clot. Thrombin acts as an anticoagulant by activating protein C after complexing with thrombomodulin. It promotes fibrinolysis by activating plasminogen and inhibits fibrinolysis by activating TAFI. APC: activated protein C; F: factor; PC: protein C; TAFI: thrombin activatable fibrinolysis inhibitor; TM: thrombomodulin. Source: Modified from Davie and Kulman.<sup>34</sup>

**Table 20.3** Inhibitors of Blood Coagulation and Their Main Functions

Plasma Protein	Main Functions
Antithrombin	Heparin-binding serpin; inhibits thrombin, factor Xa, factor IXa, and factor Xla
Protein C	Serine protease; inhibits factor Va and factor VIIIa
Protein S	Vitamin-K-dependent glycoprotein; cofactor of activated protein C
Thrombomodulin	Endothelial cell-surface glycoprotein; complexes with thrombin and activates protein C
Endothelial cell protein C receptor	Endothelial cell-specific transmembrane protein; augments protein C activation
Tissue factor pathway inhibitor (TFPI)	Trivalent protease inhibitor; inhibits TF–factor VIIa by forming a quaternary complex of TFPI, TF, factor VIIa, and factor Xa
Heparin cofactor II	Dermatan sulfate-binding serpin; inhibits thrombin
Protein-Z-dependent protease inhibitor	Serpin; inhibits factor Xa in the presence of protein Z

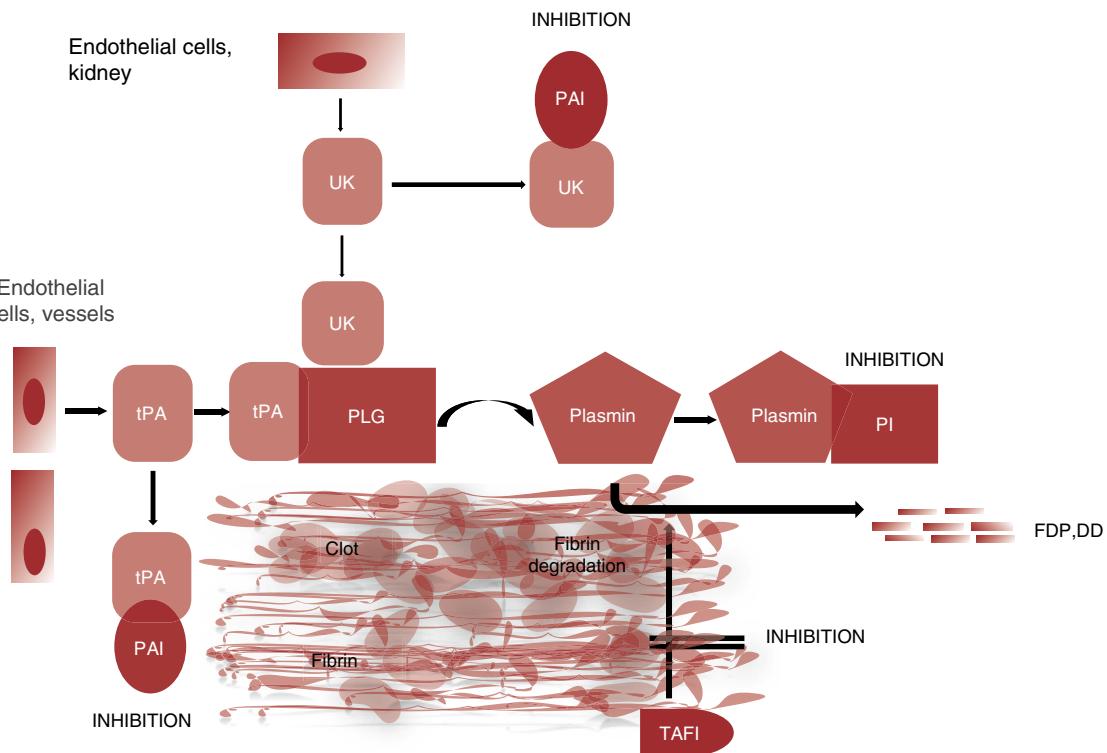

thrombin (factor II) to thrombin (factor IIa) in the presence of factor Va. Thrombin cleaves fibrin to form fibrin monomers, which polymerize spontaneously to an unstable fibrin clot.

Coagulation screening tests use fibrin polymerization as a measuring signal and have limited sensitivity to detect mild coagulation factor deficiencies or weak inhibitors against coagulation factors. Their specificity is also limited by the fact that several causes of abnormal clotting times are not associated with bleeding or thrombosis. Therefore, coagulation screening tests must be combined with the clinical history and symptoms when assessing the

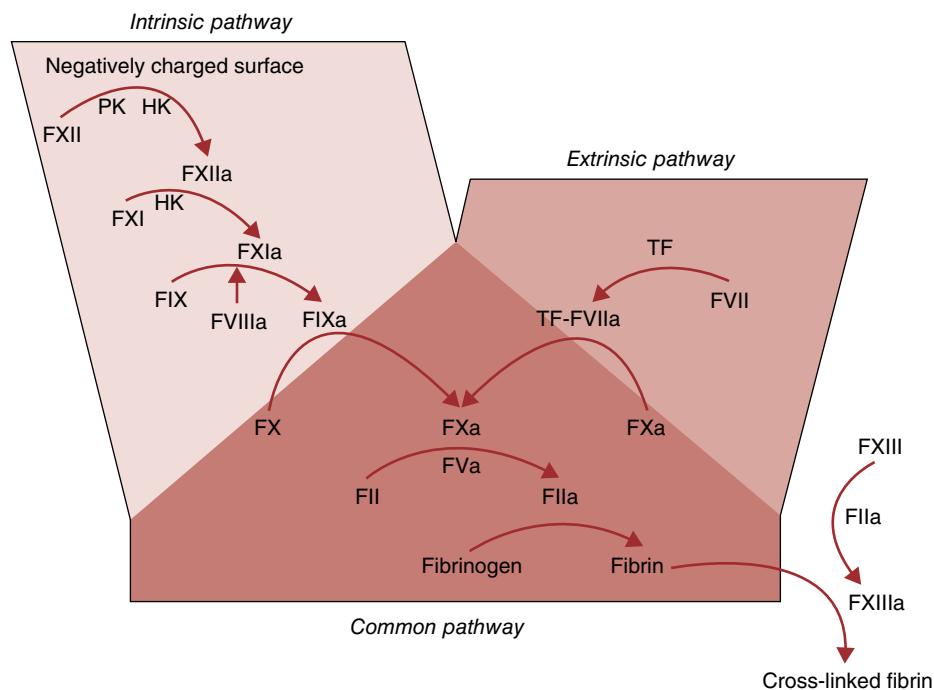

individual risk of bleeding or thrombosis.<sup>91–94</sup> Laboratories performing coagulation screening tests must consider the different sensitivities of reagents to clotting factor deficiencies, therapeutic anticoagulants, or lupus anticoagulants. Each laboratory should establish its own reference ranges, which depend not only on the reagents but also on the instruments used for analyses. It is also important to define a gray area of borderline assay results that should prompt specific coagulation assays despite a lack of clearly abnormal screening test results.

The *activated partial thromboplastin time* (aPTT) measures the intrinsic and common pathways of coagulation activation. The recalcification clotting time of citrated plasma is determined after addition of kaolin, celite, micronized silica, or ellagic acid, providing a large artificial surface area, and phospholipids functioning as a platelet substitute. The *prothrombin time* (PT) is performed by adding brain tissue or recombinant thromboplastin and calcium to citrated plasma and recording the clotting time. This screening test assesses coagulation activation via the extrinsic and common pathways. The *thrombin time* (TT) measures the time for clot formation to occur in citrated plasma after addition of thrombin. It reflects the amount and quality of fibrinogen and the rate of fibrin formation. The reasons for abnormal aPTT, PT, and TT values and their clinical relevance are shown in Table 20.4.

The main use of aPTT is for screening coagulation defects and inhibitors. The test is relatively sensitive to factor VIII, IX, XI, and XII deficiencies and to prekallikrein and HMW kininogen deficiencies. It may also be prolonged by more severe defects of

**Figure 20.3** Activation of fibrinolysis. Endothelial cells release tPA or UK. Both activators can generate plasmin from plasminogen. Plasmin cleaves fibrin and fibrinogen to degradation products. tPA and urokinase are inhibited by PAI-1 and plasmin by PI. TAFI inhibits plasmin-induced cleavage of fibrin by removing lysine residues from fibrin. DD: D-dimers; FDP: fibrin degradation products; PAI: plasminogen activator 1; PI: plasmin inhibitor; PLG: plasminogen; tPA: tissue plasminogen activator; TAFI: thrombin activatable fibrinolysis inhibitor; UK: urokinase.

**Figure 20.4** Classical model of the coagulation cascade, with intrinsic, extrinsic, and common pathways. F: factor; HK: high-molecular-weight kininogen; PK: prekallikrein; TF: tissue factor.

Hereditary dysfibrinogenemia may be associated with bleeding or thrombosis or both, or not associated with any symptoms. aPTT: activated partial thromboplastin time; PT: prothrombin time; TT: thrombin time.

fibrinogen, factors V and X, and fibrin polymerization. Factors affecting the clotting response of the aPTT test include the composition and concentration of phospholipids, the type of contact activator and buffer, and the length of incubation with the plasma. An aPTT should be sufficiently sensitive to record single clotting factor deficiencies of 30% of normal or less.<sup>95</sup> Some aPTT reagents fail to detect individual coagulation factor deficiencies as low as 20%. When used as a screening test for lupus anticoagulant, the detection sensitivity is predominantly determined by the type and concentration of the phospholipid reagent. The aPTT is still the most widely used method for monitoring treatment with unfractionated heparin. Therapeutic thrombin and factor Xa inhibitors also prolong the aPTT. Conditions associated with a prolonged aPTT but not with any increased risk of bleeding include factor XII, prekallikrein, and HMW kininogen deficiencies; lupus anticoagulants; transient phospholipid antibodies; increased hematocrit resulting in citrate anticoagulant excess; and heparin contamination of samples. Recent findings suggest that moderate factor XII deficiency might be associated with vascular mortality.<sup>96</sup> Transient phospholipid antibodies and concomitant prolonged aPTT without any clinical symptoms are frequently observed in children suffering from repeated infections.<sup>97</sup> Increased plasma levels of fibrinogen, factor VIII, and factor IX sometimes cause an abnormally short aPTT, which has been associated with overall poor prognosis and venous thromboembolism.<sup>98,99</sup>

The PT reflects changes in the three vitamin-K-dependent clotting factors (prothrombin and factors VII and X) and the non-vitamin-K-dependent factor V. Its sensitivity to clotting factor deficiencies or to vitamin K deficiency or antagonism by oral anti-coagulants strongly depends on the source and type of TF thromboplastin reagent. PT prolongations not associated with clotting factor deficiencies may be caused by lupus anticoagulants, increased hematocrit, or impaired fibrin polymerization. Because the heparin sensitivity of PT reagents is reduced by adding heparin-neutralizing substances, only very high unfractionated heparin concentrations may cause prolonged PT. The PT is still the most widely used test for monitoring treatment with warfarin or other oral anticoagulants. For this purpose, the PT is calibrated against the international reference thromboplastin and given as an international normalized ratio (INR).<sup>100</sup> Therapeutic thrombin and factor Xa inhibitors also prolong the PT.

The TT detects an impaired fibrin polymerization resulting from fibrin(ogen) degradation products, monoclonal gammopathies, or dysfibrinogenemias more sensitively than the aPTT and PT. Hereditary dysfibrinogenemia is heterogeneous and may be associated with bleeding and/or thrombosis, or it may be asymptomatic.<sup>31</sup> Unfractionated heparin and therapeutic thrombin inhibitors such as hirudins, argatroban, and dabigatran cause a marked prolongation of the TT. The *reptilase time* performed by adding the snake venom reptilase to citrated plasma is unaffected by heparin and even more sensitive to impaired fibrin polymerization than is the

TT. Because none of the coagulation screening tests are usually prolonged until the fibrinogen level falls below 0.5 g/L, a specific assay for *clottable fibrinogen* should be included in the basic screening tests for detecting coagulation factor deficiencies. Functional fibrinogen is either measured by the Clauss method based on thrombin-induced clotting or calculated from the change of turbidity during measurement of the PT (PT-derived fibrinogen).

Coagulation screening tests do not detect factor XIII deficiency, which must be confirmed by appropriate assays.

There is presently no simple and adequately sensitive screening test for detecting mild *hyperfibrinolysis*. D-dimer latex agglutination, and turbidimetric and enzyme-linked immunosorbent assays quantify the plasmin-degraded products of crosslinked fibrin in plasma using monoclonal antibodies. However, elevated D-dimer levels are found in numerous clinical conditions that are not inevitably associated with hyperfibrinolysis-induced bleeding. Severe hyperfibrinolysis can be diagnosed easily by markedly elevated D-dimers, prolonged TT and reptilase time, thrombelastography/thrombelastometry, and low fibrinogen, plasminogen, and plasmin inhibitor levels. However, the detection of mild hyperfibrinolytic states associated with bleeding continues to be a diagnostic challenge.<sup>101</sup>

The need for “global screening tests” allowing on-site assessment of the overall hemostatic potential has resulted in further developments of old viscoelastic tests using new technologies. Thromboelastography originally described by Hartert<sup>102</sup> and rotational thrombelastometry (ROTEM<sup>TM</sup>) are able to detect thrombocytopenia, platelet dysfunction, coagulopathies, impaired fibrin stabilization, and hyperfibrinolysis when performed in whole blood.<sup>103</sup> Although these tests have been used successfully in guiding blood component administration in hepatic and cardiac surgery and in trauma,<sup>104–106</sup> validation studies are lacking on their sensitivity and specificity to detect mild disorders of hemostasis in all clinical settings. Studies demonstrated a low sensitivity of thromboelastography to detect platelet dysfunction and vitamin-K-dependent coagulation factor deficiency.<sup>107,108</sup> The endogenous

thrombin potential as measured by a thrombin generation curve invented by Hemker<sup>109</sup> may be a useful tool for estimating the risks of both bleeding and thrombosis. However, data justifying its use in clinical routine are still sparse<sup>110</sup>.

## Summary

Plasma is used therapeutically or as starting material for manufacturing albumin, immunoglobulins, protease inhibitor, clotting factor, and coagulation inhibitor concentrates. Plasma protein levels are subject to wide intraindividual and interindividual variation. Age, gender, ABO blood group, acute phase reactions, physical exercise, mental stress, and hormones substantially influence the plasma levels of therapeutically used plasma proteins. Hemostasis is now understood to involve complex interactions between vessel walls, platelets, blood cells, proteins circulating in blood or being fixed to cells, and other humoral factors such as ionized calcium. Clinically useful coagulation screening tests include activated partial thromboplastin time, prothrombin time, and thrombin time. The detection of mild hyperfibrinolysis and mild coagulation disorders requires additional specific assays, a clinical history, and an examination.

### Plasma for transfusion

Plasma for transfusion can be collected through centrifugation of whole blood or by plasma apheresis. It can then be stored frozen as fresh-frozen plasma (FFP) or used to produce more purified constituents, including cryoprecipitate, concentrates of coagulation factors and fibrin sealant, immunoglobulins (e.g., Rh immune globulin), anticoagulants (e.g., antithrombin and protein C), complement related proteins (C1-esterase inhibitor), and albumin. FFP is frozen within a short-specified time period after collection and then stored at a defined temperature, typically at -25 °C.<sup>1</sup>

Internationally, the methods of manufacturing FFP for transfusion varies between countries<sup>2</sup> and some of these differences are summarized in Table 21.1. For example, in the United States, FFP must be frozen within 6–8 hours of collection, while plasma that is produced from whole blood donation that has been stored at 4 °C for up to 24 hours prior to separation is labeled as a different component (i.e., FP24).<sup>3</sup> Clinically, both FFP and FP24 are used interchangeably. In Europe, FFP can be prepared from whole blood donation and stored at 20–24 °C for 24 hours prior to it being separated and is labeled the same as frozen plasma that is produced <8 hours from donation (i.e., FFP),<sup>1,4</sup> and both components are used for the same clinical indications. Once thawed, FFP and FP24 must be used within 24 hours of thawing. In some countries, thawed plasma can be used beyond 24 hours and for up to five days from initial thawing, if stored at 4 ± 2 °C. It is then relabeled as “Thawed Plasma” or “Extended Thawed Plasma.”<sup>2</sup> In this chapter, we refer to *frozen plasma* as FFP, unless otherwise stated.

A typical unit of plasma derived from a collection of whole blood has a volume of 250–300 mL, and local and national guidelines for usage generally specify a dose of around 10–20 mL/kg. The composition of FFP can be influenced by many factors. These would include gender, ABO-type, age, genetic, and other environmental factors, all potentially modifying levels of individual proteins. The composition of collected plasma would also be affected by the processing procedure, including anticoagulants used, processing (for instance pathogen reduction and pooling), how quickly the plasma is frozen after collection, storage time, and preparation before administration.<sup>5</sup>

Although clinicians tend to assume approximate equivalence in clinical effectiveness between individual units of FFP, it is likely that

there is heterogeneity, reflecting the biological variation in constituents between donors (e.g., vWF and FVIII levels being lower in Group O donors). Such variation might be expected to be less marked for pooled plasma components such as pooled solvent-detergent treated plasma. Figure 21.1 illustrate the variation in content for selected coagulation factors between 66 units of (white-cell-depleted) FFP.

Immediately following thawing, plasma contains near normal levels of most plasma proteins, including procoagulant and anticoagulant components of the coagulation system. Over time, there is a loss of clotting factors in thawed plasma, with FVIII being the worst affected factor with losses ranging from 30% to 40% after storage over five days, and most of the decline occurring in the first 24 hours after thawing.<sup>2</sup> As Factor VIII is a labile clotting factor, its levels are used for quality control for the specification of the product. Other coagulation factors are less affected by extended thawed storage, with the decrease in most clotting factors being typically <10% by Day 5, with negligible change in levels of fibrinogen, antithrombin, and protein C.<sup>2</sup>

An alternative to FFP or extended thawed plasma in some countries (USA, Sweden, UK) is plasma that has never been frozen following manufacturing process, known as “liquid plasma” (LP) with its shelf life ranging from 7 to 21 days, depending on countries.<sup>2</sup> The primary use of LP is for immediate transfusion to treat acutely bleeding patients. In vitro studies have demonstrated increase in contact activation with the duration of LP storage, and this is more pronounced in women than men.<sup>6</sup> It is for this reason that some countries have chosen a shorter shelf life for LP, due to clinical concerns, although a retrospective study of 84,986 patients that had received LP in Sweden showed no evidence that the storage time of LP was associated with an increased risk of mortality.<sup>7</sup>

### Alternative preparations of plasma

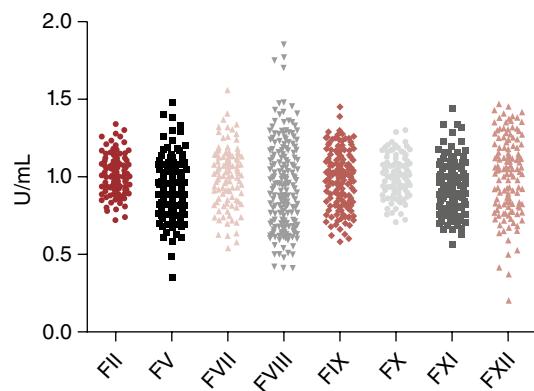

#### Dried plasma

Historically, the use of plasma started as early as the 1930s when methods to produce dried plasma were established.<sup>9</sup> The methods used were lyophilization (freeze drying) or spray drying. Drying plasma allowed for its use in remote areas where freezing facilities were not available, and it was therefore used extensively during the

**Table 21.1** Current Guidelines for the Preparation and Storage of Fresh-Frozen Plasma.

	AABB <sup>3</sup>	Australia <sup>8</sup>	Fresh-frozen plasma (FFP)	Fresh-Frozen plasma (FFP)	Council of Europe <sup>1</sup>
	Fresh-frozen plasma (FFP)	Plasma frozen within 24 hours (FP24)			Pathogen-reduced Fresh-frozen plasma (FFP)
Time from donation to freezing	<8 hours for CPD <6 hours for ACD	<24 hours	Within 18 hours of collection for whole blood derived and within 6 hours for apheresis	Preferably <6 hours <24 hours if whole blood rapidly cooled and stored 20–24 °C	
Freezing process	Not stated		Not stated	<25 °C within 1 hour	
Storage once frozen	≤18 °C: 12 months ≤-65 °C: 7 years	≤-18 °C: 12 months	<-25 °C: 12 months	18 to -25 °C: 3 months ≤-25 °C: 36 months	
Storage once thawed	<24 hours 1–6 °C ("thawed FFP")  <5 days at 1–6 °C labeled as "thawed plasma"	<24 hours 1–6 °C ("thawed FP24")  <5 days at 1–6 °C labeled as "thawed plasma"	Transfuse immediately or stored at 2–6 °C for up to five days	Use immediately or stored for 4 hours at 20–24 °C, 24 hours at 2–6 °C. For patients with major bleeding can be stored at 2–6 °C for up to five days	Use immediately
Clotting factor requirement for routine quality monitoring	None		>0.70 IU/mL of FVIII	>0.70 IU/mL FVIII	>0.50 IU/mL FVIII

World War II (WWII). Currently, dried plasma is commercially available from three different companies producing dried plasma in centralized production units: French Lyophilized Plasma (FLYP), produced by the French Military Blood Institute (Centre de Transfusion Sanguine des Armees [CTSA]); LyoPlas N-w, produced by the German Red Cross; and Bioplasma FDP, produced by National Bioproducts Institute, Pinetown, South Africa. All three alternatives use the lyophilization method. Two of the methods pool plasma from either 11 or 1500 donors and provide an ABO universal product (FLYP and Bioplasma FDP), whereas the third producer use single donor quarantine plasma (LyoPlas N-w). The shelf life of dried plasma is 15–24 months stored in room temperature (below 25 °C), and the products shall be used immediately after reconstitution that takes only a few minutes. No increase in adverse events has been reported.<sup>9</sup> As during the WWII, dried plasma is currently mainly in use for prehospital transfusions both in military and civilian health services serving as a “bridge” to balanced transfusion for patients with life-threatening bleeding.

### Pathogen reduced plasma

During WWII, millions of dried plasma units were transfused to treat bleeding soldiers, but by the end of the war, it became apparent that the transfusion of plasma was related to the risk of viral infections such as hepatitis. The use of human plasma was therefore discouraged, and an effort to improve safety of plasma transfusion was initiated. Measures are now implemented to reduce the risk of transfusion transmitted disease, and these include screening of plasma donors for viral disease and implementation of pathogen reduction methods. Current methods for pathogen inactivation of plasma involve four major processes using solvent–detergent (SD), methylene blue (MB), amotosalen, and riboflavin as additives.<sup>10</sup> The latter three are used in combination with visible or ultraviolet light. Whereas the solvent–detergent treatment is performed in large centralized manufacturing centers for large pools of plasma, the other three methods are designed for localized production in a Blood Bank/Blood Center. All methods result in a reduction in protein values with the percent retention of FVIII activity in the range of 67–78% and fibrinogen of 65–84%. Protein S and alpha<sub>2</sub>-antiplasmin are lower following solvent–detergent treatment. Alterations in fibrinogen structure have been reported with methylene blue.<sup>2,10–13</sup> An overview of pathogen reduced plasma components is presented in Table 21.2.

### Cryoprecipitate for transfusion

Cryoprecipitate is a plasma component that is rich in cryoproteins, namely, FVIII, von Willebrand factor (VWF), FXIII, fibronectin, and fibrinogen. Cryoprecipitate is manufactured by slowly thawing of FFP overnight at 4 °C, which precipitates out the cryoproteins. After centrifugation, the cryoproteins are resuspended in a reduced (20–60 mL) plasma volume (see Table 21.3 for specifications). Cryoprecipitate can be produced in a single unit, derived from one donor, or it can be produced by pooling several units (e.g., in the UK pooled cryoprecipitate is prepared from five single donations), which have larger volume (200–280 mL) than a single unit and higher concentration of cryoproteins (i.e., 700 mg fibrinogen and 350 IU FVIII). Like FFP, cryoprecipitate is stored at ≤25 °C for a maximum of 36 months, and prior to use it requires thawing.<sup>4</sup>

Cryoprecipitate was originally used as FVIII replacement therapy for hemophilia patients; however, currently cryoprecipitate is used as a standard concentrated source of fibrinogen in countries such as UK, Australia, United States, etc. Other countries use concentrates of fibrinogen. In the UK, a typical adult dose is two five-donor pools (equivalent to 10 single donor units). One such treatment administered to an average adult would typically raise the plasma fibrinogen level by about 1 g/L.<sup>14</sup> Larger doses of cryoprecipitate may be considered in patients with fibrinogen concentration <0.5 g/L and/or larger individuals. Cryoprecipitate should not be considered for transfusion solely as a more concentrated form of FFP (e.g., when there are concerns about fluid overload) as it predominantly contains cryoproteins.

The remaining product, following the removal of cryoprecipitate, is termed cryosupernatant, cryopoor plasma, or cryoprecipitate-depleted plasma.<sup>1</sup> It has been used in the treatment of TTP because of the theoretical benefit of its reduced content of von Willebrand factor, high-molecular-weight multimers, although the added benefit of cryosupernatant has not been proven. There is no current indication for cryoprecipitate-depleted plasma in the UK.<sup>4</sup>

Viral-inactivated purified fibrinogen concentrate is now available and may represent a safer concentrate for direct fibrinogen replacement in isolated deficiencies, for example inherited hypofibrinogenemia. This product is not licensed for broader clinical use in many countries; however, its use has been reported in other clinical situations, including trauma, cardiac surgery, and obstetrical hemorrhage.

## Clinical use of plasma transfusion

Clinical use of FFP has been maintained over the last two decades in many countries, although the defining characteristic of plasma transfusion is wide variation in transfusion rates. This variation in usage is seen both within and between countries. In a comparison of FFP use in five countries, the ratio of FFP units to red blood cell units transfused varied from 1:3.6 in the United States to 1:8.5 in France.<sup>15</sup> Studies have reported a wide variation in the use of FFP also among centers within countries and even within hospitals.<sup>16,17</sup> This variation is exemplified in multiple UK audits following transfusion practice for example adult patients undergoing cardiac surgery during a three-month period in 2010. In this audit, data on each patient were obtained from the Central Cardiac Audit Database and blood transfusion laboratories. The range of blood components usage, including plasma, was very wide across the different centers; for example, for patients undergoing CABG, the mean use of red cells was reported as nearly 3 units (2.98 units, range 0–32) and for FFP at nearly 2 units (1.98 units, range 0–22).<sup>18</sup> Although there may be some heterogeneity in the clinical characteristics of patients between different cardiac surgical centers in this audit, it seems unlikely to provide a full explanation for the differences between centers in transfusion rates.

FFP is given primarily for two indications: to stop bleeding (therapeutic) or to prevent bleeding (prophylactic). In addition, plasma is used as replacement fluid in patients undergoing therapeutic apheresis procedures. The core rationale for these uses is plasma as a source of procoagulants. The main specific recommendations for the transfusion of FFP have remained relatively consistent over the years, including (1) active bleeding as part of a massive transfusion protocol and/or due to acquired deficiencies of coagulation factors (such as in trauma, surgery, invasive procedures, etc.); (2) reversal of vitamin K deficiency related to vitamin K antagonists effect (such as warfarin) in patient with active bleeding, or prior to surgery or an invasive procedure (in conjunction with the use of prothrombin complex concentrates [PCCs]); (3) disseminated intravascular coagulopathy (DIC) or consumptive coagulopathy with active bleeding; (4) as replacement fluid in plasma exchange procedures in TTP; and (5) active bleeding due to congenital factor deficiency where there is no alternative therapies.<sup>4,19–22</sup> Variations of these indications will be found in most national guidelines. In a survey of Finnish hospitals, nearly 6000 FFP units were tracked indicating that FFP was transfused most often to surgery patients, especially cardiac surgery.<sup>23</sup> This finding is consistent with reports of FFP transfusions in other countries.<sup>17,24–26</sup> Uses of FFP that are considered inappropriate include the correction of hypoalbuminemia or nutritional support, and immunoglobulin replacement.

In 2020, an additional use of plasma was the focus of intense clinical and research interest.<sup>27</sup> During the COVID-19 pandemic, convalescent plasma (CP) was collected from recovered patients as a source of neutralizing anti-COVID-19 antibodies that may lower or eliminate the viral load in sick patients.<sup>28–30</sup> CP has been used previously in clinical studies for treating severe acute respiratory syndrome including SARS, MERS, avian influenza A (H5N1), and Ebola with some promising results, but many countries and groups provided CP in the context of randomized trial evaluations. Indeed, a staggeringly large number of trials have been registered, nearly 100, although there are many differences in protocol design, including the use of CP to treat adults or children in the intensive care unit (ICU) or in settings other than ICU or even as prophylaxis (for people in close contact with those confirmed to have COVID-19). Although recent studies indicate no effect of CP in unselected hos-

pitalized patients, it remains to be seen whether there is a benefit in patient groups such as those who are immunocompromised. Other factors will be relevant to the interpretation of the results when they become available, for example the different types of products (apheresis plasma and whole-blood-derived plasma) and the definitions of threshold anti-COVID antibody titers within the product. Another treatment option is to collect plasma to extract hyper immune immunoglobulins that may be infused in a concentrated form as passive immunization.

## Plasma transfusion in treatment of bleeding

For many years, national guidelines recommended that the transfusion of FFP for the management of bleeding was guided by conventional clotting tests. These recommendations were based on expert opinion rather than randomized control trials (RCTs). From 2005 onward, the initial transfusion of FFP during major hemorrhage was switched from laboratory-test-based protocols to empiric or ratio-driven protocols where FFP is issued based on a specified plasma to red cell component ratio before any clotting test result is available. Current guidelines now advocate that FFP transfusion should be given in a near-physiological ratio (1:1) with red blood cells and platelets in patients with massive hemorrhage.<sup>2,14,27,31</sup> This new approach came from observational studies in trauma showing that around one-quarter of all trauma patients who present with bleeding have a coagulopathy (defined as abnormal PT or APTT) that occurs early.<sup>32,33</sup> These studies have shown that the presence of acute traumatic coagulopathy is associated with increased risks of major hemorrhage, massive transfusion, and an increased risk of death. Therefore, the reversal of this coagulopathy with early balanced blood transfusion is an integral part of damage control resuscitation for major blood loss due to trauma.<sup>34</sup>

The role of higher and early doses of plasma and platelets has been addressed in the PROPPR randomized trial in North America, which compared 1:1:1 vs. 1:1:2 ratios of plasma, platelets and red cells.<sup>35</sup> For the composite main outcome of 24-hour and 30-day all-cause mortality, there were no significant differences between the groups, and this lack of a difference was also seen across most secondary outcomes. However, more patients in the 1:1:1 group achieved hemostasis and fewer experienced death due to exsanguination by 24 hours. The interpretation of this trial has been discussed previously;<sup>36</sup> however, the trial results have led in the implementation of a 1:1:1 ratio of plasma, platelet, and red cell transfusion in trauma bleeding patients in many countries.<sup>14</sup>

Another area of practice that is developing very fast is prehospital resuscitation support of bleeding patients in the “field” and outside the hospital setting. Evidence from the military, where evacuation time to definitive care may be prolonged, has provided evidence for pushing resuscitation with blood transfusion far forward and placing emphasis on early hemostatic resuscitation prior to arrival at definitive care. Two recent civilian prehospital RCTs have evaluated the effect of plasma transfusion versus standard of care (saline and/or red cell transfusion), giving conflicting results regarding the benefit of prehospital plasma in reducing mortality, with one trial (the COMBAT study) showing no difference in mortality at 28 days<sup>37</sup> whereas the other (the PAMPER study) showed significantly lower mortality at 30 days after plasma transfusion.<sup>38</sup> However, the transport times differed between the two studies, with median transport time for the COMBAT study being 19 (plasma group) and 16 minutes (standard group) compared to a median transport time of 42 (plasma group) and 40 minutes (standard group) in the PAMPER study. A post hoc analysis of

these two trials suggested that early plasma transfusion had the most benefit in patients in hemorrhagic shock with transport time over 20 minutes from a trauma center.<sup>39</sup> Neither studies observed any difference between the plasma group and the standard group with regard to safety. These results are consistent with findings from the military setting, showing improved survival with early transfusion of erythrocytes and/or plasma.<sup>40</sup>

In accordance with the ratio-driven transfusion strategy, whole blood for transfusion has been launched as an alternative to a 1:1:1 blood component strategy for red blood cells, plasma, and platelets.<sup>41–43</sup> Whole blood contains red cells, plasma, and platelets in a physiological ratio. It is an all-in-one solution to a balanced transfusion preferred by some over a blood-component-based strategy due to the logistical advantages and because it offers a more concentrated blood product.<sup>44</sup> Whole blood has been implemented in several hospitals and for prehospital transfusion both in military and civilian settings,<sup>45</sup> and several studies have been performed and are in progress evaluating the clinical effects of whole blood transfusion.<sup>46</sup> Whole blood is suggested as a preparedness product enabling a platelet containing transfusion alternative for use in smaller rural hospitals if platelets are not available in inventory or in case of blood shortages.<sup>27,47</sup>

### **Plasma in the treatment of patients with disseminated intravascular coagulation (DIC)**

Disseminated intravascular coagulation (DIC) is a syndrome characterized by the systemic activation of blood coagulation, but there is debate about definitions. DIC may occur as a complication of infections, solid cancers, hematologic malignancies, obstetric diseases, trauma, aneurysm, and liver diseases, among others, and each type of DIC presents characteristic features related to the underlying disorder. The most important treatment for DIC is the specific treatment of the underlying disorder. Blood component therapy with platelet or FFP transfusion should not be instituted on the basis of laboratory results alone but should be reserved for those with active bleeding.<sup>48</sup> The administration of FFP may be useful in patients with active bleeding with either prolonged PT/APTT (>1.5 times normal) or decreased fibrinogen (<1.5 g dL<sup>-1</sup>). It should also be considered in DIC patients requiring an invasive procedure with similar laboratory abnormalities.<sup>48</sup>

### **Plasma transfusion for prophylactic use**

In this section, we discuss the role of plasma transfusion to prevent bleeding (prophylactic) and the use of plasma transfusion in the absence of bleeding to correct abnormal clotting tests.

### **Plasma transfusion to correct abnormal clotting tests in the absence of bleeding**

The laboratory tests of aPTT and PT were developed to investigate coagulation factor deficiencies in patients with a bleeding history by providing an end assessment of thrombin generation by fibrin formation. The PT and aPTT results may be abnormal for a number of reasons not associated with bleeding risk, not least normal variation for some individuals. Some laboratories report the international normalized ratio (INR), which is based on PT and was developed to monitor warfarin therapy, by standardizing results to account for different sensitivities of thromboplastins. The INR can potentially quantify the coagulation status of other types of patient populations, like patients with liver disease, but the results should not be interpreted as having the same meaning in these patients, as for the INR patients receiving warfarin.<sup>49</sup>

In two early trials, evidence for a lack of benefit for prophylactic use of FFP was reported. Both were designed to carefully evaluate the effectiveness of FFP in a large group of patients and provided information about the sample sizes required to allow adequate power to detect clinically important differences between the groups of patients. In the first trial, the Northern Neonatal Nursing Initiative (NNNI) Trial Group randomized 776 neonates to FFP or to volume expanders (gelofusin or dextrose–saline) and did not show any differences in the prevention of intraventricular hemorrhage.<sup>50</sup> Allocation concealment and blinding of outcome assessors (to monitor clinically relevant long-term developmental outcomes) were reported. Of note, the study did not include the measurement of coagulation tests. In the other trial, the effectiveness of FFP was evaluated in patients with acute pancreatitis, and, in total, 275 patients were randomized to receive either FFP or a colloid solution. No evidence for the benefit of FFP was reported.<sup>51</sup>

A systematic review investigating whether a prolonged PT or elevated INR predicts bleeding during invasive diagnostic procedures published in 2005 found little evidence to support this common perception of a link between abnormal clotting tests and a higher bleeding risk.<sup>52</sup>

Patients with liver disease have a complex coagulopathy, with abnormalities of platelets, fibrinolysis, and inhibitors of coagulation as well as coagulation factor deficiency. Observational studies have demonstrated that the prolongation in clotting times is not necessarily indicative of bleeding risk in these individuals, particularly in the setting of common liver-related complications, such as variceal hemorrhage.<sup>53,54</sup> There is variable clinical practice in the use of FFP and cryoprecipitate for prophylaxis in patients with liver disease.<sup>55</sup>

A study by Abdel-Wahab and colleagues showed that the transfusion of plasma for mild abnormalities of coagulation values results in partial normalization of PT in a minority of patients and fails to correct the PT in 99% of patients.<sup>56</sup> Youssef and colleagues reported the effects of FFP transfusion in 100 patients with liver disease and found that it was difficult to correct abnormalities of coagulation tests unless large volumes of FFP were transfused and that the effects of transfusion were short-lived.<sup>57</sup>

A recent guideline from the British Society of Hematology states that PT and APTT do not reflect the true hemostatic status of patients with advanced liver disease and that abnormalities of PT and APTT need to be interpreted with caution in these patients. The guideline writing group found no good evidence to endorse the routine use of prophylactic FFP for correction of abnormal clotting tests in nonbleeding patients prior to interventions such as elective variceal banding or low-risk interventions.<sup>4</sup>

The risk–benefit ratio of a liberal FFP transfusion strategy for critically ill patients is often summarized as not favorable.<sup>58</sup> The Transfusion of Fresh Frozen Plasma in Nonbleeding ICU Patients (TOPIC) trial was a noninferiority, multicenter, randomized trial that investigated whether it is safe to withhold FFP transfusion to critically ill patients with abnormalities of coagulation tests undergoing an invasive procedure.<sup>59</sup> In the intervention group, prophylactic FFP transfusion prior to an invasive procedure was omitted compared to transfusion of a fixed dose (12 mL/kg) in the control group. Due to slow inclusion, the trial was stopped before the predefined target enrolment was attained, at which time 81 patients had been randomized for a total of 1 major and 13 minor bleeds. Preprocedural omission of FFP was not associated with increased occurrence of bleeding (relative risk, 1.17; 95% confidence interval [CI], 0.62–2.19;  $p=0.78$ ). FFP transfusions resulted in only a small reduction of international normalized ratio (INR), and to <1.5 in

only around half (54%) of the transfused patients. On the question of side effects, there were no differences in lung injury scores between the two groups, but there was an increased duration of mechanical ventilation in patients receiving FFP. In summary, although a small randomized study, the findings did not support a difference in complications of bleeding by FFP use as prophylaxis or not.<sup>59</sup>

A prospective pilot study of 119 intensive care patients also concluded that surgical tracheostomy in intensive care unit patients can be performed without bleeding complications in the case of normal thromboelastometry results (EXTEM CT) despite increased PT-INR.<sup>60</sup>

A systematic review that evaluated prophylactic use of FFP to either no FFP or no plasma product after cardiopulmonary bypass (CPB) showed no evidence of consistent significant beneficial effect on blood loss or transfusion requirement with the use of FFP, and no significant difference on other outcomes.<sup>61</sup> The hemostatic changes related to CPB are multifactorial, and not solely related to coagulation factor deficiency, and perhaps it is not surprising that FFP use prophylactically fails to provide benefit.

In conclusion, there is no evidence to support routine prophylactic use of FFP in nonbleeding patients with abnormal standard coagulation test preprocedure. The impact on commonly used doses of FFP to correct clotting results or reduce bleeding risk is also recognized to be very limited, particularly when the PT ratio or INR is between 1.5 and 1.9.<sup>4,61,62</sup>

### Reversal of warfarin effect

In patients with acquired vitamin K deficiency and the absence of bleeding, primary treatment should be initiated with oral/IV vitamin K.<sup>4</sup> Prothrombin complex concentrates (PCCs) are considered the product of choice in several countries for reversal of warfarin over-anticoagulation in patients who are bleeding or undergo urgent surgery or invasive procedures.<sup>63,64</sup> PCCs are produced by fractionation of pooled plasma and contain coagulation factors II, IX, X, and VII (no VII in the three-factor PCC) at a significantly higher concentration than FFP, as well as the natural anticoagulants (proteins C and S). A noninferiority RCT comparing the safety and efficacy of a four-factor PCC vs. FFP ( $n = 202$ ) in patients with elevated INR ( $\geq 2.0$ ) and experiencing an acute major bleeding event reported a faster correction in the INR in patients receiving PCC than with transfusion of FFP.<sup>65</sup> There were no differences in hemostatic efficacy or safety in patients receiving PCC or FFP. A multi-center RCT that compared FFP (20 mL/kg) vs. four-factor PCC (30 IU/kg) in patients with intracranial hemorrhage was terminated earlier than planned due to safety concerns seen with FFP.<sup>66</sup> Of the 50 patients that received study drug (23 FFP and 27 PCC), two patients in the FFP group vs. 18 in the PCC group reached the primary end point (i.e., of  $\leq$ INR 1.2 within three hours of treatment initiation,  $p = 0.0003$ ). However, a total of 13 patients died: 8 in the FFP group (5 from hematoma expansion, all occurring within 48 hours after symptom onset) and 5 in the PCC group (none from hematoma expansion). There were 43 serious adverse events (20 in the FFP group and 23 in the PCC group): six serious adverse events were judged to be FFP related and two PCC related. The results suggest that for the treatment of vitamin K antagonist-related intracranial hemorrhage, PCC should be administered instead of FFP.<sup>66</sup> Further studies should be undertaken to investigate whether the faster improvements in coagulation screening tests translate into clinical benefit in specific populations and if there are any increased risks of thromboembolic complications.

### Therapeutic plasma exchange

FFP is frequently used as a replacement fluid in patients undergoing therapeutic apheresis procedures.<sup>67</sup> Evidence-based guidelines with grading and categorization of apheresis indications are published by The American Society for Apheresis (ASFA) guideline.<sup>68</sup> Plasma exchange with FFP is the first-line treatment of choice for TTP, providing a source of ADAMTS13 (A Disintegrin And Metalloprotease with ThromboSpondin type 1 motif 13).<sup>22</sup> TTP is a medical emergency. Due to high risk of preventable early deaths in TTP, treatment with therapeutic plasma exchange should be initiated as soon as possible, and preferably within 4–8 hours regardless of time of day at presentation if a patient presents with a microangiopathic hemolytic anemia and thrombocytopenia in the absence of any other identifiable clinical cause.

In relation to the COVID-19 pandemic, discussions have been undertaken on the role of therapeutic plasma exchange in the treatment of the cytokine release syndrome in COVID-19. Removal of these cytokines by therapeutic plasma exchange prior to end-organ damage may potentially improve clinical outcomes. As per the ASFA-2019 guidelines, TPE for patients with infections and multi-organ failure due to various causes falls under Category III Grade 2B, meaning that the optimum role of apheresis therapy in treating these patients is not established and that the current moderate quality of peer-reviewed evidence only supports an overall weak recommendation for this approach. TPE for COVID-19 patients with MOF may also be considered under this category.<sup>69</sup>

### Clinical use of cryoprecipitate

Cryoprecipitate is a source of concentrated fibrinogen, and its use is largely focused on patients with clinical bleeding and low-fibrinogen concentrations. A common approach is that if fibrinogen level is  $< 1.5$  g/L, fibrinogen should be supplemented.<sup>14</sup> In these patients with a critically low-fibrinogen level, the concentration of fibrinogen in FFP is insufficient to achieve the rapid rise in levels required. Clinical data do not clearly support one form of concentrated fibrinogen replacement therapy over another, whether cryoprecipitate or fibrinogen concentrate. Fibrinogen is the key final component of the clotting pathway and forms fibrin insoluble protein that is the foundation of a stable clot. Fibrinogen is one of the earliest coagulation proteins to fall in major bleeding,<sup>70</sup> and when levels fall, patients have a reduced ability to form clots and may bleed for longer periods.

Trauma hemorrhage remains the clinical setting where much of the research on fibrinogen replacement is being conducted. Low levels of fibrinogen and increased breakdown are key components of the early coagulopathy in trauma, and low-fibrinogen levels on admission to hospital are independent predictors of early mortality in trauma patients.<sup>70</sup> Fibrin strands that form in a low-fibrinogen environment are more susceptible to clot breakdown (fibrinolysis), and this process is both overactivated and ubiquitous in major trauma.<sup>71</sup> Fibrinogen supplementation using concentrates may improve outcomes for trauma hemorrhage, by improving clot strength and reducing blood loss.<sup>72,73</sup> In an uncontrolled observational study of 131 hemorrhagic patients, mortality rates fell by 14% after fibrinogen treatment.<sup>74</sup> Two observational cohort trauma studies have also reported reduction of mortality in patients receiving higher fibrinogen content during massive transfusion therapy.<sup>75,76</sup> Despite very high doses of fibrinogen (up to 12 g), plasma levels did not increase beyond the normal range in healthy subjects, and there were no reported adverse events.<sup>74</sup>

A recent trial that compared fibrinogen concentrate with cryoprecipitate in patients undergoing elective aortic surgery who develop clinically significant bleeding and hyperfibrinogenemia after cardiopulmonary bypass showed no significant differences for adverse events, and its results indicated that fibrinogen concentrate was noninferior to cryoprecipitate with regard to the number of blood components transfused in a 24-hour period post bypass.<sup>77</sup> There is a paucity of other good-quality clinical or cost-effectiveness comparative research between fibrinogen concentrate and cryoprecipitate in many clinical settings.

### The side effects of plasma and cryoprecipitate transfusion

Crucial to recommendations in guidelines for FFP transfusion practice is the need for a clear understanding of the risk of harm. As with all blood components, FFP is not without risk.<sup>78–81</sup> More immediate and serious complications of FFP are transfusion-related acute lung injury (TRALI) and transfusion-related circulatory overload (TACO), although there are ongoing issues of reporting and diagnosing these conditions that make accurate estimation of prevalence difficult.<sup>82</sup> In the UK, an association between cases of TRALI and female donors has been identified through the Serious Hazards of Transfusion hemovigilance scheme, and this has resulted in the policy of using male donors only for the production of plasma components, with significant reduction in the incidence of TRALI.<sup>1</sup> In other jurisdictions, requirements on negative tests for anti-HLA and/or anti-HNA antibodies are applied for single donor plasma. Fluid overload is another important complication associated with the transfusion of larger doses of FFP in an attempt to reverse abnormal coagulation tests, particularly in patients undergoing cardiac surgery or for critically ill elderly patients. Other risks are transfusion-transmitted infections, including an unquantifiable risk of prion disease. Allergic reactions to FFP are relatively common, and they can be extremely troublesome or, rarely, life-threatening.

Understanding the risks of FFP transfusion is important when considering its use as prophylaxis. A prophylactic policy should only be justified if the risk of bleeding is greater than the risk of harmful effects. Without evidence of benefit, such policy aimed at preventing (uncommon) bleeding complications could involve transfusing FFP to a large number of patients, many of whom might not bleed even if prophylactic FFP were not given.

Dara *et al.* reported a single-center retrospective cohort study of FFP use in medical ICU patients.<sup>83</sup> They identified patients in whom an INR  $\geq 1.5$  was found during ICU stay and evaluated FFP use in the subgroup who were not actively bleeding. In addition to variability in FFP transfusion practice, the authors observed that

patients who received FFP had a similar rate of hemorrhage to matched cases, but had a higher incidence of “acute lung injury” during the 48 hours after transfusion (18% vs. 4%;  $p = 0.02$ ). This association raises the possibility that critically ill patients, many with concurrent inflammatory problems, may be more susceptible to TRALI after receiving plasma-rich blood products, although distinguishing TRALI from other clinical problems such as volume overload remains problematic. These findings do not prove cause and effect, but again emphasize a need for concern about inappropriate use of FFP, in view of the real risk of harm.<sup>58</sup>

Risks from cryoprecipitate transfusion are generally considered small but include those common to FFP (i.e., allergic reactions, infection, transfusion-associated acute lung injury, and transfusion-associated circulatory overload).<sup>4,84</sup>

### Conclusions

FFP and cryoprecipitate are important sources of procoagulants for the treatment of patients with bleeding. When administered as prophylaxis, an understanding of the full risks of FFP and cryoprecipitate transfusion is particularly important. A prophylactic policy should only be justified if the risk of bleeding is greater than the risk of harmful effects, and these components should not be routinely used to correct abnormal clotting tests in the absence of bleeding when the risk of bleeding is low.

### Introduction

It has been noted that blood plasma is the largest human proteome containing approximately 20,000 proteins plus splicing and post-translational variants.<sup>1,2</sup> As it is part of the circulation system, plasma contains other tissue proteomes as subsets through its contact with all organs of the body and their diverse cellular components. In addition, it contains specific plasma cells involved in the immune response and homeostasis. Proteins found in plasma can constitute proteins secreted by solid tissues that act in plasma; immunoglobulins (Ig); “long-distance” receptor ligands, such as hormones; “local” receptor ligands, such as cytokines and growth factors; and tissue leakage products.

The true plasma proteins are considered to be those that carry out their functions in circulation.<sup>3</sup> These constitute a number of proteins predominantly produced by the liver and immunoglobulins from the bone marrow.<sup>4,5</sup> The hepatic-derived plasma proteins encompass key proteins that constitute:

- The coagulation pathway and its regulation; these include the clotting factors (fibrinogen [factor I], prothrombin [factor II], and factors V, VII, VIII, IX, X, XI, XII, and XIII) and the regulatory factors or protease inhibitors (antithrombin III, heparin cofactor H, and proteins C, S, and Z).
- Components of the immune response and reaction to foreign bodies via the classic and nonclassic pathway, consisting of the complement factors and mannose binding lectin.
- Acute phase reactants, such as  $\alpha_1$ -acid glycoprotein, C-reactive protein, serum amyloid protein, serum amyloid A, and  $\alpha_2$ -HS glycoprotein, constitute part of the body's response to injury and infections; increased production of several hundred-fold can occur.
- Plasma proteinase inhibitors, which regulate the action of key proteolysis enzymes such as plasmin cathepsin G, elastase, and kallikrein and include  $\alpha_1$ -antichymotrypsin,  $\alpha_2$ -macroglobulin, inter- $\alpha$ -trypsin inhibitor, C1 inhibitor, and  $\alpha_1$ -antitrypsin.
- Carrier proteins, which are involved in the transport of iron, copper, hemoglobin, heme, bilirubin, and fatty acids; these include albumin, transferrin, ceruloplasmin, transthyretin, retinal binding protein, haptoglobin, hemopexin, and vitamin D binding protein.

- Biochemical regulators involved in immune cell regulation such as interleukins, interferons, and growth factors, for example, tumor necrosis factor and transforming growth factor  $\beta$ .

The immunoglobulins, produced in the bone marrow, exist as a number of subtypes—IgG, IgM, IgA, IgE, and IgD. IgG and IgM have the highest concentration and play the prime role in immune surveillance, the sequestration of foreign bodies, and the initiation of subsequent immune cellular and humoral responses.<sup>6</sup>

With increased understanding of the biochemical basis of disease, researchers see plasma proteins as possible therapeutic agents in several conditions either as a means of supplementation in cases of deficiency or to regulate biochemical pathways to achieve desired therapeutic outcomes. The biochemistry, clinical use, and production of these proteins have been reviewed recently.<sup>7,8</sup> Of the many identified plasma proteins, 20 therapeutic products have been developed and are in clinical use, with approximately another five in various stages of development.<sup>9–32</sup> These are presented in Table 22.1.

The production of plasma-derived medicinal products (PDMPs) has led to the development of a large global industry involving the complex activities of collecting blood and plasma donations and applying bioprocessing procedures to produce products with validated efficacy and pathogen safety.<sup>33</sup>

It is generally agreed that the start of plasma fractionation can be traced to the work of Edwin J. Cohn in his Harvard Laboratory in the 1940s, where he developed a cold ethanol-based precipitation process for the purification of albumin to be used as a resuscitative fluid in theatres of war.<sup>34</sup>

This chapter describes the manufacture of plasma proteins for therapeutic use and makes extensive use of divergent examples to illustrate the range of approaches that can be taken. In addition, it covers the relevant pathogen removal methodologies that ensure product safety and important information relating to specifications of the final product. This information will be of use to the reader involved in the assessment, purchase, or use of plasma products, who is often confronted with literature on products containing unfamiliar concepts and terminology relating to plasma fractionation, viral removal procedures, and product specifications. An increased understanding of the production of plasma protein therapeutics will facilitate communication with manufacturers of plasma products and aid in the assessment of existing products and the exploration of possibilities for future development.

**Table 22.1** Plasma Proteins with Established Clinical Use or Under Active Investigation

Protein or Therapeutic Product	Established Clinical Use
Albumin Immunoglobulins: Intravenous and subcutaneous	Fluid replacement in trauma, burns, sepsis, and cirrhosis Replacement therapy in primary and secondary immunodeficiency, immunomodulation in certain autoimmune diseases including immune thrombocytopenia purpura, Kawasaki disease, Guillain–Barré syndrome, autoimmune polyneuropathy, and myasthenia gravis Treatment of hepatitis A, hepatitis B, cytomegalovirus, varicella-zoster, and tetanus infections
Immunoglobulin hyperimmune to viral and bacterial antigens	
Anti RH(D) immunoglobulin	Prevention of Rh(D) isoimmunization due to fetus-maternal rhesus D incompatibility, treatment of immune thrombocytopenia purpura
Factor VIII	Replacement in hemophilia A-factor VIII deficiency; induction of immune tolerance for antifactor VIII antibodies Treatment of vWF deficiency
Von Willebrand factor (vWF)	Replacement in hemophilia B-factor IX deficiency
Factor IX	Treatment of patients with inhibitory antibodies to factor VIII or factor IX
Activated prothrombin complex concentrate (aPCC) Composed predominantly of prothrombin and factors VIII, VII, VIIa, IX, X, Xa; and protein C. Brand name: Factor VIII Inhibitor Bypassing Activity (FEIBA®)	Treatment of the rare conditions of factor VII and factor X deficiencies, reversal of the anticoagulant activity of warfarin and prevention of massive bleeding, often in combination with fibrinogen
Prothrombin complex concentrate (PCC); factors II, VII, IX, and X; and regulatory proteins: protein C, S, and Z	Replacement in congenital fibrinogen deficiency and in acquired deficiency following massive bleeding
Fibrinogen	Treatment of Factor XI deficiency; incidence: 1:10 <sup>6</sup>
Factor XI	Treatment of Factor VIII deficiency; incidence: 1:2 × 10 <sup>6</sup>
Factor XIII	Treatment of Factor X deficiency; incidence: 1:1 × 10 <sup>6</sup>
Factor X	Used in surgery as a sealant to achieve hemostasis, as a surgical glue and to promote wound healing
Fibrin glue (fibrinogen and thrombin components)	Treatment of alpha <sub>1</sub> -proteinase inhibitor deficiency
Alpha <sub>1</sub> -proteinase inhibitor	Treatment of acquired and hereditary deficiency of Antithrombin III
Antithrombin III	Treatment of hereditary angioedema
C1-esterase inhibitor	Treatment of purpura fulminans and venous thrombosis in patients with severe congenital protein C deficiency
Protein C	Treatment of hemoglobinemia or hemoglobinuria due to hemolysis after burn, trauma, blood transfusion or open-heart surgery
Haptoglobin	Use in Ukraine and Russia has been as an adjunct therapy in cancer therapy, emergency medicine indications, and infection; outcomes thought to be enhanced by the antioxidant and ferroxidase activity of ceruloplasmin
Ceruloplasmin	
<b>Under Investigation</b>	
Plasmin	Potential Clinical Applications Dissolution of clots by direct application in peripheral arterial occlusion, stroke, deep vein thrombosis, myocardial infarction, and clotted intravascular devices
Reconstituted plasma-derived high-density lipoprotein (derived from apolipoprotein A1)	Atherosclerotic plaque stabilization in acute coronary syndrome through reduction in lipid content and other anti-inflammatory and antithrombotic mechanisms
Transferrin	Treatment of hypotransferrinemia, enhancing erythropoiesis, and reducing anemia in β-thalassemia.
Plasminogen	Used in hematological stem cell transplantation to sequester free iron binding of iron reduces free-iron-mediated ischemia/reperfusion injury in transplanted organs
Hemopexin	Treatment of ligneous conjunctivitis related to plasminogen deficiency Removal of free heme arising from hemolysis in sickle cell disease

## Key components of the manufacture of plasma protein therapeutics

### Plasma for fractionation

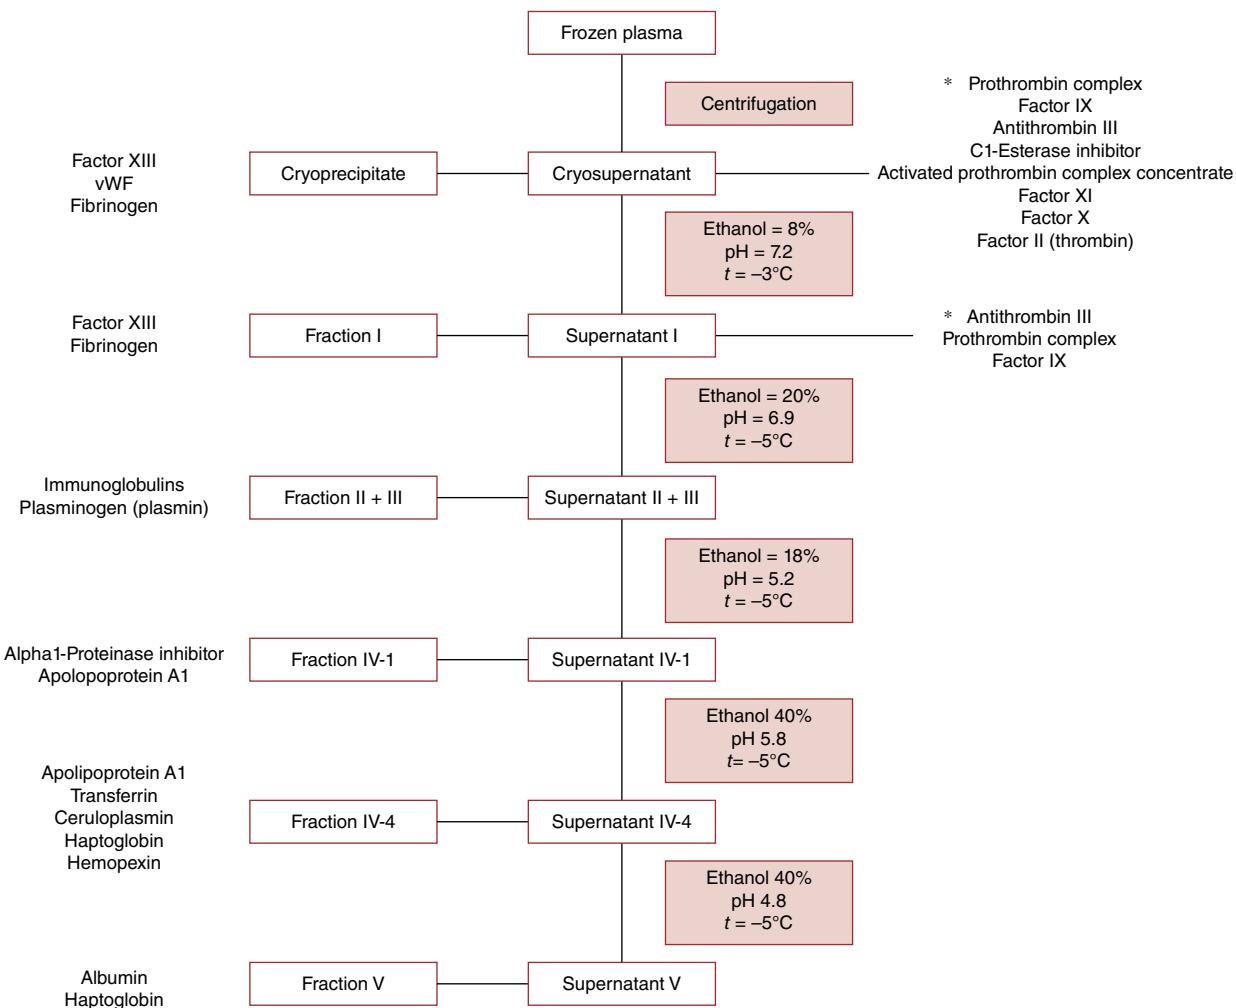

The manufacture of plasma-derived medicinal products commences with the collection of plasma. This is a logistically and technically complex activity due to the need to ensure product quality and safety.<sup>35</sup> The viral safety of plasma collected for fractionation is ensured by what has been referred to as a “Five Layer Safety.”<sup>36</sup> These layers are donor screening, blood testing, donor referral, quarantine, and investigation. Details of these activities are provided in Chapters 4, 5 and 44.

Plasma used in the United States for manufacture is either recovered plasma (plasma derived from whole blood collection) or source plasma (collected by plasmapheresis). No specific monograph exists in the United States which details the handling conditions to be applied to collected plasma. However, the pharmacopoeia of the European Union (European Pharmacopoeia) specifically details the freezing conditions applicable for labile proteins and recommends that plasma to be used in the manufacture of labile

proteins needs to be frozen within 24 hours of collection, and that the rate of freezing should be such that –25 °C is attained in 12 hours of being placed in the freezing apparatus. For the recovery of nonlabile proteins,<sup>37</sup> the plasma must be frozen to –20 °C or below within 24 hours of collection. During storage and transportation, the temperature of the plasma can exceed –20 °C for not more than a total of 72 hours, it must not transiently exceed –15 °C on more than one occasion and at no time must the temperature exceed –5 °C.

### Cold ethanol fractionation

The cold ethanol fractionation procedure that continues to have a pivotal role in plasma fractionation was developed by Cohn in the 1940s. It is based on the differential precipitation of plasma proteins by manipulation of ethanol concentration and pH of a low-ionic-strength solution maintained at a subzero temperature.<sup>34</sup> The original process, known as the *Cohn method*, is presented in Figure 22.1 and shows the conditions for the generation of specific fractions. Also shown is the recovery of cryoprecipitate from freeze-thawed plasma by centrifugation, typically incorporated in the processing of plasma. In addition, the source of current therapeutic proteins or

**Figure 22.1** The cold ethanol fractionation process for plasma (Cohn method 6) with the fractions indicated that are the source of various therapeutic proteins. Proteins that are recovered from the cryosupernatant and Supernatant I fractions require specific adsorption using chromatographic resins (denoted by \*).

those under development, listed in Table 22.1, is detailed. An example is considered to specifically illustrate the principle of the Cohn process: if one takes Supernatant I, adding ethanol to a final concentration of 25% (v/v) and adjusting the solution to pH 6.9, while ensuring that the ionic strength and temperature remain at approximately  $I = 0.09$  and  $-5^\circ\text{C}$ , respectively, result in the generation of the immunoglobulin-enriched Fraction II + III and Supernatant II + III.

It is important to have an understanding of the cold ethanol fractionation process as the terminology associated with the process is often used in literature associated with various plasma-derived products. Each fraction is an enriched, albeit crude, source of various plasma proteins that can be further purified to generate a therapeutic product. How this is achieved is covered in the subsequent sections. Prior to this, however, a description of viral removal procedures commonly used in manufacturing processes is undertaken. These need to be incorporated in any manufacturing process to ensure the viral safety of the therapeutic product.

### Chromatographic procedures

The cold ethanol fractionation process can generate highly purified albumin and immunoglobulin products.<sup>34,38</sup> Today, albumin is still predominately purified by the cold ethanol fractionation procedure,

and this was the case until the late 1990s to produce immunoglobulin products. The purification of other therapeutic proteins from the other enriched fractions has only been able to be achieved by the application of chromatographic techniques.<sup>39</sup>

Details of the purification of the major plasma-derived therapeutic proteins are provided in this chapter. However, an appreciation and understanding of these processes requires knowledge of the principles of chromatography and the orthogonal approaches that need to be applied to obtain highly purified preparations.

Chromatographic techniques allow the purification of proteins because of their differences in molecular weight, charge, hydrophobicity, and specific affinity for ligands. This involves the use of size exclusion, ion exchange, hydrophobic interaction (HIC), and affinity chromatography, respectively.<sup>40–43</sup> Chromatography is typically performed with columns packed with resin beads of about 50–90  $\mu\text{m}$  in diameter and derivatized with particular functional groups to allow the separation to be performed.

Size exclusion separation occurs as proteins percolate through the beads. Smaller proteins enter the pores of the beads, and hence their passage through the column is retarded, leading to the separation of proteins on the basis of molecular weight, with higher molecular weight proteins eluting first followed by the smaller species.

Ion exchange chromatographic resins exist in either the anion (positively charged) or cation (negatively charged) forms. Typical ion exchange ligands include diethylaminoethyl (DEAE), quaternary amino ethyl (QAE), quaternary ammonium (Q), carboxymethyl (CM), sulfopropyl (SP), and methyl sulfonate (S) for anion and cation exchange chromatography, respectively. As proteins are zwitterion molecules, the net charge of the molecule can be modulated by changing the pH of the protein environment. Proteins have different pI values—the pH at which the net charge of the protein is zero.<sup>43</sup> Therefore, the net charge of a protein depends on pH, and this determines the degree of interaction with an ion exchange resin. Interaction can be further modulated by changes in ionic strength. Thus, by utilizing conditions that promote differential binding to ion exchange resins, coupled with defined elution conditions—again involving specific conditions of pH and conductivity, the fractionation of a mixture of proteins can be achieved.

Proteins exhibit differences in their hydrophobic profile, reflecting differences in the composition of amino acids with hydrophobic (nonpolar) or hydrophilic (polar) properties.<sup>43</sup> This difference is exploited in hydrophobic interaction chromatography (HIC) and mixed-mode chromatography. Solution conditions can be manipulated so that the more hydrophobic proteins are retained on a column while less hydrophobic proteins flow through.

Proteins exhibit unique surface epitopes and functional domains.<sup>43</sup> Immobilized antibodies and specific ligands on chromatographic resins, which can specifically interact with these parts of proteins, can be the basis of affinity chromatography for the purification of proteins from complex mixtures. Immobilized monoclonal antibodies, heparin, and metal affinity ligands are used in the purification of several plasma proteins.<sup>39</sup>

### **Pathogen reduction of plasma-derived medicinal products**

Since the occurrence of human immunodeficiency virus (HIV) transmission by transfusion of blood components and plasma-derived medicinal products (PDMPs) in the early 1980s, the plasma fractionation industry has invested a significant effort to vastly improve the safety of PDMPs through implementation of the complementary measures of donor selection, plasma testing, and strategic manufacturing.

PDMPs are manufactured from relatively large pools of human plasma (~2000–4000 L). Intermediates from multiple pools of plasma may be combined such that a final container may contain proteins from more than 50,000 individual donations. Compared to blood components derived from single individuals, the pooling of many donations may increase the risk that the starting material is contaminated by an unknown or untested-for virus. However, judicious qualification of donors, coupled with serological and nucleic acid testing (NAT) of plasma donations for relevant blood-borne viruses, effectively screens out donations containing high titers of viruses known to have been transmitted by blood or plasma products in the past. Moreover, the pooling process provides a dilution factor that also contributes to safety. Importantly, the plasma pools can also be tested for viruses by NAT methods as a redundant practice to minimize the risk that plasma for further manufacture is contaminated.

By 1994, plasma fractionation companies had made remarkable progress, as indicated by the absence of disease transmission of hepatitis viruses or HIV by any product manufactured by American or European biological producers. After the introduction of second-generation serological testing for, and exclusion of, hepatitis C virus

(HCV) antibodies from plasma for further manufacture, the loss of inherent anti-HCV protection in immune globulin products unintentionally allowed for instances of HCV transmission.<sup>44</sup> However, the occurrence of further transmission was prevented by the introduction of NAT testing of plasma donations and plasma manufacturing pools, as well as the inclusion of effective and robust virus reduction steps into the manufacturing processes of immune globulin for intravenous administration (IVIG).<sup>45</sup>

The manufacturing processes of all PDMPs contain steps specifically designed to have a high capacity to inactivate or remove viruses. Such capacity is imparted to a process by incorporation of, typically, two effective and robust virus reduction steps that are orthogonal and complementary to one another in their modes of action. Taken together, donor selection, plasma testing, and manufacturing concepts have been highly successful in ensuring the safety of PDMPs against known and (re)emerging viruses.

### **Incorporation of virus reduction capacity into biomanufacturing processes**

A manufacturing process step can be intentionally designed with a mechanism to inactivate viruses (such as pasteurization developed by Norbert Heimburger<sup>46</sup> or solvent/detergent treatment developed by Bernard Horowitz)<sup>47</sup> or remove viruses from the process stream (e.g., filtration). Such dedicated mechanisms are relied upon to confer effective and robust virus reduction capacity. Alternatively, a step primarily designed to purify the target protein may also possess virus reduction capacity via partitioning of viruses along with impurities. Because purification steps are designed to isolate the protein of interest, these partitioning steps often offer only limited virus reduction capacity. Careful assessments are required to determine the extent that such purification steps contribute to the overall virus reduction capacity of a product's manufacturing process.

Successful incorporation of virus reduction capacity into biomanufacturing processes requires that the functional activity of the target therapeutic protein be maintained. Furthermore, it must be demonstrated that neoantigens, which could lead to immunogenicity, have not been introduced into the product stream.<sup>48,49</sup> Amino acid analysis, cleavage with proteolytic enzymes, circulatory survival in animal models, and measurement of sedimentation and diffusion coefficients, viscosity, circular dichroism, and optical rotary dispersion are examples of analytics used to ensure the integrity of the target biotherapeutic.<sup>50</sup>

### **Validation of the capacity of a manufacturing process to inactivate and/or remove viruses**

A successful virus reduction strategy also requires that steps be formally validated for their capacity to inactivate and/or remove viruses. Virus validation studies must be performed by trained staff in dedicated, properly equipped laboratories kept separately from manufacturing facilities so as not to contaminate the production line.

In a virus validation study, a selected step (or a series of steps) of the manufacturing process is studied to assess and quantitate how effectively it can inactivate or remove a broad range of viruses. Experiments are carried out using a small-scale version of the commercial manufacturing process with aliquots of starting material (production intermediate) obtained from the commercial-scale process. The production-scale manufacturing process is closely mimicked in the small-scale model by tightly controlling key operating parameters. The suitability of the small-scale model is confirmed by comparing key performance characteristics and by demonstrating that the biochemical characteristics of the resultant

output material from the small-scale model are comparable to those of the production-scale process.

A virus validation experiment is performed by deliberately spiking a small volume of high-titer virus into an aliquot of product intermediate derived from the commercial manufacturing process. The virus-spiked product intermediate is then run through the qualified small-scale model of the commercial manufacturing process, and samples are removed for subsequent assay. A process step capable of removing  $\geq 4 \log_{10}$  of infectious virus particles is considered effective when the manufacturing process step can be reliably performed and is insensitive to modifications within the specifications of the manufacturing process.<sup>51</sup>

In addition to providing an accurate reflection of the full-scale manufacturing procedure, small-scale versions of the production process are used to study the robustness of the virus clearance capacity. These robustness experiments evaluate the production parameters that may have an influence on virus inactivation and/or removal. Examples of relevant production parameters include protein concentration, the concentration of precipitating agents, temperature, pH, reaction time, amount of stabilizer, and the amount of chemical inactivating agents. For chromatographic steps, protein concentration, flow rate, washing and elution volume, and resin reuse should be assessed. Robustness experiments are designed to assess the impact of extreme production conditions on virus reduction capacity. As such, they are performed for given parameters using operating conditions at the boundaries of their ranges or even beyond the specifications of routine production. The goal of these experiments is to demonstrate that the capacity of a process to remove viruses is robust across the ranges of operating parameters at which the manufacturing process is licensed.

Viruses chosen for validation studies should closely resemble the viruses that may potentially be present in contaminated plasma (i.e., transfusion-relevant viruses). To test the ability of the manufacturing process to remove viruses in general, the chosen test viruses should also exhibit a wide range of physicochemical properties. For these studies, strains of viruses should be chosen that replicate to high titers in cell culture and can be assayed in an effective, sensitive, and reliable manner via *in vitro* infectivity methods.

Virus validation studies should be performed with HIV and hepatitis A virus (HAV) as relevant viruses. For those blood-borne viruses that cannot be propagated in cell culture systems, model viruses must be used. Model viruses for HCV include, for example, bovine viral diarrhea virus (BVDV) (a flavivirus) or Sindbis virus (SINV) (a togavirus). A specific model virus for hepatitis B virus (HBV) is not available; therefore, nonspecific model viruses must be used. In situations where a novel inactivation method is under test, duck hepatitis B virus could also be used as a surrogate for HBV. For parvovirus B19 (B19V), currently only experimental cell culture systems are available; therefore, animal parvoviruses, e.g., canine parvovirus (CPV), minute virus of mice (MVM), or porcine parvovirus (PPV), are used as model viruses. In the case of interactions between human immunoglobulins with viruses used in virus validation studies, the use of model viruses may be essential: HAV can be replaced by porcine or bovine enteroviruses or encephalomyocarditis virus (EMCV).<sup>51,52</sup>

## **Virus inactivation**

### **Heat treatment in aqueous solution (pasteurization)**

Heating in aqueous solution at 60 °C for 10 hours or greater can be a highly effective method for the inactivation of both enveloped and nonenveloped viruses. The effectiveness of inactivation is dependent

upon the composition of the solution and the concentration of stabilizers that are used to protect proteins and minimize neoantigen formation; stabilizers can also protect viruses (especially nonenveloped virus). Stabilizer concentrations are carefully chosen to find conditions that maximize retention of biological activity of the therapeutic molecule while maximizing virus inactivation. The impact of stabilizers and temperature on the virus inactivation capacity for a wide range of viruses must be carefully validated.<sup>53</sup>

Pasteurization has proven to be an effective virus inactivation method for albumin products for several decades. The pharmacopoeia method for albumin requires formulation with sodium caprylate alone or with *N*-acetyl tryptophan as a stabilizer prior to sterile filtration, filling, and treatment at 60 °C for 10–11 hours in the final product container. The method has since been successfully applied to a range of other plasma protein therapeutics including immunoglobulins, fibrinogen, alpha<sub>1</sub>-proteinase inhibitor, haptoglobin, C1 esterase inhibitor, and even labile molecules such as factor VIII concentrates.<sup>54,55</sup> This is only possible by the use of high concentrations of glycine and sucrose or selected salts.<sup>54</sup> This approach was developed by Heimburger in the late 1970s, resulting in a plasma-derived factor VIII/vWF product with no proven cases of virus transmissions over more than 30 years.<sup>56</sup>

## **Dry heat**

For lyophilized PDMPs, dry heat treatment, which involves heating at 80 °C for 72 hours or 100 °C for 30 minutes, is also an effective virus inactivation step. Higher residual moisture in the lyophilized product can enhance the inactivation of some viruses, but such conditions can increase protein aggregation while decreasing a product's stability. However, even at residual moisture levels as low as 0.3%, effective inactivation of most viruses can be obtained. In a commercial manufacturing process, the residual moisture of the lyophilized product is controlled, and the process is validated to ensure that the moisture of each vial remains between predefined limits informed by viral validation studies.<sup>57</sup>

## **Vapor heat**

Lyophilized (intermediate) products are heated at defined (relatively high) residual moisture (e.g., 60 °C for 10 hours followed by 80 °C for 1 hour). Low residual moisture levels of dry heat treatment do not interfere with the success of this method because the product intermediate is further processed to the final product.

## **Solvent/detergent (S/D) treatment**

Organic S/D treatment acts by disrupting the lipid membrane of enveloped viruses, rendering them unable to bind to and infect cells. This method has been shown to be extremely robust and effective in inactivating a broad range of enveloped viruses, including WNV, HIV, HBV, and HCV.<sup>58</sup> This method does not inactivate nonenveloped viruses. An example of conditions used for virus inactivation is 0.3% tri (*n*-butyl) phosphate (TNBP) and 1% ionic detergent (usually either Tween 80 or Triton X-100) at approximately 24 °C for 4–6 hours. It is even possible to treat some preparations at 4 °C; however, a longer contact time is required to achieve equivalent inactivation to that obtained at higher temperatures.<sup>59</sup> Following addition of S/D to the product, the resultant intermediate must be filtered to eliminate virus trapped in gross aggregates. Continuous mixing is generally carried out, and homogeneity of the S/D reagents throughout the treatment step is ensured at the commercial scale through validation studies. As every droplet must be treated, solutions are often transferred from a formulation tank to

the incubation tank to ensure that material on the ports, lid, or surfaces of the first tank is subject to the treatment. Following treatment, the S/D reagents are removed by downstream unit operations such as chromatographic or precipitation steps.

Despite Triton X-100 being a highly effective detergent for inactivation of enveloped viruses, it is considered ecologically unsustainable given its slow degradation rate and that its degradant, 4-*tert*-octylphenol, has endocrine disrupting properties for aquatic organisms.<sup>60</sup> For this reason, the European Commission has placed Triton X-100 on the REACH Annex XIV authorization list, meaning that it cannot be supplied to the market without specific authorization.<sup>61</sup> Manufacturers of therapeutic products using Triton X-100 have therefore looked to replace it with alternative detergents such as Tween 80 or have investigated the use of novel, eco-friendly detergents.<sup>60–62</sup>

### Octanoic acid (caprylate) treatment

Octanoic acid treatment works by disrupting the lipid membrane of enveloped viruses, rendering them unable to bind to and infect cells.<sup>63</sup> Similar to S/D treatment, this method is not effective against nonenveloped viruses. The rapidity and effectiveness of inactivation are dependent upon the amount of free nonionized octanoic acid present; thus, octanoic acid concentration, pH, temperature, and protein concentration are all critical variables that need to be controlled during treatment.<sup>64,65</sup>

### Low pH

Low pH (approximately pH 4) has been shown to be an effective method for some immune globulin preparations to inactivate enveloped viruses and certain nonenveloped viruses such as human parvovirus B19V.<sup>66,67</sup> The effectiveness and robustness of a low-pH inactivation treatment are highly dependent on parameters including pH, time, temperature, and the type and concentration of excipients.

### UV irradiation

Ultraviolet-C (UV-C) irradiation has long been known to be virucidal and microbiocidal;<sup>68</sup> however, its application as a viral inactivation method in the manufacture of protein therapeutics has been limited, especially with regard to uniform irradiation processes.<sup>69</sup> UV-C irradiation acts by damaging the nucleic acids of viruses, mainly through the formation of cyclobutane pyrimidine and pyrimidine pyrimidone dimers.<sup>70</sup> Because viruses lack the ability to repair these modifications, dimer formation prevents their ability to infect cells.<sup>71,72</sup> Although it is widely used for water treatment, its use in the manufacture of protein therapeutics has been modest

owing to concerns that it may also modify proteins.<sup>73</sup> A serum protein solution, BISEKO (manufactured by Biotest for several decades), includes a combined beta-propiolactone–UV-C irradiation treatment step.<sup>74</sup> More recently UV-C irradiation has been employed for the manufacturing of trimodulin, an IgM-containing immunoglobulin preparation, investigated in a clinical phase II study<sup>75</sup> and a COVID-19 treatment trial.<sup>76</sup>

UV-C irradiation has shown to be effective against a broad range of viruses, including small nonenveloped viruses,<sup>73,77,78</sup> and has also been investigated in a continuous flow format in which plasma protein activity was preserved.<sup>79</sup> Continuous-flow UV-C irradiation has been further developed into the UVivatec® device, employing a spiral tube around a UV-C irradiation source.<sup>80,81</sup> The geometry of the spiral flow in the reactor generates Dean vortices, thereby ensuring homogeneous mixing and uniform exposure to the UV-C rays.<sup>82</sup>

UV-C irradiation can be an option to provide inactivation of small, nonenveloped viruses for proteins that may be too large or preparations that are too complex for efficient virus filtration.

### Dedicated virus removal

#### Virus filtration

**Virus filtration**, also called *nanofiltration* (Figure 22.2), is specifically designed to remove viruses.<sup>83</sup> It does so by removing virus particles based on size while allowing the flow through of the desired protein. Large protein molecules or easily aggregated proteins pose a challenge for this method. Virus filtration using small-pore (~20 nm) or parvo-virus-retentive filters is generally a robust and effective means for removing viruses as small as 18–24 nm from process streams. Successful filtration can depend not only on pore size but also on hydrodynamic forces, adsorption of the virus to the filter surface, and removal of virus that has aggregated within antigen–antibody or lipid complexes.<sup>84</sup> Virus filtration is considered gentle; however, appropriate testing during process development must ensure that shear forces do not damage the protein of interest. Following integration into manufacturing processes over 20 years ago, virus filtration has proven to be a robust method that is complementary to other virus inactivation methods.<sup>83</sup>

### Contributing virus removal by protein purification

#### Ethanol, polyethylene glycol (PEG), and caprylate precipitation

At the low temperatures and pH ranges typically used in plasma fractionation processes, the inactivation property of ethanol against enveloped viruses is minimal. However, cold ethanol fractionation of plasma can contribute to virus safety by partitioning viruses away from the therapeutic protein of interest.<sup>85</sup> Prior to the incorporation

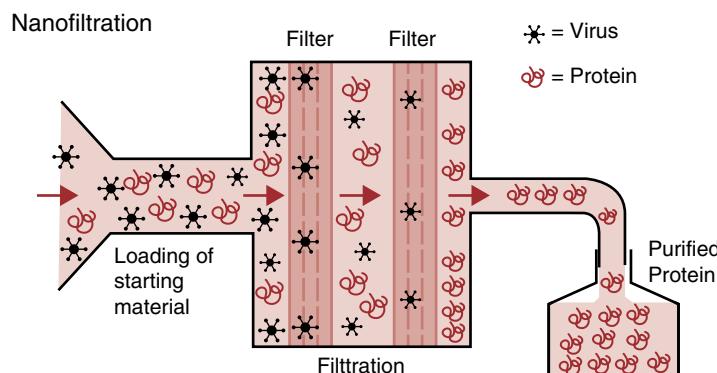

Figure 22.2 A diagram of virus removal by virus filtration nanopore size exclusion.

of dedicated virus reduction steps into manufacturing processes, partitioning during fractionation and purification, along with antibody neutralization in plasma pools, was largely responsible for ensuring the safety of immune globulin products. Comparable principles related to ethanol precipitation steps apply to other precipitation principles such as octanoic acid (caprylate) precipitation, PEG precipitation, glycine and NaCl precipitation, and ammonium sulfate precipitation. Although octanoic acid can rapidly inactivate enveloped viruses, under some process conditions nonenveloped viruses and certain enveloped viruses have been shown to partition with the precipitate (rather than be inactivated) by octanoic acid.<sup>67,86,87</sup> Virus removal by precipitation and depth filtration is virus specific, but it can significantly contribute to the overall safety of the final product.

### Chromatography

Ion exchange, gel filtration, hydrophobic interaction, or affinity chromatography can remove viruses.<sup>88,89</sup> When the resin of the chromatography column is reused, efficient sanitization of resins (and internal column hardware) is a necessary step to avoid batch-to-batch contamination.

### Prion safety

Prions, the causative agents of human transmissible spongiform encephalopathy (TSE) such as Creutzfeldt–Jakob disease (CJD) and variant (v)CJD, cannot be inactivated under conditions used for the manufacture of PDMPs without negatively impacting the qualities of the therapeutic protein. However, manufacturing processes have been shown to contain process steps that have the potential to significantly reduce prion agent infectivity.<sup>90</sup> The prion removal capacity of a manufacturing process can be measured in small-scale laboratory investigative studies and model infectious agents of TSE using principles consistent with virus validation studies. In such investigative studies, a variety of commonly used manufacturing steps (virus filtration [nanofiltration], octanoic acid and caprylate precipitation, PEG precipitation, and affinity chromatography) have been shown to significantly reduce TSE infectivity. These studies provide reasonable assurance that low levels of prions, if present, would be removed by the manufacturing process. There has been one putative report of vCJD (not CJD) transmission of a medium-purity factor VIII concentrate to a hemophiliac patient who did not develop clinical vCJD.<sup>91</sup> The hemophiliac had multiple prion risk exposures, including exposure to 8Y (BPL) factor VIII concentrate manufactured from UK-sourced plasma, which in at least one lot contained plasma from a preclinical vCJD donor. It should also be noted that the prion removal capacity of the 8Y process was also relatively low versus that of other PDMPs ( $3.3 \log_{10}$ ).<sup>92</sup> Importantly, even with heightened surveillance measures in place, there have been no other reports of clinical or nonclinical vCJD (or CJD) transmission by PDMPs manufactured by products that were manufactured from high-prion-risk UK-sourced plasma.

### Manufacturing controls and assessment of final product for virus safety

Each manufacturer must carry out process-specific validation for the licensed manufacturing process used to produce a plasma-derived therapy. The manufacturing process conditions and in-process monitoring for virus inactivation/removal steps must be clearly defined and justified. Segregation of intermediates pre- and postvirus reduction must be ensured by the use of closed systems

and/or different manufacturing zones with dedicated equipment, air-handling systems, gowning, and restricted personnel movement. Virus reduction is further ensured by confirmation of the production records that the conditions validated for the process were rigidly adhered to and that opportunities for cross-contamination and recontamination are prevented.<sup>52</sup>

In general, it is not appropriate to test the final product for viral markers as such tests are not reliable and are difficult to interpret. Testing of final products by NAT is not suitable to demonstrate a safe product due to statistical methods of sampling (Poisson distribution); furthermore, NAT detects genomic sequences and not infectivity of a virus. Virus inactivation techniques such as S/D treatment, octanoic acid treatment, dry heat treatment, and pasteurization disrupt the envelope and/or capsid proteins of the virus but can leave nucleic acid fragments that may be detected by NAT methods but have no bearing on the virus safety of the final product.<sup>52</sup> An assessment of virus safety in the finished product is a regulatory requirement by some authorities.

## Manufacturing processes for plasma-derived medicinal products

In this section, specific processes used in the recovery of all the major plasma proteins for therapeutic use are described. The focus is on illustrating the range of techniques that can be used in the manufacture of these products and exposing the reader to a wide range of concepts underpinning the fractionation of plasma proteins. In addition, the expected pharmacopeial specifications of the final product, which ensure desired product safety and efficacy, are detailed.

### Albumin

The cold-ethanol fractionation process remains the dominant process for the manufacture of albumin (Figure 22.1).<sup>34</sup> Details on the production of albumin by the cold-ethanol fractionation process in a modern facility and the required quality attributes expected of the product have been reviewed elsewhere.<sup>19</sup>

As previously described, the cold-ethanol fractionation process involves manipulation of ethanol concentration and pH of solutions at low ionic strength, while maintaining subzero temperatures, to achieve differential precipitation of proteins. The recovery of albumin involves the generation of Supernatant I, II + III, IV-I, IV-4, and finally the precipitation of albumin as Fraction V at 40% (v/v) ethanol, pH 5.8, with temperature maintained at  $-5^{\circ}\text{C}$ . A variation to the cold-ethanol fractionation process developed by Cohn was reported by Kistler and Nitschmann in 1962.<sup>93</sup> The aim was to maximize albumin yield and decrease the use of ethanol. Precipitate A, the equivalent of Fraction II + III in the Cohn process, is produced with 19% (v/v) ethanol, pH 5.85, and allows the recovery of the albumin-containing Supernatant A. This then progresses through the generation of Supernatant IV (40% v/v ethanol, pH 5.85,  $-8^{\circ}\text{C}$ ) and Precipitate C (40% v/v ethanol, pH 4.8,  $-8^{\circ}\text{C}$ ). Resuspension of Precipitate C and recovery of Supernatant D (10% v/v ethanol, pH 4.6,  $-3^{\circ}\text{C}$ ) provide the final purified albumin. This process was initially used by the Swiss manufacturer ZLB and continues to be used following its incorporation into CSL Behring.<sup>33</sup> The albumin recovered by ethanol fractionation is highly purified, although trace amounts of residual plasma proteins—typically, haptoglobin, ceruloplasmin,  $\alpha_2$ -macroglobulin,  $\alpha_1$ -acid glycoprotein, hemopexin, and transferrin—can be detected<sup>94,95</sup> (CSL data on file).

A small number of manufacturers have incorporated chromatographic steps into their albumin purification processes. This

includes the fully chromatographic method developed by CSL Behring (Australia) and a hybrid method that was developed by BioProducts Laboratories (BPL). The chromatographic purification method employed by CSL Behring (Australia) was developed in the 1990s for the Albumex product and was based on the method of Curling *et al.*<sup>94,96,97</sup> The process was initially developed for the purification of albumin from Supernatant II + III but was later adapted for the processing of Supernatant I.<sup>98</sup> The process incorporates three chromatographic steps—anion and cation exchange chromatography with DEAE and CM Sepharose<sup>\*</sup>, respectively, and size exclusion chromatography using Sephadex<sup>†</sup> S200 resin. This last step markedly contributes to the purity of the recovered albumin, removing residual proteins and aggregates. The BPL method for Zenalb takes the Fraction V intermediate and utilizes a DEAE anion exchange resin to further reduce trace levels of residual plasma proteins.<sup>99</sup> The purified albumin is formulated, and bulk pasteurized before filling and a second pasteurization step in the vial. The Albumex and Zenalb processes are shown in Figure 22.3.

Chromatographically purified albumin is purer than that derived by cold-ethanol fractionation and exhibits a lower aggregate content.<sup>94</sup> This increased purity has been associated with a decreased rate of adverse reactions for patients infused with chromatographically purified albumin.<sup>98</sup>

The cold-ethanol fractionation process for the manufacture of albumin contributes to the viral safety of the product through partitioning virus away from the product stream.<sup>100–103</sup> With the alternative chromatographic process, similar partitioning is achieved at the chromatographic steps.<sup>104,105</sup> In addition, a specific viral inactivation step is included in the manufacturing process—pasteurization at 60 °C for 10 hours.<sup>100–103</sup> This has been part of the production of albumin from the very beginning and undoubtedly accounts for the fact that there has never been a viral transmission from an albumin product.<sup>106</sup> The pasteurization of albumin was possible due to the finding that *N*-acetyl tryptophanate and sodium octanoate (caprylate), or sodium octanoate alone, stabilized the molecule during heating.<sup>107,108</sup>

The European Pharmacopoeia (EP) and US regulations (CFR21) stipulate that pasteurization be performed in the final container following dispensing in order to completely remove the risk of recontamination.<sup>109,110</sup> Reflecting advances in bioprocessing execution and control, CSL Behring (Australia), in addition to developing a novel chromatographic manufacturing process, obtained approval from the Australian regulatory authority to implement bulk pasteurization of its albumin product prior to dispensing.<sup>94</sup> Albumex<sup>\*</sup> has an additional viral inactivation step consisting of incubation at low pH in the presence of caprylic acid at 30 °C for 10 hours.<sup>111</sup> This step was introduced to add further viral safety to the product and reflected the regulatory expectations that plasma protein products have at least two dedicated viral inactivation or removal steps.<sup>112</sup>

The specifications of the albumin products are governed by EP and US Pharmacopoeia and National Formulary (USP) or CFR pharmacopeial requirements, which provide limits for physical properties, biological safety, purity, excipients, and contaminants.<sup>109,110,113</sup> Purified albumin solutions are supplied by various manufacturers as 4, 4.5, 5, 20, and 25% (w/v) solutions and typically exhibit a shelf life of up to five years at room temperature (25–30 °C).<sup>19</sup> It is a requirement that the solution must be clear and can be almost colorless, yellow, amber, or green (EP). The variation in color reflects differences in the presence of residual heme as well as colored protein impurities such as haptoglobin, ceruloplasmin, transferrin, and hemopexin.<sup>95,114</sup> While chromatographically purified albumin has lower levels of colored protein impurities than cold-ethanol purified albumin, it contains higher levels of albumin-bound bilirubin (yellow) and its oxidized derivative biliverdin (green), which contribute to the color.<sup>114</sup>

The product should have a pH (at 20 °C) of 6.7–7.3 (EP) or 6.4–7.4 (USP). Osmolality should be equivalent to that of plasma (USP). With respect to excipients, sodium should not exceed 160 mmol/L (EP) or 130–160 mmol/L (USP). Sodium caprylate (sodium octanoate) should be 0.16 mmol/g albumin if it is the single stabilizer (CFR21). In preparation where dual stabilizers, sodium caprylate and *N*-acetyl tryptophanate, are used, the concentration of each should be 0.08 mmol/g albumin (CFR21).

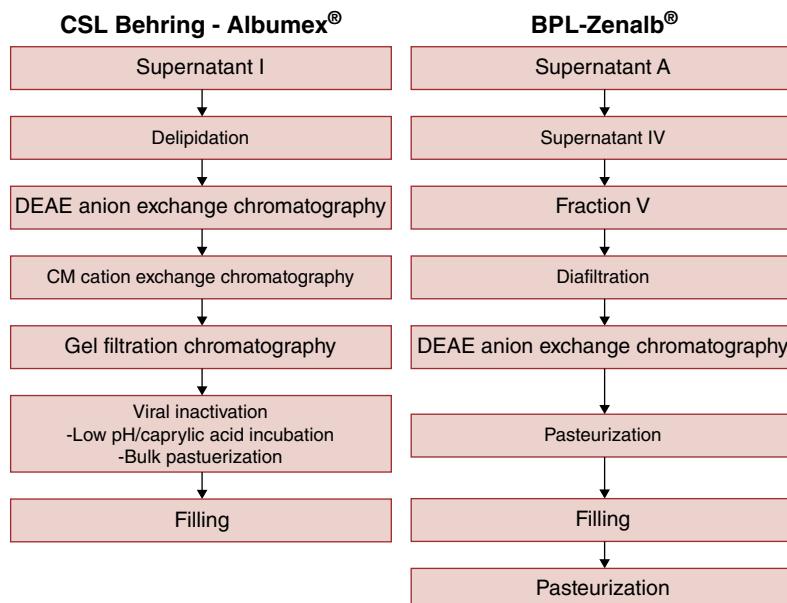

Figure 22.3 Chromatographic processes for the purification of albumin—Albumex<sup>\*</sup> (CSL Behring, Australia) and Zenalb<sup>\*</sup> (BioProducts Laboratories).

Albumin purity should be at least 95% (EP) or 96% (USP), with aggregate content not more than 10% of total protein. Heme levels as determined by adsorption at 403 nm should not exceed 0.15 AU (EP).

Prekallikrein activator (PKA) activity should not be more than 35 IU/mL (EP). This is an important specification as PKA (also known as factor XIIa or Hageman factor fragment), if present, can lead to a clinical hypotensive reaction.<sup>115</sup>

Contaminant levels, of which potassium and aluminum are specified, should be less than 0.05 mmol/g albumin (EP) or 2 meq/L (USP) and 200 µg/L (EP), respectively. The limit for aluminum was introduced into the British Pharmacopoeia in 1993 to ensure albumin safety for use in renal dialysis and with premature babies.<sup>99</sup> Another concern was the accumulation of aluminum with the treatment of burn patients.<sup>116</sup> The source of aluminum is from the glass containers used for the product. Leaching of aluminum is abetted by even very low concentrations of citrate (<0.1 mmol/L), which originates from the anticoagulant used during plasma collection.<sup>117</sup> Through optimization of diafiltration processes used in manufacturing, to minimize citrate content, current albumin products meet the required aluminum pharmacopeial limit.<sup>19,118</sup>

The solution should be sterile, nonpyrogenic, and with endotoxin levels not more than 0.5 EU/mL (EP/USP). The pharmacopoeias also specify that the final product be incubated for a period prior to final inspection to provide additional assurance of product sterility. CFR21 requires incubation for at least 14 days at 20–35 °C, and the EP states not less than 14 days at 30–32 °C, or not less than four weeks at 20–25 °C.

## Immunoglobulins

The Cohn process also served as the starting point for the purification of immunoglobulins.<sup>34</sup> Oncley developed a process for the recovery of purified immunoglobulins from Cohn Fraction II + III.<sup>38</sup> In the process, the immunoglobulin fraction is resuspended and reprecipitated with 20% v/v ethanol, at pH 7.6 (modifications exist with pH 6.7), with the temperature maintained at –5 °C. The recovered precipitate is then resuspended, and the solution adjusted to 17% v/v ethanol, at pH 5.2, with the temperature maintained at –6 °C. This results in the precipitation of IgM and other impurities (Fraction III), while the IgG remains in the supernatant (Supernatant III). IgG is then recovered as Fraction II by precipitation with 25% v/v ethanol, pH 7.4, with the temperature maintained at –5 °C.

A modification of the Oncley process was developed by Kistler and Nitschmann in 1962.<sup>93</sup> The aim was to increase the yield of IgG and reduce ethanol use. In this process, Precipitate A (corresponding to Cohn Fraction I + II + III) is obtained at 19% v/v ethanol, pH 5.85, with the temperature maintained at –5 °C. Following the resuspension of the precipitate in water, the solution is adjusted to pH 5.1 and ethanol is added to 12% v/v while maintaining the temperature at –5 °C. This results in the precipitation of impurities, including IgM (Precipitate B), with IgG remaining in the supernatant (Supernatant B) (equivalent of Cohn Supernatant III). The IgG is recovered by precipitation (Precipitate G) at 25% v/v ethanol, pH 7.0, with the temperature maintained at –7 °C. This precipitate corresponds to Cohn Fraction II. The above-mentioned processes, with various modifications, for many years, have accounted for the bulk of commercially produced immunoglobulins.<sup>119,120</sup> The Kistler-Nitschmann process was particularly identified with the ZLB (later CSL Behring) facility in Bern, for the production of Sandoglobulin.<sup>121</sup>

The development of new immunoglobulin manufacturing processes from the mid-1990s has reflected the desire of manufacturers

to improve product characteristics and safety. This has led to the increase in protein concentration in the final formulation in order to increase the convenience of use, the introduction of viral inactivation steps to improve safety, and the introduction of procedures to improve yield and manufacturing efficiency.<sup>119,120,122</sup> A number of companies have developed hybrid processes where the crude IgG precipitate generated by cold-ethanol precipitation (Fraction II + III or Precipitate A) is subjected to further chromatographic processing to recover the purified immunoglobulin.<sup>20,119,120,122,123</sup> CSL Behring (Australia) developed a unique completely chromatographic procedure, and in 2000, its use commenced for the production of immunoglobulin for the Australian market and other toll customers.<sup>124–126</sup> A key feature of this process was the increased yield in IgG that was achieved when compared to the cold ethanol-based process.<sup>127</sup>

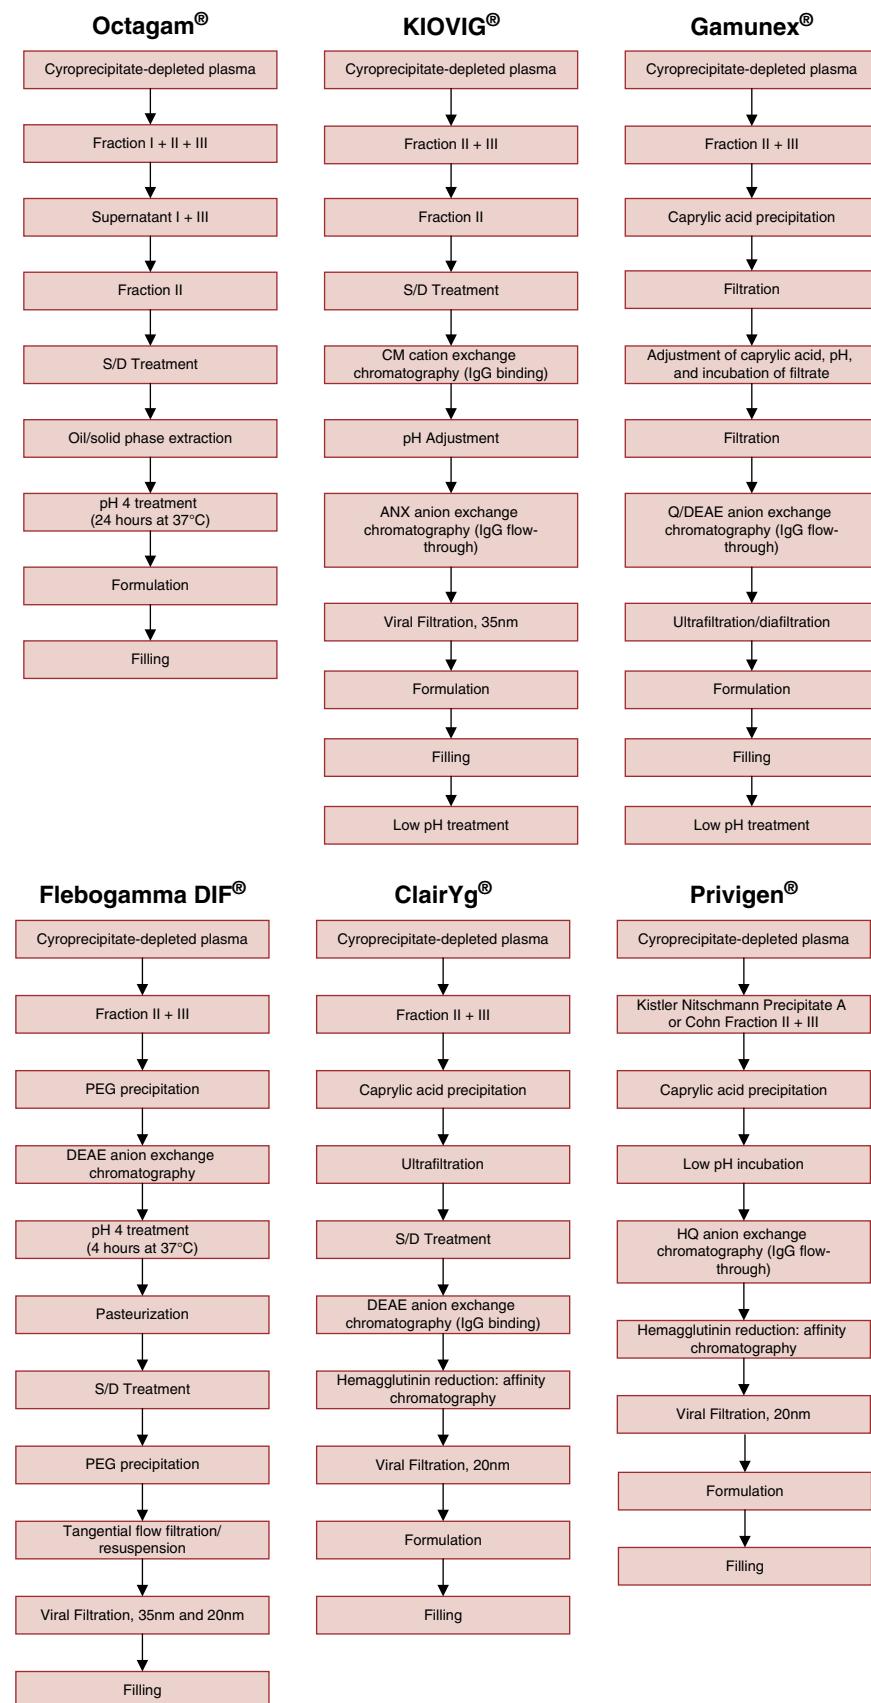

In the following, a brief description is presented for the manufacturing processes of all the major immunoglobulin products currently produced and the expected pharmacopeial specifications of immunoglobulin products. This area has also been reviewed extensively elsewhere.<sup>20</sup>

A few products are purified essentially by the complete application of the Oncley ethanol fractionation process. In the manufacture of Octogam<sup>®</sup> (Octapharma), purified IgG is recovered as Fraction II (Figure 22.4). In addition to the viral partitioning that occurs during the fractionation process, there is solvent-detergent (S/D) treatment and low-pH incubation, as described above, for viral inactivation. The oil/solid phase extraction step is a means of removing the S/D used during the viral inactivation procedure.<sup>20,128,129</sup> Octapharma has recently registered a new immunoglobulin product, Panzyga, which incorporates an ion exchange chromatography step to increase product purity and a virus filtration step.<sup>130</sup>

KIOVIG<sup>®</sup> or Gammagard<sup>®</sup> produced by Takeda (European and US trade names, respectively) is also produced by the Oncley process resulting in the generation of purified IgG as Fraction II (Figure 22.4).<sup>131</sup> The purified immunoglobulin is then subjected to three viral inactivation or removal procedures—S/D treatment, viral filtration with a 35 nm filter, and low-pH formulation and incubation of the dispensed product. The cation exchange chromatography step is used to bind the immunoglobulin and thereby allows the removal of the S/D used in the viral inactivation procedure. Passage through the anion exchange column retains impurities and results in further purification of the immunoglobulins.

The manufacture of Gammunex<sup>®</sup> (Grifols) is one of the several hybrid manufacturing processes that involve the generation of a crude IgG fraction by ethanol precipitation followed by further purification by chromatography (Figure 22.4). Cohn Fraction II + III is suspended and caprylic acid added to precipitate impurities. The caprylic acid concentration is adjusted in the recovered filtrate and incubated at 25 °C for one hour. This constitutes the first viral inactivation procedure in the manufacturing process. The generation of pure IgG is achieved by sequential passage through a strong (Q) and a weak (DEAE) anion exchange chromatographic column. Following buffer exchange, concentration, and formulation, where pH is adjusted approximately 4.25, the product is dispensed and then incubated at 28 °C for 21 days. This constitutes the second viral inactivation step.

In the manufacture of Flebogamma DIF<sup>®</sup>, Cohn Fraction II + III is resuspended, partially purified by precipitation of impurities by the addition of polyethylene glycol (PEG), and then further purified by anion exchange chromatography. The purified immunoglobulin

**Figure 22.4** Comparison of IgG manufacturing processes. Source: Based on Teschner *et al.*<sup>131</sup> and Roch *et al.*<sup>133</sup>

is subjected to three dedicated viral removal or inactivation procedures: pasteurization, S/D treatment, and viral filtration through 20 nm filters. The PEG precipitation of the resuspended Cohn Fraction II + III is also associated with significant viral clearance. The second PEG precipitation after the low-pH treatment, pasteurization, and S/D treatment serves to remove immunoglobulin aggregates and facilitates the passage of the solution in the subsequent viral filtration step<sup>132</sup> (Figure 22.4).

The purification of Clair Y g<sup>+</sup> (LFB) involves the use of Cohn Fraction I + II + III. Following solubilization, impurities are removed by caprylic acid precipitation. The filtrate is ultrafiltered to remove caprylic acid, and the retentate is subjected to S/D treatment. The immunoglobulin is then captured on an anion exchange column allowing the removal of the S/D. The eluted immunoglobulin is then passed through an affinity resin to reduce the anti-A and anti-B isoagglutinin titer. The immunoglobulin then undergoes viral filtration, the second viral removal step, prior to formulation and filling (Figure 22.4).<sup>133</sup>

The manufacture of Privigen<sup>®</sup> (CSL Behring) is also a hybrid manufacturing process that involves the generation of a crude IgG fraction by ethanol precipitation followed by further purification by chromatography.<sup>134</sup> Kistler–Nitschmann precipitate A or Cohn Fraction II + III is resuspended, and caprylic acid addition is used to precipitate impurities. The recovered partially purified immunoglobulin solution is subjected to low-pH incubation in the presence of a detergent as part of the first viral inactivation procedure. Final purification of the immunoglobulins is achieved by passage through a Q anion exchange chromatographic column under conditions where impurities (predominantly IgM and IgA) are bound and IgG flows through. The purified product is in turn passed over an affinity column to decrease the anti-A and anti-B hemagglutinin titers.<sup>135</sup> The recovered immunoglobulin solution is then subjected to viral filtration, the second viral removal procedure in the process, prior to formulation and dispensing (Figure 22.4).

Gammimune N<sup>®</sup> (Miles Cutter/Bayer) in 1992 was the first immunoglobulin for intravenous use to be available as a 10% (w/v) formulation.<sup>136</sup> There has been a consistent trend over the last 20 years of moving from a final protein concentration of 5 or 6% (w/v) to 10% (w/v). The increased protein concentration reduces the volume that needs to be infused and, hence, is more convenient for the patient.<sup>137</sup> Today, all the major immunoglobulin products on the market which have been described here are available at the 10% w/v formulation.<sup>138</sup> A number of manufacturers have developed immunoglobulin products at protein concentrations of 16–20% w/v (Hizentra<sup>®</sup>-CSL Behring; Cuvitru<sup>®</sup>-Takeda; Cutaquig<sup>®</sup>-Octapharma; Xembify<sup>®</sup>-Grifols), which are intended for subcutaneous administration.<sup>139–142</sup>

A key challenge in the development of an immunoglobulin preparation suitable for intravenous use identified a means of preventing the development of anticomplementary activity in the product arising from the formation of aggregates. Early success in removing the aggregates associated with anticomplementary activity was achieved in 1962 by Barandum and Isliker through mild proteolysis with pepsin at pH 4.0.<sup>143</sup> Improvements in processing, such as the use of ultrafiltration and diafiltration at pH 4.0 for the removal of ethanol from Supernatant III and for the concentration of IgG, instead of precipitation and lyophilization, minimize aggregate formation and help generate products that have good clinical tolerability.<sup>144</sup> It was then shown that the formulation of the immunoglobulin at approximately pH 4.25 generated a liquid stable product with low anticomplementary activity.<sup>145,146</sup> The stability of

immunoglobulin at low pH is due to the fact that this is below their isoelectric point and results in noninteracting positively charged molecules. Consequently, many immunoglobulin products are now formulated at less than pH 5.0.<sup>138,145,147</sup>

Excipients are used in the formulation of immunoglobulins. These serve to stabilize the immunoglobulin molecules in solution by minimizing protein–protein interactions and to ensure the clinically acceptable tonicity of the product.<sup>148,149</sup> Many immunoglobulin products in fact can be stored at room temperature for up to 36 months.<sup>138,150</sup> Currently used excipients comprising of amino acids, sugars, and sugar alcohols have a long history of use and are known to be well tolerated.<sup>148</sup> Glycine is most commonly used, but proline, maltose, sorbitol, and mannitol are also used. Low concentrations of sodium chloride and polysorbate detergent may also be added to adjust tonicity and enhance stability.<sup>151–155</sup>

Although there are differences in the manufacturing processes for immunoglobulins and differences in final formulation, there is no evidence that they significantly correlate with differences in product efficacy and tolerability.<sup>115–156</sup> As registered products, these immunoglobulin products meet the standards as prescribed by relevant regulatory authorities.

The European Pharmacopoeia has a comprehensive monograph on immunoglobulins for intravenous use.<sup>157</sup> The product is expected to be sterile and free of pyrogens and endotoxins. A liquid formulation is expected to be clear or slightly opalescent, colorless, or pale yellow. The allowable pH is 4.0–7.4. Osmolality must be greater than 240 mOsmol/kg. The minimum allowable protein concentration of a formulation should not be less than 30 g/L (3% w/v), and the purity is expected to be greater than 95%. Aggregate content must not exceed 3% of total protein. This is an important quality attribute as aggregates typically result in complement activation-mediated adverse reactions. Any propensity for this is monitored through the measurement of anticomplementary activity, with the specification set at <1 CH<sub>50</sub>/mg IgG.

The allowable maximum limit of prekallikrein activator (PKA) (factor XIIa), which can mediate the formation of the vasoactive peptide bradykinin from kininogen and lead to hypotensive reactions, is set at 35 IU/mL.<sup>158</sup>

Hemagglutinins, anti-A and anti-B antibodies to red cell antigens, can result in hemolytic reactions with the infusion of immunoglobulins. Therefore, the EP stipulates a maximum allowable titer of 1:64. Given that high-volume administration of immunoglobulins is required in some indications, specifically those associated with achieving immune modulation, manufacturers are introducing specified hemagglutinin removal steps in manufacturing their process to lower the titer in their products.<sup>133,156</sup> Therefore, the titer of some products will be considerably lower than this limit.

The EP does not define a maximum level of IgA allowed in immunoglobulin products, but the product must comply with the level stated on the label. The range for the products described here is 5–200 µg/mL.<sup>138</sup> Knowledge of the IgA content of an immunoglobulin product is important for a clinician when confronted with an IgA deficient patient who could exhibit an anaphylactic reaction if infused with a higher IgA concentration immunoglobulin product.<sup>159</sup>

Although not prescribed in the EP, immunoglobulin products are expected to exhibit a subclass distribution comparable to that normally found in plasma.<sup>159</sup> Despite a number of manufacturing processes resulting in partial depletion of IgG<sub>3</sub> and IgG<sub>4</sub>, there is no evidence that this affects the efficacy of the product.<sup>20</sup> In addition, the EP requires that the immunoglobulin purification process

maintains the integrity of the Fc portion of the immunoglobulin molecule—as this is key to its immunomodulatory role through interaction with the Fc receptor and its effector role in complement activation.<sup>159</sup> Monitoring of Fc function is not a product release requirement but is assessed during process validation. An immunoglobulin product should exhibit an Fc function of >60% of that of an EP standard.

The EP also stipulates that the antibody titer to hepatitis B should be at least 0.5 IU/g IgG, and the United States also includes minimum antibody levels for measles, diphtheria, and polio.<sup>160</sup> There is no limit for antibodies to hepatitis A, but regulatory authorities expect levels to be above 10 IU/mL. Maintaining a consistent level of antibodies to these targets is challenging as there has been a consistent decline in antibody titers in plasma due to increased vaccination and decreased disease prevalence.<sup>20,161,162</sup>

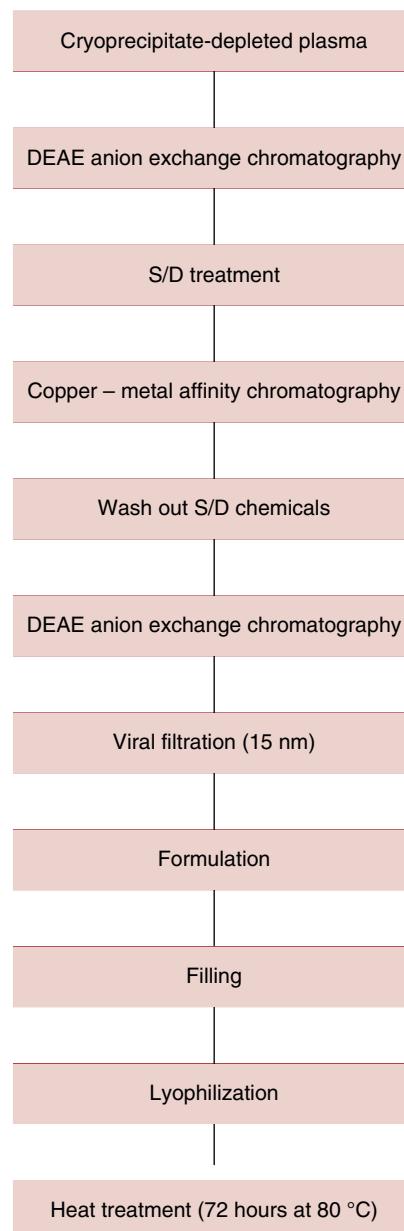

In 2010, increased incidences of thromboembolic events were reported in patients using Octogam.<sup>163</sup> Analysis showed this was due to increased levels of factor XIa caused by a process change. Following this, the regulatory agencies requested that manufacturers confirm that their processes have the capability of removing thrombogenic activity and generate a product low in procoagulant activity.<sup>157,164,165</sup> Procoagulants have been shown to be partitioned away from the product during purification and inactivated by pasteurization and exposure to low pH.<sup>163–165</sup> The commercially available immunoglobulin products typically have very low to nondetectable levels of factor XIa.<sup>166,167</sup>

### Factor XIII

The development of manufacturing processes for factor XIII has been extensively reviewed.<sup>15</sup> The focus here is on describing the production of a major commercial factor XIII product, Fibrogammaglobin P<sup>®</sup> (in Europe) and Corifac<sup>®</sup> (in the United States), as undertaken by CSL Behring. The process utilizes Cohn Fraction I precipitate derived from cryoprecipitate-depleted plasma. Following resolubilization and removal of fibrinogen by treatment with aluminum hydroxide and Vitacel<sup>®</sup> (a cellulose fiber), the clarified solution is subjected to DEAE anion exchange chromatography. The purified factor XIII is then subjected to two viral inactivation and removal procedures—pasteurization (60 °C for 10 hours) and viral filtration with 20 nm filters. Following formulation to the target potency and with the addition of albumin, glucose, and sodium chloride, the solution is sterile filtered, dispensed, and lyophilized.<sup>168,169</sup> There is no monograph for factor XIII product, but these products have been extensively characterized with respect to purity, function, and factor XIII integrity. This includes factor XIII activity, specific activity, factor XIII subunit A content, fibrinogen clotting time, PKA, and activated factor XIII.<sup>15</sup>

### Factor X

The manufacture of a therapeutic factor X produced by BPL (UK) is shown in Figure 22.5. The key steps in the process are adsorption of factor X from cryoprecipitate-depleted plasma by DEAE anion exchange chromatography. Further purification is achieved by metal affinity chromatography with a copper chelate resin. Viral removal is achieved by S/D treatment, viral filtration with 15 nm filters, and finally the lyophilized product is subjected to heat treatment at 80 °C for 72 hours.<sup>15</sup> The product has been shown to comply with required toxicity, thrombogenicity, and immunogenicity requirements. In addition, in vitro tests confirm that the product is potent, highly purified, and free of potentially hazardous residues.

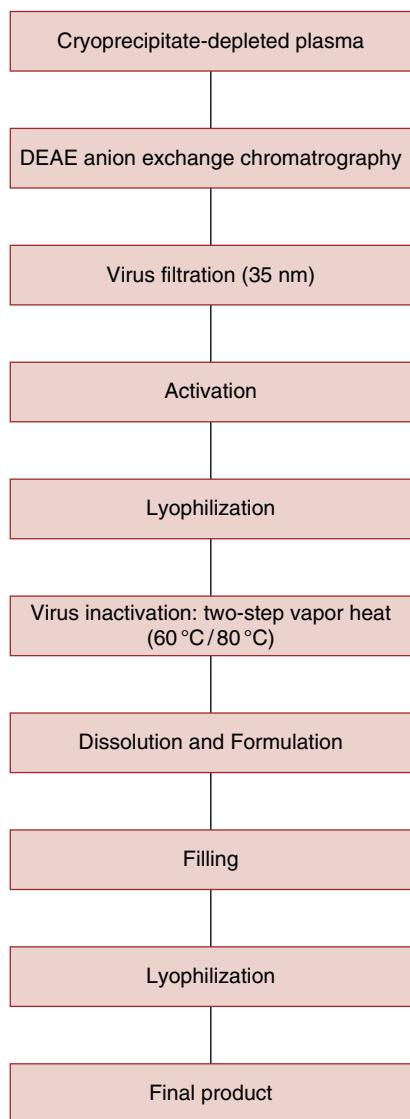

**Figure 22.5** Manufacturing process for factor X (BPL).

The testing includes the determination of factor X potency, specific activity, the presence of factor II, factor IX, proteins C and S, and NaPTT.<sup>15</sup>

### Activated prothrombin complex concentrate (aPCC)

aPCC, known as factor VIII inhibitor bypassing activity (FEIBA<sup>®</sup>), is manufactured by Takeda. Details on the development, production, mechanism of action, and clinical use of the product have been reviewed elsewhere.<sup>11</sup> The manufacturing process is shown in Figure 22.6. It involves the purification of prothrombin complex factors (II, VII, IX, and X) from cryoprecipitate-depleted plasma by DEAE anion exchange chromatography. The recovered material undergoes viral filtration with a 35 nm filter. The factors are then contact activated, generating activated Factor VII and some activated

**Figure 22.6** Manufacturing process for factor VIII bypassing activity (FEIBA®) (Takeda).

factor X. These activated factors, together with prothrombin, are thought to be important for the clinical efficacy of the product.<sup>11,170</sup> The product is lyophilized and undergoes a second viral inactivation treatment involving vapor heat treatment at 60 and 80 °C for at least 8.5 hours and 1 hour, respectively. The product is dissolved and then formulated with sodium citrate and sodium chloride, and dispensed at either 500, 1000, or 2500 arbitrary FEIBA units before lyophilization. One unit of activity is defined as the amount of product that shortens the activated partial thromboplastin time (aPTT) of a high-titer factor VIII inhibitor reference plasma to 50% of the blank value. The final product is a lyophilized preparation.<sup>171</sup>

#### Alpha<sub>1</sub>-proteinase inhibitor

The manufacturing processes for the four major alpha<sub>1</sub>-proteinase inhibitor (API) products, Aralast NP® (Takeda), Zemaira® (CSL Behring), Prolastin C® (Grifols), and Glassia® (Kamada) are presented in Figure 22.7.<sup>172–176</sup> A comprehensive examination of these manufacturing processes is available elsewhere.<sup>23</sup>

Cohn Fraction IV-I is the source material for all products. The Aralast NP® process utilizes a unique step involving an extended thaw of the Fraction IV-I paste and dissolution in pH 6.0 buffer that allows the recovery of an API-enriched precipitate. Following dissolution, all processes include an initial “activation hold” step at approximately pH 9 and at elevated temperature (approximately 45 °C). This results in increased recovery of functional protein, which could be related to refolding of denatured protein. The commencement of the purification process typically involves polyethylene glycol (PEG) precipitation of impurities or destabilization of unwanted proteins by reduction with dithiothreitol (DTT) and adsorption with fumed silica (Aerosil®). This treatment takes advantage of the fact that there are no disulfide bonds in the API molecule.<sup>177</sup> All processes utilize anion exchange chromatography for further purification. Further polishing is achieved by adsorption with bentonite (aluminum phyllosilicate clay), hydrophobic interaction chromatography, or cation exchange chromatography. The Aralast NP®, Glassia®, and Prolastin-C® processes all incorporate S/D treatment as the first viral inactivation procedure. Pasteurization is used in the Zemaira® process. All processes include viral filtration as the second viral removal step. Aralast NP®, Zemaira®, and Prolastin C® are presented as lyophilized final products, whereas Glassia® is a liquid product.<sup>23</sup>

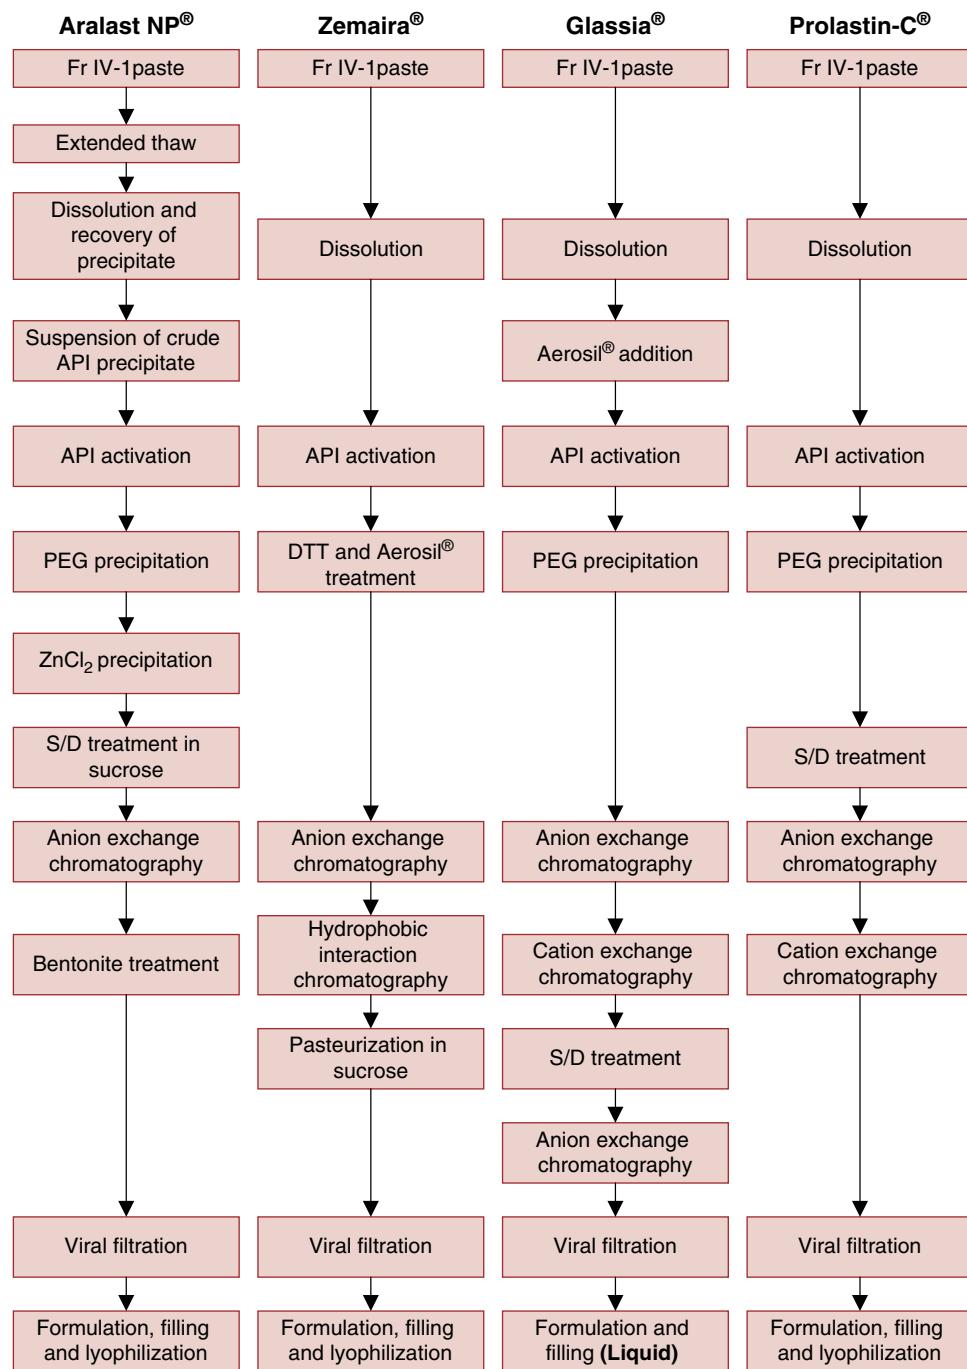

The EP prescribes certain product qualities for API preparations.<sup>178</sup> The specific activity should not be less than 0.35 mg of active API per mg of total protein. The ratio of API activity to antigen should not be less than 0.7. With respect to appearance, the liquid preparation should be clear or slightly opalescent, colorless, or pale yellow, pale green, or pale brown; the freeze-dried preparation should be a powder or solid friable mass, hygroscopic, and white, pale yellow, or pale brown.

It is required that the pH should be in the range of 6.5–7.8, the preparation should be completely soluble, and osmolality should be greater than 240 mOsmol/kg. The product must be sterile and free of pyrogens and bacterial endotoxins.

#### Factor XI

The manufacture of factor XI is undertaken by LFB Biotechnologies (France).<sup>14</sup> Cryoprecipitate-depleted plasma (cryosupernatant) is passed through a negatively charged filter to capture the factor XI. It is then eluted with 1 M NaCl containing antithrombin III (ATIII), which inhibits any proteolytic activity that could degrade the product. Following buffer exchange by ultrafiltration, the solution is subjected to viral inactivation treatment with S/D. The solution is passed through a sulfate (S) cation exchange chromatographic resin to capture the protein and allow the removal of the virus-inactivating chemicals. The factor XI is eluted and formulated with heparin and ATIII before sterile filtration, dispensing, and lyophilization. The product is highly purified, containing only trace amounts of fibrinogen, albumin, C1-esterase inhibitor, fibronectin, alpha<sub>2</sub>-macroglobulin, and IgG. The levels of other coagulation factors, kinin system components, and proteases are also low or nondetectable.<sup>179</sup>

The EP required that the freeze-dried final product should be white or almost white powder or friable solid, and it should completely dissolve within 10 minutes following reconstitution. The potency must be within 80–120% of that stated on the label. The reconstituted product should have a pH of 6.8–7.4 and have a minimum osmolality of 240 mOsmol/kg. Heparin and ATIII added as stabilizers must comply with the level stated on the label. Ensuring the absence of activated coagulation factors, the NaPTT coagulation time should not be less than 150 seconds. There should not be

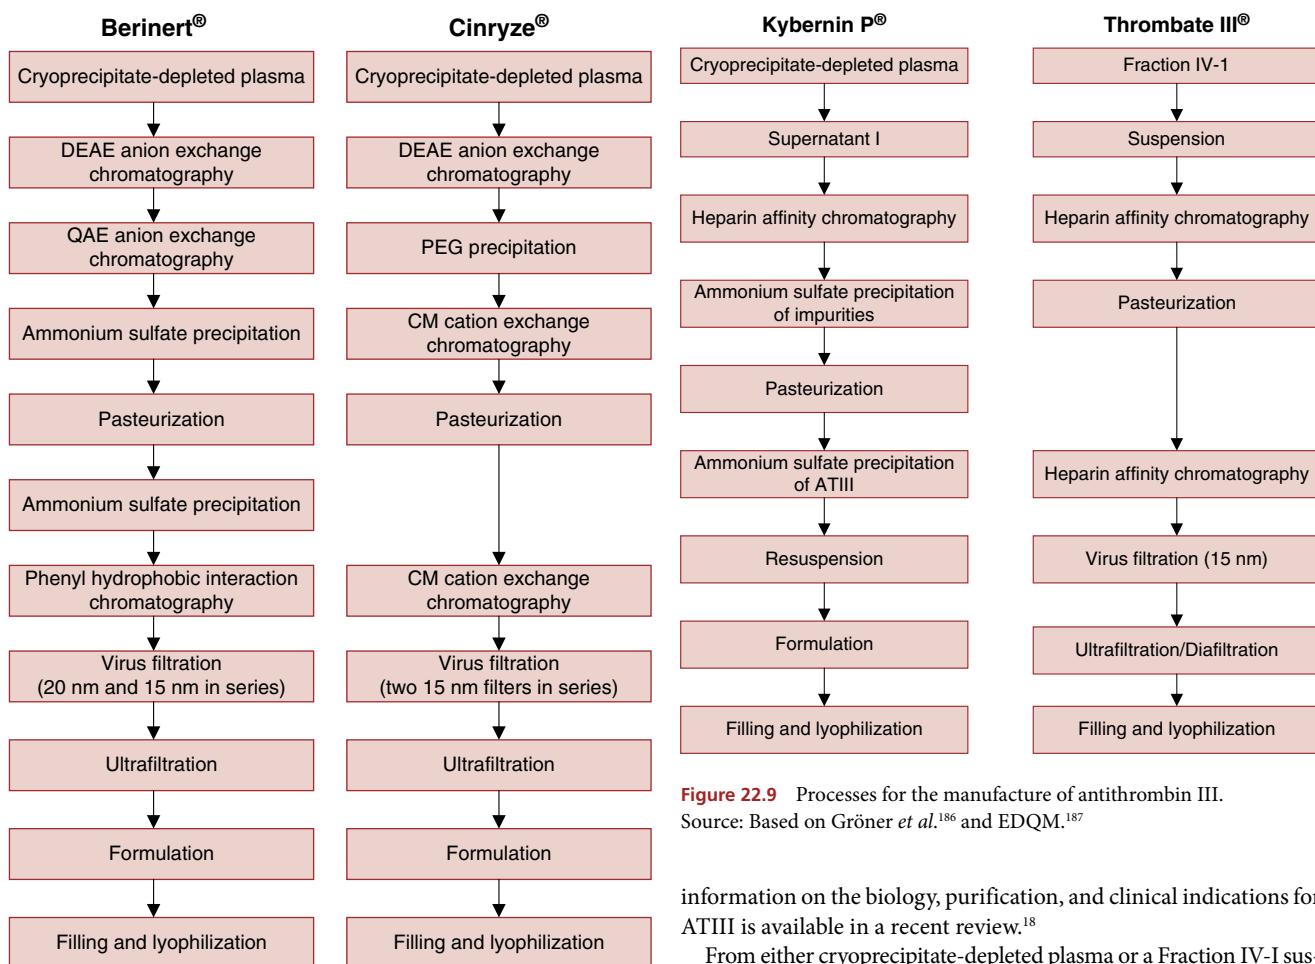

**Figure 22.7** Comparison of alpha<sub>1</sub>-proteinase inhibitor manufacturing processes. Source: Based on Hwang *et al.*<sup>172</sup>; Matthiessen *et al.*<sup>173</sup>; Kee *et al.*<sup>174</sup>; Lebing *et al.*<sup>175</sup> and Bonitz *et al.*<sup>176</sup>

any significant presence of anti-A and anti-B hemagglutinins, with no agglutination occurring at a 1:64 dilution of the product. The product must be sterile and free of bacterial endotoxins.<sup>180</sup>

### C1-esterase inhibitor

The biology, purification, and clinical use of C1-esterase inhibitor has been comprehensively reviewed elsewhere.<sup>24</sup> This section focuses on describing the manufacturing processes of two of the major C1-esterase inhibitor products on the market: Berinert<sup>®</sup> (CSL Behring) and Cinryze<sup>®</sup> (Takeda).<sup>24,181,182</sup> As can be seen in Figure 22.8,

the processes are quite distinct in the use of chromatographic processes. In the production of Berinert<sup>®</sup>, cryoprecipitate-depleted plasma is initially passed through a DEAE anion exchange column, under conditions in which the C1-esterase inhibitor flows through and subsequently captured on a QAE anion exchange resin. Further purification is achieved by ammonium sulfate precipitation steps and hydrophobic interaction chromatography (HIC). In the Cinryze<sup>®</sup> process, the C1-esterase inhibitor is captured from the starting material by anion exchange chromatography, and further purification is achieved by PEG precipitation and two separate

**Figure 22.8** Processes for the manufacture of C1-esterase inhibitor.

cation exchange chromatography steps. In both processes, viral removal involves pasteurization and virus filtration requiring two filters in series.<sup>181,183</sup> Following virus filtration, the products are formulated, dispensed, and lyophilized.

There are no pharmacopeial requirements for C1-esterase inhibitor concentrates. However, as with other lyophilized therapeutic protein products, it must have an acceptable appearance in the lyophilized state and must comply with registered residual moisture content. The product must readily dissolve and present as a colorless and clear solution with clinically acceptable osmolality and insoluble particle count. It must be sterile and free of bacterial endotoxins. Manufacturers determine and report the potency of the product.<sup>184</sup> The integrity of the product is determined by monomer content, which is a quality control release specification. Thus, for example, Berinert® must have a monomer content of >89%. Recently, a biochemical and purity comparison of four commercially available C1-esterase inhibitor products (Berinert®, Cinryze®, Cetor®, and Ruconest® [transgenic product]) was published with a view that the work would contribute to the establishment of regulatory requirements for determining purity and setting allowable threshold levels.<sup>185</sup>

### Antithrombin III

As examples of manufacturing processes for Antithrombin III (ATIII), the processes for Kybernin P® (CSL Behring) and Thrombate III® (Grifols) are described and shown in Figure 22.9.<sup>186,187</sup> Further

**Figure 22.9** Processes for the manufacture of antithrombin III.  
Source: Based on Gröner *et al.*<sup>186</sup> and EDQM.<sup>187</sup>

information on the biology, purification, and clinical indications for ATIII is available in a recent review.<sup>18</sup>

From either cryoprecipitate-depleted plasma or a Fraction IV-I suspension, ATIII is captured by heparin affinity chromatography. The Kybernin P® process then uses sequential ammonium sulfate steps to remove impurities and to concentrate the ATIII by precipitation. All processes incorporate pasteurization as a viral inactivation step. In the Kybernin P® process, a subsequent ammonium precipitation of ATIII allows the removal of pasteurization stabilizers and the production of a concentrated solution, which is formulated, dispensed, and lyophilized. In the Thrombate III® process, further purification is achieved by heparin affinity chromatography. In addition to pasteurization, the Thrombate III® process incorporates virus filtration. The recovered filtrate is then concentrated and diafiltered prior to formulation, dispensing, and lyophilization. The Thrombate III® process incorporates two dedicated viral inactivation and removal steps, while the Kybernin P® process has only one dedicated viral inactivation step—pasteurization. Despite this, additional viral clearance in the Kybernin P® process is achieved by precipitation at the first ammonium sulfate precipitation step.<sup>186</sup>

The EP prescribes a number of product specifications.<sup>188</sup> At least a 60% fraction of the product must bind heparin. The specific activity of the product should not be less than 3 IU ATIII per mg of protein (excluding albumin excipient). The lyophilized product should be a white or almost white, hygroscopic, friable solid or powder. The water content must be within limits. The product should completely dissolve within 10 minutes with gentle swirling, giving a clear or slightly turbid, colorless or almost colorless solution. The limits for pH and osmolality are 6.0–7.5 and >240 mOsmol/kg, respectively. The maximum allowed heparin content is 0.1 IU per IU ATIII. The product must be sterile and free of bacterial endotoxins.

## Fibrinogen

The manufacturing processes for the two main fibrinogen products Riastap® (US) or Haemocomplettan® (Europe) produced by CSL Behring and Fibryga® produced by Octapharma are shown in Figure 22.10. Both processes utilize cryoprecipitate as the starting intermediate. The Riastap® manufacturing process is based on a series of glycine-based precipitations—a procedure initially described by Bromback and Bromich in 1956.<sup>189,190</sup> The cryoprecipitate extract is initially adsorbed with aluminum hydroxide, and then the fibrinogen is precipitated with high-concentration glycine. The reconstituted fibrinogen is then pasteurized. Following the addition of glycine to promote precipitation of residual proteins, a purified fibrinogen is recovered by precipitation by increasing the concentration of glycine. The pure fibrinogen precipitate is redissolved, concentrated and diafiltered, formulated, dispensed, and lyophilized. For the Fibryga® process, the resuspended cryoprecipitate is also treated with aluminum hydroxide prior to the first virus inactivation step utilizing solvent/detergent. The fibrinogen is further purified via two ion exchange chromatography steps and a precipitation step. The second dedicated virus clearance step involves virus filtration, before the product is formulated, filled, and lyophilized.<sup>191</sup> A third fibrinogen product, FibClot® produced by LFB, is also commercially available.

The EP requires that the lyophilized product should be white or pale yellow in a hygroscopic powder or friable solid; that the water content is within approval limits; and that it dissolves within 30 minutes at room temperature, forming an almost colorless, slightly opalescent solution. The solution should contain not less than 10 g/L fibrinogen with a pH of 6.5–7.5 and a minimum osmolality of 240 mOsmol/kg. The product should be sterile and free of bacterial endotoxins.<sup>192</sup>

## Prothrombin complex concentrate

The manufacture of commercially available prothrombin complex concentrates (PCC) should ensure the generation of a product with a balanced content of vitamin-K-dependent factors (II, VII, IX, and X) and the presence of physiologically relevant amounts of the regulatory inhibitory proteins, proteins C, S, and Z.<sup>12</sup> A comparison of different PCC products has shown that the PCC products had similar levels of coagulation factors, but there were differences in purity and content of the inhibitory proteins.<sup>193</sup>

To specifically illustrate the principles of the manufacture of PCC, the process used for the production of Kcentra® (CSL Behring) (Beriplex® in Europe) and Octaplex® (Octapharma)—two commercial products in wide use—will be examined (Figure 22.11). The manufacture of Kcentra® is initiated by the adsorption of the PCC factors from cryoprecipitate-depleted plasma with DEAE anion exchange resin.

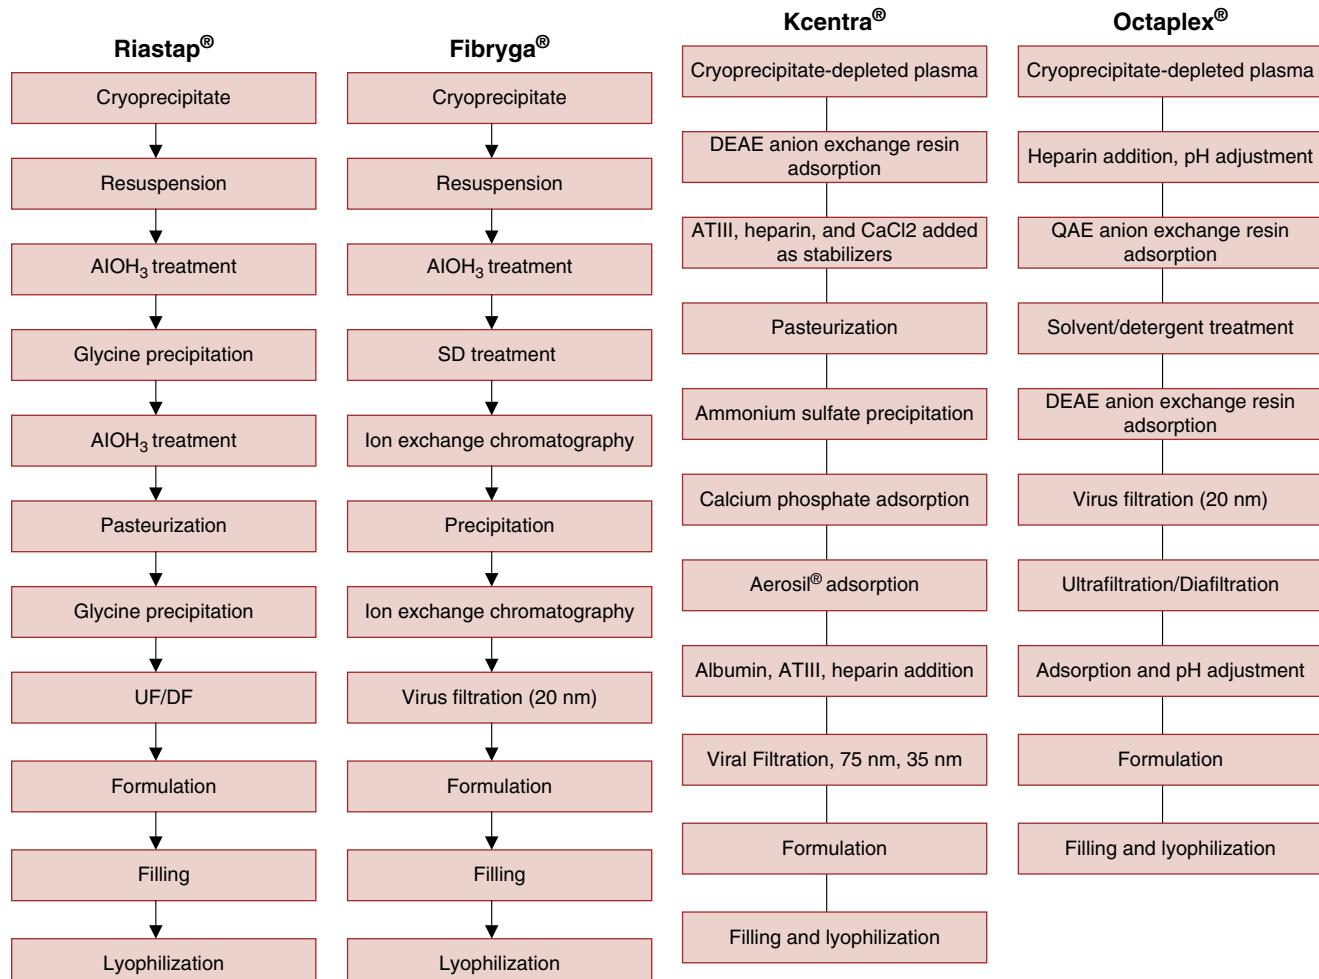

Figure 22.10 Comparison of the manufacture of two fibrinogen products.

Figure 22.11 Comparison of the manufacture of two prothrombin complex concentrate products.

The factors are eluted and stabilized by the addition of ATIII, heparin, and  $\text{CaCl}_2$ . The eluate is pasteurized to ensure viral safety. Further purification involves ammonium precipitation of impurities, binding to calcium phosphate, followed by elution and Aerosil® (fumed silica) adsorption of the eluate. The recovered solution is formulated by the addition of albumin, ATIII, and heparin to stabilize the active components, and then subjected to viral filtration through two 20 nm filters. Following dilution to a targeted factor IX concentration and the adjustment of the final albumin concentration, the product is dispensed and lyophilized.<sup>194</sup> In the Octoplex® process, PCC factors are adsorbed from cryoprecipitate-depleted plasma with a Q anion exchange chromatographic resin following pH addition and heparin addition to prevent factor activation. The recovered eluate undergoes S/D treatment for viral inactivation. Subsequent binding to a DEAE anion exchange resin allows the washing away of the viral inactivation chemicals and provides further purification. The product is then subjected to viral filtration with a 20 nm filter. Following ultrafiltration, the product is formulated with the addition of heparin (but no albumin) and then dispensed and lyophilized.<sup>12,195</sup>

There is an EP monograph for PCC products.<sup>196</sup> It stipulates that a product must contain factor IX together with variable amounts of factor II, VII, and X. The preparation may contain stabilizers (e.g., albumin, heparin, and ATIII). The lyophilized product should be a white or slightly colored, very hygroscopic powder or friable solid. Water content should be within approved limits. The preparation must dissolve completely within 10 minutes with gentle swirling. The potency of the reconstituted preparation should not be less than 20 IU of factor IX per milliliter. The pH of the solution should be between 6.5 and 7.5, and osmolality should not be less than 240 mOsmol/kg. If the content of any of the other factors is stated, it should not be less than 80% or more than 120% of the stated range. The specific activity of factor IX should not be less than 0.6 IU/mg of total protein (before addition of any stabilizer). The presence of any activated coagulation factors should not result in the coagulation time in an NaPTT assay to be less than 150 seconds. If heparin has been used in the formulation, the amount should comply with that on the label and not be more than 0.5 IU per IU of factor IX. The preparation must be sterile and free of bacterial endotoxins.

## Factor IX

The approaches taken for the purification of high-purity factor IX have been extensively documented elsewhere.<sup>13,197</sup> Predominantly, the process commences with the initial capture of prothrombin complex factors (factors II, VII, IX, and X). The isolation of factor IX can then involve the use of ion exchange or affinity chromatography, or adsorption with insoluble metal salts. The manufacturing processes incorporate specific viral removal procedures, usually S/D treatment and viral filtration.<sup>13,197</sup>

Details of the manufacture of three products—Alphanine® (Grifols), Betafact® (LFB), and Berinin P® (CSL Behring)—are shown in Table 22.2. It can be seen that all products involve initial adsorption of factor IX (and the other PCC factors II, IX, and X) from cryoprecipitate-depleted plasma by DEAE anion exchange chromatography. In the manufacture of Alphanine®, final purification involves adsorption to a barium citrate precipitate, followed by two sequential dextran sulfate affinity chromatography steps. Viral removal is achieved by S/D treatment and viral filtration.<sup>13,198</sup> The recovery of purified factor IX in the Betafact® process involves further purification by DEAE anion exchange chromatography and heparin affinity chromatography. Viral removal is achieved by S/D treatment and viral filtration.<sup>13,199</sup>

In the Berinin P® process, the eluate obtained from DEAE anion exchange chromatography undergoes a viral inactivation procedure—pasteurization—and then it is partially purified by ammonium sulfate precipitation, prior to recovery of factor IX by calcium phosphate adsorption and final purification by heparin affinity chromatography (CSL data on file). The products are then formulated, dispensed, and lyophilized.

The required properties of a purified factor IX product are detailed by an EP monograph.<sup>200</sup> The lyophilized product should be a white or pale-yellow hygroscopic powder or friable solid. The preparation should completely dissolve with gentle swirling within 10 minutes. The reconstituted product should have a pH between 6.5 and 7.5, and a minimum osmolality of 240 mOsmol/kg. Potency should not be less than 20 IU/mL, and specific activity should not be less than 50 IU/mg of total protein. Any presence of activated factors should not cause the coagulation time in the NaPTT test to exceed 150 seconds. If heparin has been used in the formulation, it should be stated on the label but in all cases should not exceed 0.5 IU of heparin per IU of factor IX. The product should be sterile and free of bacterial endotoxins.

## von Willebrand factor

Haemate P®/Humate P® (CSL Behring) was one of the first developed intermediate-purity factor VIII-vWF products. Since its licensing in Germany in 1981 for the treatment of hemophilia A, it has also been used to this day for the treatment of von Willebrand disease.<sup>201</sup> The manufacture of the product is from cryoprecipitate and involves initial adsorption of impurities from the reconstituted solution with aluminum hydroxide and then purification of the factor VIII-vWF complex by a series of glycine and sodium-chloride-mediated precipitation steps. Pasteurization is incorporated as a viral inactivation step<sup>197</sup> (CSL data on file).

In the late 1980s, new purification processes were developed incorporating chromatographic procedures to improve the efficiency

of manufacture, improve product purity, and facilitate the introduction of viral inactivation procedures. A detailed examination of the chromatographic approaches that can be used to purify vWF, and an overview of the manufacturing processes and the viral removal procedures utilized for registered vWF products have been published elsewhere.<sup>10,197</sup> They show that a range of chromatographic procedures are used, consisting of anion exchange, size exclusion, and affinity chromatography. Viral removal procedures include S/D treatment, pasteurization, dry heat treatment, and viral filtration.

The purification processes and viral removal procedures for some specific vWF products are shown in Table 22.3. The starting material in all cases is cryoprecipitate. The manufacture of Alphanate<sup>\*</sup> involves an initial purification involving PEG precipitation to remove impurities, followed by heparin affinity chromatography to recover the purified vWF.<sup>10,202</sup> The manufacture of Wilate<sup>\*</sup> and Wilfactin<sup>\*</sup> involves the use of size exclusion chromatography and gelatin affinity chromatography, respectively, to further purify the DEAE anion exchange chromatographic fraction obtained through the processing of a cryoprecipitate solution.<sup>10,203,204</sup> The manufacturing processes incorporate S/D treatment and dry heat as viral inactivation steps. In the Wilfactin<sup>\*</sup> process, viral filtration is included.

The manufacturing process for a vWF product must deliver a consistent product with respect vWF multimer composition. The EP requires that during process development the quantitative analysis of the product must be undertaken using electrophoretic and densitometric techniques to confirm that the product closely approximates the multimer distribution of a plasma reference preparation.<sup>205–207</sup> The dispensed product must contain not less than 20 IU/mL of vWF, and the measured value must be within 20% of that stated on the label. Factor VIII must be tested if there is greater than 10 IU of factor VIII per 100 IU of vWF. The measured value must be within 40% of the stated value. vWF potency must only be measured by the ristocetin cofactor assay. vWF products are characterized on the basis of specific activity and a vWF activity–FVIII ratio. For the former, it must be greater than 1 U vWF/mg of total protein excluding any protein stabilizer. A value greater than 80 U vWF/mg protein is usual, although products with lower specific activity exist.<sup>197</sup> The vWF activity–FVIII ratio is not prescribed but must comply with the approved limit for the product with the competent authority. Values for the various products are from 0.75 to 2.4. The exception is Wilfactin, where the ratio is approximately 60.<sup>197</sup> This reflects the design of the manufacturing process that reduces the copurification of factor VIII, thereby producing a predominantly vWF product.<sup>203</sup>

With respect to other product characteristics, the EP requires that the lyophilized final product should be a white or pale yellow, hygroscopic powder or friable solid with a water content that is

within the approved limits. The product should completely dissolve with gentle swirling within 10 minutes, giving a clear or slightly opalescent, colorless yellow solution. Some products allow for filtration to remove flakes or particles present after reconstitution. If this is the case, it must be shown in validation studies that there is no impact on product potency. The reconstituted product must have a pH between 6.5 and 7.5, an osmolality greater than 240 mmol/kg, and no anti-A- or anti-B-mediated agglutination at a 1:64 dilution at a defined dilution of the reconstituted preparation. The product must be sterile and endotoxin free.<sup>207</sup>

### Factor VIII

The production of cryoprecipitate for clinical use by Judith Pool in 1965 was a pivotal event in the treatment of hemophilia as it provided a high-potency product and an alternative to what hitherto had been used—fresh-frozen plasma.<sup>208</sup> In the following years, purification processes were developed that further improved the purity and viral safety of factor VIII products. Haemate P/Humate P<sup>\*</sup>, in Germany in 1981, was the first registered intermediate-purity product containing a dedicated viral inactivation procedure. The product contained both factor VIII and vWF, and it became a recognized therapeutic for both hemophilia A and von Willebrand disease.<sup>201</sup> The purification process increased the specific activity of vWF from 1 IU/mg of protein for cryoprecipitate to approximately 38 IU/mg of protein in Haemate P/Humate P<sup>\*</sup>.<sup>197</sup>

In subsequent years, the application of chromatographic steps further increased the purity of factor VIII products.<sup>9</sup> Commonly referred to as *high-purity products*, the specific activity was typically greater than 100 IU/mg and for some products as high as 180 IU/mg.<sup>9,197</sup> The different manufacturing processes resulted in a variation in the vWF content, which in some cases limited their use to the treatment of hemophilia A and the exclusion of von Willebrand disease. With the development of these new processes, the opportunity was also taken to introduce two specific viral removal procedures. Typically, these were S/D treatment and dry-heat treatment of the lyophilized final product. Vapor heat and viral filtration have also been applied.<sup>9,197</sup> The use of monoclonal affinity chromatography allowed the generation of factor VIII concentrates with higher specific activity: >3000 IU/mg. These products, of course, do not have vWF.<sup>9,197</sup>

Table 22.4 presents the manufacturing process of a number of commercially available factor VIII products. The aim is to specifically present details to illustrate the range of processes that have been used to purify factor VIII and ensure viral safety. In the manufacture of the high-purity products Beriate P<sup>\*</sup> (CSL Behring), Factane<sup>\*</sup> (LFB), and Immunate<sup>\*</sup> (Takeda), there is typically an initial Al(OH)<sub>3</sub> adsorption step. This serves to remove

**Table 22.4** Representative Manufacturing Processes for Factor VIII

vitamin-K-dependent prothrombin complex factors. Further purification then occurs by anion exchange chromatography.<sup>209–211</sup> Factane® has a unique viral filtration step involving passing the product through a 15 nm filter. It had been thought that the factor VIII–vWF complex was too large to be able to be successfully filtered. However, this was achieved by dissociating the complex prior to filtration by exposure to calcium chloride and then reassociating the complex by its removal from the filtrate. The manufacturing process for Alphanate® differs in that there is an initial PEG precipitation step that is effective in removing fibrinogen and fibronectin. Final purification utilizes heparin affinity chromatography.<sup>212–214</sup>

The examples of the manufacture of very-high-purity factor VIII products offer some interesting and distinct differences. In the case of Hemofil M®, following a cold precipitation clarification step of the cryoprecipitate suspension, the solution undergoes S/D treatment to effect viral inactivation. Factor VIII purification is achieved by antifactor VIII immunoaffinity chromatography. This step is very effective in achieving the removal of fibrinogen, fibronectin, and vWF. There is then a viral filtration step. A subsequent Q anion exchange chromatographic step binds factor VIII eluted from the affinity column and allows any leached monoclonal antibody affinity ligand to flow through.<sup>215,216</sup>

All factor VIII products are lyophilized. Various excipients are used and can include amino acids, sugar alcohols, sugars, and salts. In some cases, albumin is also included.<sup>197</sup>

The required properties of factor VIII are detailed in the EP.<sup>217</sup> The specific activity should not be less than 1 IU of factor VIII per milligram of total protein before the addition of any protein stabilizer. But, as has been noted, with modern purified products this is readily achieved. The potency of the preparation as stated on the label should result in not less than 20 IU factor VIII per milliliter. With respect to the appearance of the lyophilized preparation, water content, solubility, pH, osmolality of the reconstituted material, anti-A and anti-B hemagglutinin titer, sterility and endotoxin content, the requirements previously described for the vWF product apply.

## Summary and outlook

The production of plasma protein-based therapeutic products is a complex process commencing with the collection of plasma by a system incorporating donor selection, viral testing, and quality assurance measures that ensure the viral safety of the plasma for fractionation.<sup>35</sup> Starting with the work of Cohn, and through the subsequent application of knowledge of protein chemistry, bio-processing technology, and virology, processes have been developed for the production of therapeutic products for a range of clinical indications, which meet the high standards of safety and efficacy prescribed by the regulatory authorities.<sup>7</sup>

Today, the production of plasma protein therapeutic products is a large global industry.<sup>33,218</sup> Despite the development of many recombinant alternatives, the production of products by fractionation of plasma remains cost-effective and continues to grow, particularly for albumin and immunoglobulins.<sup>219,220</sup> Albumin is required in large amounts, and immunoglobulins have unique biological properties, which make it commercially unattractive or scientifically unjustifiable to produce these products by recombinant means, and therefore they will most likely continue to be produced from plasma for the foreseeable future.<sup>19,219,221</sup>

Plasma fractionators are continuing to explore the clinical utility of additional plasma proteins and improve existing products. Proteins with therapeutic potential which are being investigated are shown in Table 22.1. Plasmin and reconstituted HDL are the most advanced in the clinical development pathway.<sup>25,26</sup> With respect to existing products, the focus is on improving formulations and addressing issues that can lead to adverse reactions. As the plasma raw material is limited and expensive, plasma fractionators are also focused on increasing process recoveries for the various plasma-derived therapeutic products.<sup>222</sup>

The pathogen safety of manufactured PDMPs has been dramatically enhanced since the 1980s through the implementation of NAT technologies that effectively screen out units with high virus titers. Additionally, the incorporation of multiple orthogonal pathogen inactivation and removal steps into the manufacturing processes has greatly enhanced the safety of the final products against both

known and emerging/reemerging viruses. Vigilance, assessment, and verification studies to assess the effectiveness of the virus reduction technologies against emerging pathogens, especially small nonenveloped viruses, are ongoing responsibilities of the manufacturers of plasma-derived therapies. Although the safety of plasma-derived therapies has an excellent history over the last two decades, the development of robust technologies (i.e., 20-nm virus filtration) and the incorporation of these technologies into new and existing manufacturing processes continue.

The developed countries are well served for fractionation capacity. Many developing countries such as China and Brazil are extending and improving their capabilities.<sup>31</sup> However, there are many developing countries that do not have adequate access to plasma protein products and cannot afford to purchase the requirements for their population.<sup>223</sup> Arguments for and against the establishment of a localized fractionation facility have been discussed elsewhere.<sup>222,224</sup> The adoption of improvements in bioprocessing approaches could make the design and establishment of a fractionation facility less complex, cheaper, and hence feasible for construction and operation in a developing country. However, in addition to establishing fractionation capacity, supporting infrastructure is required for facilities to enable plasma collection and NAT testing of donations. Given the complexity and expense of developing these capabilities, developing countries must decide whether it is worthwhile to establish their own facilities or simply obtain the plasma-derived therapeutics on the commercial market.

The plasma fractionation industry will continue to deliver unique therapeutics essential for human health. It is likely that the future will be as eventful as the period from Cohn to the present day.

## Acknowledgments

The authors acknowledge the efforts of Joe Bertolini and Nathan Roth for the preparation of the chapters in the previous edition of Rossi's Principles of Transfusion Medicine (Chapters 27 and 56). The current authors have refined the original chapters with recent developments in the plasma protein therapies and other relevant information.

## CHAPTER 23

# Immunoglobulin products

Melvin Berger

Departments of Pediatrics and Pathology, Case Western Reserve University, Cleveland, OH, USA

Plasma-derived immunoglobulin (Ig) is used for an increasingly wide range of autoimmune and inflammatory diseases in addition to its traditional uses for the prevention of infection and for antibody replacement and augmentation therapy in immune deficiency diseases<sup>1–3</sup> (Figures 23.1 and 23.2). Increased recognition and treatment of immune deficiencies in the developing world have added to the global demand for IgG. However, the major reason for the continued strong growth in demand for IgG products is the increased use of “high-dose” therapy, particularly in autoimmune neurologic diseases.<sup>1–3</sup> Long-term treatment of adults with doses in the range of 1–2 g/kg or even more per month is the major contributor to the continuously growing global utilization of Ig products, which exceeded 230 metric tons in 2020 (Figures 23.1 and 23.2).<sup>4</sup> Indeed, the demand for Ig is the major driver of the continuously increasing demand for plasma and growth in fractionation capacity.

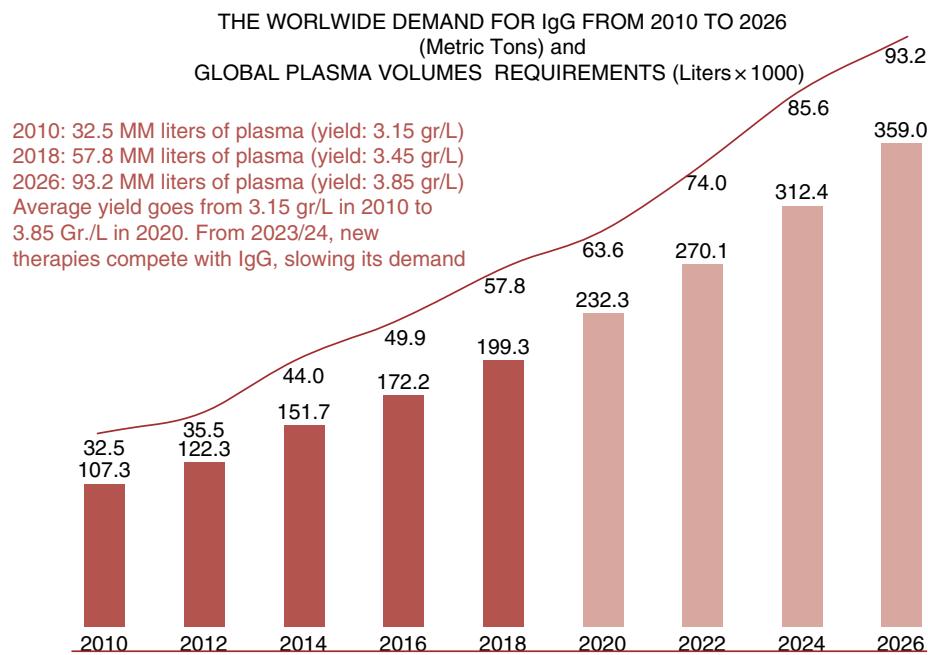

### Structure and origin of Ig molecules

In order to understand the many uses for serum immunoglobulin preparations, it is necessary to understand the major difference between immunoglobulins and most other plasma proteins: diversity.<sup>5–8</sup> The prototypic immunoglobulin molecule is a tetramer composed of two identical heavy chains, each with a molecular mass of approximately 55 kD, and two identical light chains of 22 kD, giving an overall molecular mass of 155 kD.<sup>5,7</sup> There are four major classes, or *isotypes*, of immunoglobulins in plasma: IgA, IgE, IgG, and IgM, with IgG accounting for 75% of all of the immunoglobulin in plasma. These classes are defined by their heavy chains  $\alpha$ ,  $\epsilon$ ,  $\gamma$ , and  $\mu$ , respectively. Gamma heavy chains are actually a family of four types,  $\gamma 1$ – $\gamma 4$ , which are grossly related but contain differences that result in different effector functions (Table 23.1). Depending on which chain a particular IgG molecule contains, it is assigned to “subclass” 1–4. Besides IgA, IgE, IgG, and IgM, there is a fifth class, IgD, composed of molecules with  $\delta$  heavy chains. These play an important role in B-cell differentiation, but are only a minor component of the total plasma Ig pool. There are two types of light chains,  $\kappa$  and  $\lambda$ . Only one type is used in any individual Ig molecule. In addition, there are loci in the  $\gamma$  and  $\kappa$  chain genes at which different individuals may have different alleles or markers called Gm1–17

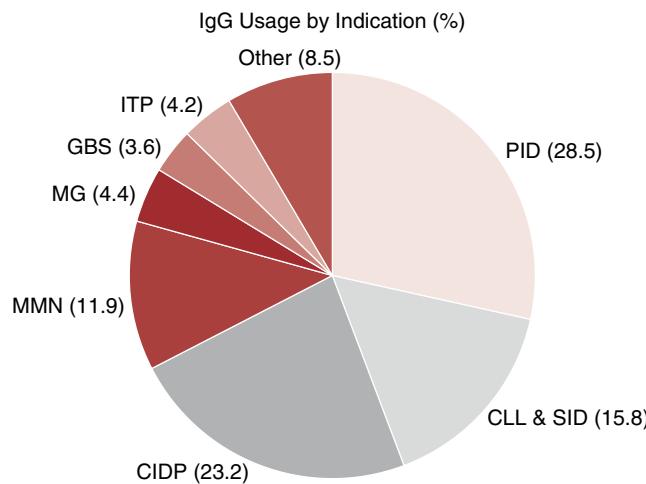

and Km1–3. These are useful as markers termed *allotypes* in genetic studies, but their clinical significance is not known.

The four chains are arranged into a pair of dimers linked together with varying numbers of interchain disulfide bonds and sugar chains at characteristic positions in each class or subclass. Immunoglobulin molecules are generally depicted as having a Y-like structure (Figure 23.3).<sup>5,7</sup> Each light chain contains a single variable region and a single constant region, whereas each heavy chain also has a single variable region, but three to four constant regions. The junction between the first and second constant regions of the heavy chain is considered a “hinge” that gives some flexibility to the arms. The variable regions of the light and heavy chains are aligned together to form the antigen binding sites, whereas the heavy chain constant domains align to form a “handle,” which binds receptors and other proteins that facilitate the effector functions and determine the metabolic fate of each class of molecules. IgA and IgM may contain an extra *joining* (J) chain, which binds to the heavy chains and holds together two of the four-chain units in the former, and five in the latter.

Ig molecules are cleaved into characteristic fragments by proteolytic enzymes such as papain or pepsin (Figure 23.3). The dimer containing the second and third constant domains of each of the heavy chains from all members of a class is crystallizable, and it has therefore been termed Fc. In contrast, because of the diversity of the variable regions, the fragments containing the antigen-binding sites are not crystallizable. With papain, the cleavage occurs toward the amino terminus side of the “hinge,” and two separate but identical antigen-binding fragments (Fab') are released. With pepsin, cleavage occurs toward the carboxyl side of the hinge, and a single fragment with two identical antigen-binding sites (F[ab']<sub>2</sub>) is produced. The antigen-binding specificity of each immunoglobulin molecule is determined by the sequences of several short stretches of amino acids in the N-terminal domain of each heavy and light chain, which are called *hypervariable* or *complementarity-determining* regions. Each person's immune system can make approximately 10<sup>12</sup> different antibody specificities. This remarkable diversity initially arises by *rearranging* or splicing together multiple DNA segments for different variable and constant region domains at slightly different junctions, to make a single antibody gene unique to that

**Figure 23.1** Global demand for IgG products (IVIG and SCIG) (Bars) and estimated volume of plasma (in millions of liters) necessary to produce that amount of IgG (upper line and numbers). Source: IFPA, Ref. 4.

particular immature B cell and its progeny.<sup>5–8</sup> Upon exposure to an antigen, a naive B-lymphocyte with a complementary binding site is selected and stimulated to proliferate, forming a germinal center in a lymph node or the spleen. Among the progeny of that B cell, in the appropriate milieu of antigen, helper T cells, and cytokines, some cells undergo further cutting and splicing of their heavy chain genes, resulting in isotype switching. Somatic hypermutation can also occur in their variable region genes,<sup>5,6</sup> resulting in *affinity maturation*. At any point, some cells may stop differentiating and become plasma cells, which are totally devoted to producing antibodies of a single isotype and specificity. Other cells may

**Table 23.1** Mechanisms of Action of IgG

**Dependent on Antigen-Binding (Fab') Region**

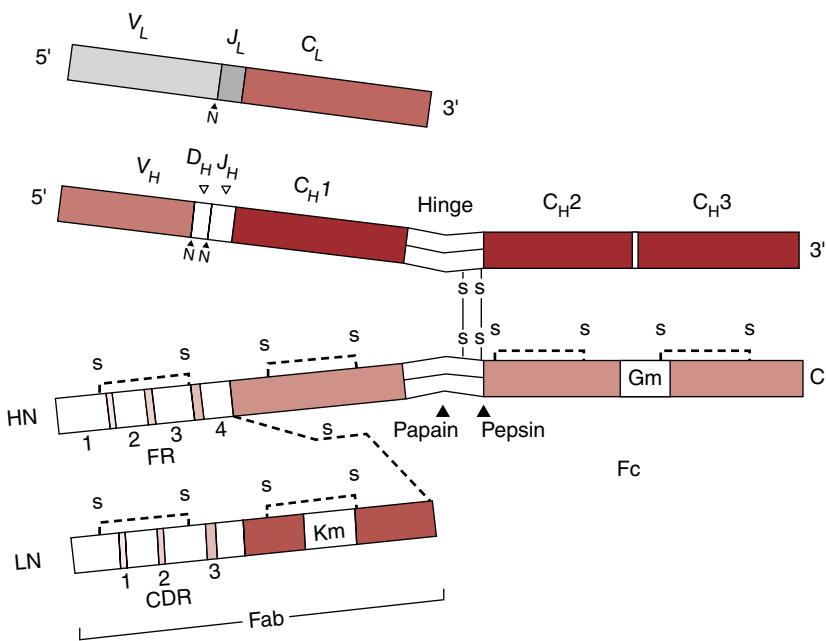

- Precipitation, agglutination, and neutralization of toxins and antigens
- Sensitizing targets for phagocytosis, complement, and cell-mediated cytology
- Neutralize viral adhesion
- Neutralizing superantigens
- Elimination of complement-activating circulating immune complexes
- Neutralizing autoantibodies (anti-id)

**Dependent on Fc Interactions with Effectors/Receptors**

- Binding to cellular receptors and activating phagocytosis and cell-mediated cytology
- Binding C1q and activating complement
- Increasing catabolism of autoantibodies by saturating FcRn
- Inhibiting C3 deposition or further activation
- Downregulation of B- and T-cell function
- Cytokine regulation
- Fc receptor blockage, altering phagocyte function

become quiescent “memory” cells, which can be rapidly stimulated on re-exposure to antigen. Upon initial exposure to an antigen or vaccine, the “primary” antibody response usually consists of IgM and relatively low-affinity IgG. Upon re-exposure, however, or during progression of an infection, class switching and affinity maturation will result in an increased ratio of IgG to IgM and an increase in the *avidity*: a product of the affinity, specificity, and quantity or “titer” of the overall antibody response. High-avidity IgG production is characteristic of “secondary” responses to vaccines and convalescent sera following infections.

The unique combination of light and heavy chain hypervariable regions that form the antigen-binding sites of any given antibody molecule may, in turn, seem “new” to the body and can serve as an antigen itself. Each unique antigen-binding site is called an “idiotype” because it belongs only to that specificity. An antibody that recognizes or blocks the antigen-binding site of another antibody is therefore called an “anti-idiotype” (anti-id).<sup>5,8</sup> Thus, the circulating

**Figure 23.3** Diagram of IgG structure: a single IgG molecule consists of two heavy chains and two light chains. The upper pair shows regions of the proteins encoded by different DNA segments: 5': 5' end of the DNA segment coding for that part of the protein; 3': 3' end of the DNA segment. V<sub>L</sub>, light chain variable region; J<sub>L</sub>, light chain joining region; C<sub>L</sub>, light chain constant region; V<sub>H</sub>, heavy chain variable region; D<sub>H</sub>, heavy chain diversity region; J<sub>H</sub>, heavy chain joining region; C<sub>H1</sub>, first heavy chain constant region; C<sub>H2</sub>, second heavy chain constant region; C<sub>H3</sub>, third heavy chain constant region. The lower pair shows structural features of the protein chains: HN and LN, amino terminus of heavy and light chains, respectively; C, carboxy terminus; S–S, disulfide bonds. The hinge region is shown in white. Sites of cleavage by papain and pepsin are shown by arrows above labels. Papain cleavage results in the formation of two monovalent F(ab) fragments and a disulfide-linked Fc fragment. Pepsin cleavage yields a bivalent disulfide-linked F(ab')<sup>2</sup> fragment. CDRs, complementarity determining regions (1–3, also known as *hypervariable regions*). FRs, framework regions (1–4), which are conserved. Note that FRs and CDRs are found in both heavy and light chains, as illustrated by white versus colored regions, but the labels are attached to only one chain each for readability. pool of IgG contains thousands or even millions of different antibody and anti-id specificities (Figure 23.4). Anti-ids are believed to be important in regulating B- and T-cell responses, forming a major component of the “network” hypothesis for which Jerne received a Nobel Prize in 1984.<sup>8</sup> Anti-idiotype neutralization of autoantibodies may be a major mechanism by which therapeutic IgG ameliorates autoimmune diseases (discussed further in this chapter).

### A short history of commercial IgG production

Although sera from vaccinated animals had been used for passive immunity since the late 1800s, and convalescent human sera and placental extracts were used in the 1920s and 1930s, large-scale purification of immunoglobulins from plasma did not begin until the 1940s. With a grant from the US Navy, Edwin Cohn, a physical biochemist at Harvard University, developed a process for fractionating plasma using sequential precipitations with increasing concentrations of cold ethanol to produce large amounts of purified, stable albumin (fraction V) for the treatment of shock on the battlefield during World War II.<sup>9</sup> The globulins containing most of the antibody activity were found in fractions II and III, which also contained clotting factors and lipoproteins. Oncley modified the procedure by manipulating the pH, ionic strength, and ethanol concentration, and succeeded in recovering most of the 7s gamma globulins (now recognized as IgG) in fraction II, with the clotting factors and faster-sedimenting globulins in fraction III. During the 1940s, intramuscular (IM) injections of fraction II *immune serum*

*globulin* (ISG) were studied for the prevention of hepatitis and measles. Janeway *et al.* in Boston and Barandun in Switzerland attempted to give ISG intravenously, but their efforts were abandoned because of severe immediate reactions, including hypotension, chills, and fever.<sup>9,10</sup> IM injections of 16% plasma-derived ISG were routinely used for antibody replacement in immune deficiency patients and for prophylaxis against infectious disease until the 1980s, but the doses that could be tolerated by this route were limited, and efficacy in immune deficiencies was far from ideal.

Studies through the 1960s and 1970s suggested that the majority of vasomotor reactions and other immediate adverse effects (AEs) that accompanied the early trials of intravenous (IV) administration of ISG were attributable to complement activation by aggregates of the 7s globulins. Barandun *et al.* showed that these could be removed by ultracentrifugation or dissociated by treatment with low concentrations of pepsin, incubation at pH 4, and/or reduction and alkylation of disulfide bonds.<sup>10</sup> Other protein modifications such as S-sulfonylation and treatment with β-propiolactone were also studied. The first commercial IVIGs were pepsin- or plasmin-treated preparations that contained fragmented IgG molecules that sedimented slower than intact IgG (i.e., at 5–6.5 s) and had shortened half-lives and decreased effector function compared to the IgG in the IM preparations.

By the late 1970s, combined treatments including mild reduction and alkylation, reconstitution in 0.3 M glycine, and/or treatment at pH 4 with low concentrations of pepsin were introduced to prevent aggregate formation while leaving the IgG molecules intact. These

**Figure 23.4** Idiotypic antibodies produced against different determinants on antigen—in this case, ganglioside sugars in a bacterial lipo-oligosaccharide and different anti-idiotypes produced in response to a single idiotypic antibody. processes eventually led to the first preparations that could safely be given by the IV route: Gammimune® and Sandoglobulin®, respectively. The most important contribution to the tolerability of these preparations, however, was arguably the use of high concentrations of sugars as stabilizers: maltose in Gammimune and sucrose in Sandoglobulin.

Despite minimizing complement-binding aggregates, early IVIG preparations still frequently caused hypotension and/or vasodilatation and increased capillary permeability, which were shown to be associated with the presence of contaminating amounts of proteins such as prekallikrein activator and kallikrein itself.<sup>10</sup> Contamination with factor XIa was also found to be responsible for procoagulant activity in many ISG and early IVIG preparations.<sup>11</sup> In addition, other studies showed that isolated Fc fragments, IgG aggregates, and antigen–antibody complexes induced secretion of prostaglandin E<sub>2</sub> from monocytes, suggesting that this mediator might also be contributing to pain and other adverse effects of early IVIG preparations.<sup>12</sup>

In 1981, the World Health Organization published a set of “Desirable Characteristics of IVIG Preparations”:<sup>13</sup>

- IVIG should be extracted from a pool of at least 1000 individual donors.
- IVIG should contain as little IgA as possible.

- The IgG should be modified biochemically as little as possible and possess opsonizing and complement-fixing activities.
- IVIG should be free from preservatives or stabilizers that might accumulate in vivo.

These characteristics were not fully achieved until the most recent generation of IVIG products was developed in the new millennium. Because there is no suitable alternative to polyclonal human IgG for antibody replacement therapy in immunodeficient patients, and because of the critical role of IVIG in treating a number of other diseases, the WHO includes IgG in its “Model List of Essential Medicines.”<sup>14</sup>

### Current IgG products

Additional methods to increase the yield of IgG per liter of plasma, improve the convenience of administration, and minimize AEs resulted in liquid IVIG preparations that are >95% pure IgG and are readily available in most countries. Many manufacturers now utilize modified purification procedures which only employ a single ethanol precipitation step and substitute precipitation with fatty acids such as caprylate, or medium-chain alcohols, together with depth filtration, for the serial Cohn–Oncley ethanol steps.<sup>15</sup>

Anion-exchange column chromatography is used to improve the purity by decreasing the concentrations of IgA and potentially vasoactive and/or thrombogenic protein contaminants, and some manufacturers also add cation-exchange chromatography to further purify the IgG. The use of ion-exchange chromatography, and other refinements in fractionation and purification processes, has allowed the recovery of IgG from fractions which had previously been separated from the predominant IgG-containing Cohn fraction II, increasing the yield of IgG per liter of plasma.

To improve the convenience of preparing and administering IVIG, most manufacturers have developed IVIG preparations that are available as 10% liquids and can be kept at room temperature for at least part of their shelf life.<sup>16</sup> Currently, three IV products—Gammagard<sup>®</sup> (Takeda), Gamunex<sup>®</sup> (Grifols), and Privigen<sup>®</sup> (CSL Behring)—dominate the US market. Gammagard and Gamunex are stabilized with glycine, and Privigen is stabilized with L-proline. All are available as 10% liquids, none contain any sugars as stabilizers, and none contain more than 50 mcg/mL IgA. IM ISG is rarely used in the United States, but Gammagard, Gamunex, and Gammaked<sup>®</sup> are labeled for subcutaneous administration, and CSL Behring markets a 20% proline-stabilized product, Hizentra<sup>®</sup>, specifically for subcutaneous use. In addition, Cuvitru<sup>®</sup> (20%), Xembify<sup>®</sup> (20%), and Cutiug<sup>®</sup> (16.5%) are subcutaneous products marketed in the United States by Takeda, Grifols, and Octapharma, respectively. Other manufacturers also have IV and SC products in the US market. Interested readers should consult current sources such as UpToDate<sup>®</sup>, or websites maintained by the US Food and Drug Administration (FDA), Immune Deficiency Foundation (IDF), or major distributors to track what is available at any given point in time.

### **Prevention of pathogen transmission**

Although clotting factor concentrates prepared by Cohn fractionation were known to have transmitted what is now recognized as hepatitis B virus, fraction II ISG had been given to hundreds of children for measles prophylaxis with only one case of apparent transmission of that virus. This was likely due to the presence of antibodies that neutralized possible virus in the product. The subsequent widespread use of fraction II ISG provided confidence that this product carried little risk of transmission of blood-borne infectious agents. Unfortunately, that turned out to be false confidence. Even after the recognition of AIDS, complacency persisted because HIV (then termed HTLV III) was inactivated and HIV and hepatitis-virus–antibody complexes were partitioned out by the ethanol precipitation procedures.<sup>17</sup> In the late 1980s, reports of “non-A, non-B” hepatitis (now termed *hepatitis C*, caused by hepatitis C virus [HCV]) began to appear among recipients of IVIG<sup>18</sup> and other plasma products. Solvent–detergent (SD) treatment and other dedicated steps were added to disrupt the lipid envelopes and/or coat proteins; and to inactivate, partition, or remove by nanofiltration nonenveloped viruses, to ensure the safety of these products (see Chapter 22). To date, there have been no reports of virus or prion transmission by current IgG products, but we must continue to be vigilant because of the threat of emerging pathogens.

### **Pharmacokinetics and metabolism of IgG**

#### **Conventional-dose IVIG therapy (for immune deficiencies)**

As recognition of primary immune deficiencies increased in the 1950s, a study by the British Medical Research Council resulted in

the recommendation that most patients with hypogammaglobulinemia could be successfully treated with 25 mg/kg/week of IM ISG.<sup>19</sup> Within a few years after IVIG became available in the early 1980s, this was increased to 400–500 mg/kg at intervals of 3–4 weeks, which kept the serum IgG levels in most recipients at or above the lower limit of normal, approximately 500 mg/dL, at the “trough” just before the next dose was given.<sup>20,21</sup> An intravenous bolus of 400 mg/kg of IgG given intravenously immediately raises the serum IgG level by about 1000–1200 mg/dL. The levels then drop by 40–50% over 48–72 hours, because IgG is distributed into the total extracellular fluid volume, of which only about 50% is intravascular.<sup>20,22</sup> After this equilibration phase, the IgG is catabolized with first-order kinetics and a half-life of 21–30 days, which differs in different individuals. Dosing is usually repeated every 3–4 weeks.<sup>21</sup> A major reason for this relatively long half-life of IgG, compared to IgA, IgM, and other plasma proteins, is the presence of a specific, saturable receptor on the surface of endothelial cells termed FcRn (n for neonate) because it is also found in the placenta and is responsible for the transfer of IgG into the fetus.<sup>23,24</sup> IgG, which binds to FcRn, is internalized into recycling endosomes, in which it is protected from lysosomal degradation, returned to the apical surface, and exocytosed back into the circulation.<sup>24</sup> Because IgG is distributed intra- and extravascularly but not sequestered into other compartments such as intracellular or lipophilic pools, *two compartment (i.e., intra- and extravascular) models* are traditionally used to describe its kinetics, although *single-compartment models* are sometimes used as an alternative. Early studies with radioactively labeled IgG showed that after equilibration 45–50% of the IgG remained intravascular.<sup>22</sup> Although the ratio of total extracellular fluid volume to body mass index (BMI) is relatively constant across a range of BMIs from 15 to 40,<sup>25</sup> many authorities limit the maximum dose of IVIG to 100 g in a single infusion or suggest that dosing in very obese individuals should be based on “ideal” rather than actual body weight.<sup>26</sup>

### **Subcutaneous IgG therapy**

Although first introduced in the late 1970s as an alternative to IM injections of ISG,<sup>27</sup> the use of small portable pumps to deliver concentrated IgG solutions subcutaneously has increased in popularity and is now employed by more than half of the PID patients in several countries. There are two fundamental differences between the subcutaneous route of administration of IgG (SCIG) and the intravenous route (IVIG), which lead to most of the practical differences between the two routes. The first of these is the lack of a requirement for venous access with SCIG; the second is the relatively slow adsorption of SCIG into the intravascular compartment, which was described in detail more than a hundred years ago.<sup>28</sup> In contrast, a trained professional is usually required to administer IVIG, and rapid infusion may contribute to systemic adverse events (AEs).<sup>27</sup> The doses of IgG that are practical to give by the subcutaneous (SC) route are smaller than those by the IV route, so SCIG is usually given weekly or even more frequently. Studies have shown little difference in the steady-state serum IgG levels if the same total dose of SCIG is fractionated into smaller doses given at intervals from daily to once every two weeks, and the approved US labels for most subcutaneous products allow dosing intervals from 1 to 7 days, and some labels allow dosing once every 14 days.<sup>29–30</sup>

These differences in kinetics of absorption result in several other effects that may lead to a preference for one route versus the other in a variety of different individual situations. With SCIG, the initial direction of the movement of IgG is opposite that of

IVIG: the IgG must first diffuse from a subcutaneous depot into lymphatics, from which it reaches the bloodstream indirectly via the thoracic duct.<sup>27,28</sup> Equilibration of SCIG from its injection sites into the total intravascular and extracellular fluid space requires about the same amount of time as equilibration of IVIG out of the intravascular compartment.<sup>22,28,31–32</sup> Thus, with SCIG, the intravascular IgG concentration increases more gradually, peaking at 36–72 hours after the end of an infusion. Most other features of SCIG are consequences of this difference in kinetics. For example, many of the systemic AEs of IVIG are related to the rate of the infusion and resolve when the infusion is slowed. The  $C_{\max}$  achieved with SCIG is, on average, only 61% of the peak achieved with IV infusions.<sup>27,31</sup> Studies comparing IVIG and SCIG in PID patients have shown the mean peak serum  $C_{\max}$  of 2303 mg/dL immediately after IV infusions.<sup>31–34</sup> In contrast, the mean peak with SCIG was 1410 mg/dL, and the interval ( $t_{\max}$ ) between beginning an SCIG infusion and the peak IgG concentration was 62.6 hours (2.61 days).<sup>31–34</sup> The slower rate of rise toward the peak and the truncation of its height are believed to be responsible for the much lower incidence of systemic AEs with SCIG. The safety and tolerability of SCIG has been confirmed in multiple studies and is consistent with observations that many AEs of IVIG infusions are rate related.<sup>27,33,35,36</sup> No differences have been reported in the 30–35-day half-life ( $t_{1/2}$ ) of current IgG preparations given by the subcutaneous versus IV routes.<sup>22</sup> With weekly SCIG, there are only about four days between the  $t_{\max}$  of one dose and the administration of the next dose, suggesting that only about 10–20% of the administered IgG is metabolized before the serum level starts to rise again. In contrast, with IVIG dosing intervals of 3–4 weeks, approximately 36–48% of the IgG may be metabolized by the time the next dose is due. These differences in the dosing intervals used in most SCIG-versus-IVIG regimens result in increased trough ( $C_{\min}$ ) serum IgG levels with SCIG. Pooled data from seven studies in which equivalent monthly IgG doses were given as weekly SCIG infusions versus IVIG infusions every 21–28 days showed that trough serum IgG levels were 10–20% (mean, 12.7%) higher with weekly SCIG.<sup>31,37</sup> After 6–12 weekly infusions, SCIG results in near-steady-state IgG levels, with differences between  $C_{\min}$  and  $C_{\max} \leq 5\text{--}10\%$  of the overall mean. (This steady state can also be achieved by “loading” the patient with five or six consecutive daily infusions of what will then be the weekly SCIG dose.)<sup>38</sup> In contrast, with IVIG, the trough-to-peak difference is often  $\geq 100\%$  of the overall mean.<sup>22,27,31</sup>

Another approach to subcutaneous IgG therapy involves the use of recombinant human hyaluronidase to temporarily depolymerize the hyaluronan chains that crosslink the subcutaneous tissue.<sup>39</sup> This increases the dispersion and absorption of medications delivered into the subcutaneous space and allows full monthly doses of 10% IVIG (in the range of 200–500 mL) to be given as a single SC infusion into a subcutaneous site.<sup>39,40</sup> The  $C_{\max}$  is between that of standard SCIG and an IV bolus, but the  $C_{\min}$  (trough) is not changed from that experienced with conventional 3–4 weekly IVIG dosing. The combination product, containing one vial of recombinant hyaluronidase and one of 10% Gammagard, is marketed as HyQvia® by Shire (Takeda). In clinical studies in immune-deficient patients, HyQvia was well-tolerated and efficacious.<sup>39,40</sup>

The area under the curve (AUC) of serum concentration versus time of a drug after a single intravenous infusion is defined as 100% bioavailability.<sup>41,42</sup> The bioavailability of the drug when given by any other route is generally lower, so this is not unexpected with subcutaneous versus IV administration of IgG, and it is also found

with monoclonal IgG antibodies and therapeutic fusion proteins containing its Fc domains.<sup>42</sup> In licensing studies of SCIG, the US FDA mandated determination of the bioavailability of SCIG as compared to IVIG and calculation of the dose adjustment which would be necessary to achieve an AUC with SCIG equal to that previously measured with IVIG in the same patients. Multiple studies and different lines of evidence demonstrated that the bioavailability of SCIG is about two-thirds of that of IVIG regardless of the preparations being compared.<sup>41</sup> Interestingly, and in close agreement with the results of the SCIG licensing trials, the results of pooled analyses including 500 subjects and 20 different IgG preparations show that the slopes of regression lines for IgG level versus monthly dose indicate an increment in the steady-state serum IgG level of 87 mg/dL for every 100 mg/kg increase in monthly SCIG dose compared to an increment of 121 mg/dL in the trough level of IgG for every 100 mg/kg increment in monthly IVIG dose, suggesting a bioavailability of 71.9%.<sup>43,44</sup> The decreased bioavailability may involve degradation in the tissues and/or local binding in the intercellular matrix but seems to be a general property of IgG. The European Medicines Agency does not require dose adjustment for SCIG as compared to IVIG, and analyses of large payor databases in the United States suggest that equivalent or even slightly lower total monthly doses of SCIG versus IVIG are actually given to PIDD patients.<sup>45</sup>

### **High-dose IVIG therapy for autoimmune and inflammatory diseases**

The initial dose of IVIG used for most autoimmune/inflammatory diseases is 2 g/kg given over 2–5 days, followed by maintenance doses of 1–2 g/kg every 3–4 weeks. This regimen is based on the serendipitous 1981 observation that five consecutive daily repetitions of the monthly dose of IVIG for immune deficiencies at that time (400 mg/kg) normalized the platelet counts in immune-deficient patients who also had immune thrombocytopenia.<sup>46,47</sup> Infusion of 2 g/kg of IVIG increases the serum IgG level greater than fourfold, from pretreatment means of 700–1060 mg/dL to peaks well over 3000 mg/dL,<sup>47</sup> and IgG levels as high as 5000–7000 mg/dL have been reported.<sup>48,49</sup> These extremely high levels may contribute to vaso-occlusive AEs due to hyperviscosity in some patients.<sup>48,49</sup> The distribution phase of the IVIG is not expected to be altered by the IgG level, but if serum levels are sufficient to saturate FcRn, the catabolic rate may be increased.

### **Drug interactions**

Standard polyclonal IVIG is not known to bind or influence the distribution or metabolism of small molecules, neither does conventional drug therapy alter the levels or metabolism of IgG. Although not formally studied, high-dose IVIG might be expected to increase the catabolism of IgG monoclonal antibodies and fusion proteins containing the Fc of IgG, due to saturation of FcRn,<sup>24,42</sup> as explained further in this chapter. IgG therapy, whether given by the IV or SC route, may decrease the antigenicity of live virus vaccines, such as measles, mumps, and rubella (MMR), and varicella, so it is recommended that a period of six months be allowed to elapse between the last IgG therapy and administration of any of these vaccines.<sup>50</sup> If a patient has not been immunized and has received IgG therapy more than one month before potential exposure to measles, mumps, rubella, or varicella viruses, passive immunization with IgG would be recommended.

## Adverse reactions to IVIG and SCIG

### Immediate reactions

Mild reactions to IVIG infusions are common, occurring in 15–20% of infusions and in 50% of patients at one time or another.<sup>35,36</sup> These AEs are mostly uncomfortable and/or unpleasant but rarely serious. Symptoms may include headache, nausea, musculoskeletal pain, and flushing and tachycardia. When severe, IVIG infusion reactions may resemble anaphylaxis, but they usually do not involve IgE and should be termed *anaphylactoid*.<sup>36</sup> A key difference between these anaphylactoid reactions that accompany IVIG infusions and true IgE-mediated anaphylaxis is that the former are usually associated with hypertension rather than hypotension. Furthermore, anaphylactoid IVIG reactions are often less severe with subsequent infusions rather than more severe as would be expected with true allergy. In most cases, symptoms during IVIG infusions can easily be managed by slowing or temporarily stopping the infusion until the symptoms subside and/or by prophylaxis or treatment with acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and/or antihistamines.<sup>35,36</sup> Some patients may require corticosteroids; and many patients are given NSAIDs or steroids prophylactically. Most AEs are related to the rate of infusion and can be avoided by beginning the infusion slowly (0.01 mL/kg/minute) and gradually increasing the rate stepwise as tolerated.

Patients who are naive to IVIG replacement have had interruptions in their therapy, and/or who are actively or chronically infected have an increased risk of infusion-related AEs.<sup>51</sup> This may be related, in part, to the formation of antigen–antibody complexes as the IgG is being given, and/or the rapid release of lipopolysaccharide or other components of pathogens already present in the recipient. The risk of these reactions can be reduced by making sure that patients are afebrile and that those with active infections are on antibiotics before giving an IVIG dose. The incidence of reactions may increase when patients already on therapy are given a different brand of IVIG,<sup>35,36</sup> so whenever this occurs, it is prudent to begin the infusion slowly and/or to premedicate the patient.<sup>51</sup>

True anaphylaxis may occur in patients receiving IVIG, particularly in those who are deficient in IgA but still have the capacity to produce IgE. This occurs very rarely, but may be life threatening, and can be avoided by slow administration of low-IgA products<sup>35,36</sup> and/or by administering the IgG subcutaneously.<sup>52</sup>

Systemic reactions to SCIG infusions are rare. Gardulf *et al.* reported only 30 systemic reactions in 25 immunodeficient patients given 3232 infusions (0.93%).<sup>53</sup> A subsequent review, which included additional studies totaling over 40,000 infusions, showed that only one study reported a rate of systemic AEs >1%.<sup>27</sup> Although nearly 75% of patients may have some local discomfort associated with swelling and redness at the site of the infusions, the local symptoms usually subside within 24–48 hours and do not usually deter patients from continuing with their SCIG regimen. Because of the infrequency of systemic side effects with SCIG, premedication is rarely necessary, and close monitoring is not required during the infusion. SCIG has thus emerged as an ideal route for home use in many patients.<sup>38,53,54</sup>

The increasing use of IVIG, particularly with high doses for inflammatory and autoimmune diseases, has resulted in other serious adverse events, including thromboembolism, renal dysfunction/failure, aseptic meningitis, and hemolytic anemia.<sup>35,36,55–57</sup> This has led to the requirement (in the United States) that all IVIG products contain a “Black Box” warning about the risks of thromboembolic events (TEEs) and acute renal dysfunction/failure, as well as

“Warnings and Precautions” about hemolytic anemia, aseptic meningitis syndrome, and transfusion-associated acute lung injury (TRALI).<sup>56</sup> Most reports of acute renal failure or dysfunction were due to osmotic nephrosis related to the former use of sucrose as a stabilizer in certain products.<sup>57</sup> The risk of aseptic meningitis seems to be highest in patients receiving high-dose IVIG for neurologic diseases, and TRALI seems very rare.<sup>55,56</sup> The only “Black Box” warning on subcutaneous IgG products marketed in the United States is about the risk of thrombosis. Other potentially severe adverse effects are described in “Warnings and Precautions.” Especially in patients with other risks for thromboembolic events or hyperviscosity, adequate hydration should be ensured before administering IgG by any route, and the minimum dose and infusion rate practicable should be used.

### Thromboembolic events (TEEs)

Determining the true rates of TEEs and hemolytic incidents are difficult because the FDA and manufacturers’ pharmacovigilance efforts rely on voluntary efforts of patients/providers and because there are little data with which to calculate a denominator such as the numbers of doses given or patients treated. Hyperviscosity due to high-dose IVIG and slow blood flow in critical vascular beds may contribute to TEEs in some patients; and endothelial cell and/or platelet activation also likely play a role. There are multiple reports of myocardial infarction, transient cerebral ischemic attacks, and strokes related to high-dose IVIG therapy.<sup>56</sup> Best estimates suggest a baseline incidence of 0.16–0.6 TEEs for every million grams of IVIG sold.<sup>56,58,59</sup> Considering 50 g as a median adult dose, these rates represent roughly 0.8–3 cases per 100,000 doses. In a particularly well-investigated episode, TEEs were reported in nine patients involving seven different lots of a single product.<sup>58</sup>

Subtle changes in the procedure used to fractionate the plasma and produce that product, including the use of affinity resins to isolate certain clotting system proteins, apparently increased contact activation of factor XI, which had copurified with the IgG during the initial ethanol precipitation.<sup>55</sup> Because the total factor XI plus XIa was still within acceptable limits by the assays in use at that time, the affected product was within specifications. Only newer thrombin-generation assays have sufficient sensitivity to detect activated FXIa. Factor XI and kallikrein are difficult to separate from IgG because their isoelectric points are similar to IgG’s, and they coprecipitate during ethanol precipitation.<sup>10</sup> On the one hand, the results suggest that contamination of one or two individual lots was not responsible for the increase in factor XIa because many lots were affected. On the other hand, even with the affected lots, TEEs were extremely rare, suggesting that multiple risk factors in the individual affected patients also contributed.

Better chromatographic purification methods, and the use of specific immunoadsorbents to remove FXI/FXIa from products that are made by multiple precipitations without ion-exchange chromatography, should decrease the risk of factor-XIa-related AEs. Furthermore, the use of thrombin-generation assays should ensure the absence of procoagulant activity in current and future IgG products.

### Hemolytic reactions

An analogous problem is the presence of antibodies to erythrocytes (isoagglutinins), resulting in positive Coombs’ tests, occasional cases of clinically significant hemolytic anemia, and extremely rare

episodes of acute severe intravascular hemolysis.<sup>59,60</sup> In the original Cohn-Oncley fractionation scheme, isoagglutinins, which have higher isoelectric points than other IgGs, were greatly reduced by removing fraction III and continuing with fraction II alone.<sup>61</sup> Several current production schemes combine the fraction II and III precipitates as the starting material for IgG purification, and many manufacturers have substituted caprylic acid or fatty alcohols for the ethanol steps that removed more of the isoagglutinins, resulting in 2–4-fold increases in isoagglutinin titers in the final products.

As with TEEs, true rates of Coombs' positivity, hemolytic anemia, and acute severe hemolysis in relation to IVIG therapy are difficult to estimate. However, risk factors for clinically significant hemolytic episodes include non-O blood group, underlying associated inflammatory states, and high cumulative doses of IVIG over several days. Some studies of high-dose IVIG therapy report that as many as 20% of patients may convert to Coombs' positivity shortly after infusions, but the incidence of clinically significant anemia or acute severe hemolysis is significantly lower than that.<sup>36,55,56</sup> Analysis of US and Canadian series reported clinically significant hemolysis after IVIG in a combined total of 37 patients, including 23 patients with blood type A, 9 with type B, 4 with type AB, and only 1 with type O.<sup>59,60</sup>

Prescreening of donors to avoid using plasma units with high isoagglutinin titers in the pools from which the IVIG is prepared,<sup>62</sup> and/or the use of specific immunoabsorbents<sup>63</sup> to lower the titers of Anti-A and Anti-B, is used by some manufacturers to decrease this problem.

### Mechanisms of action of IVIG

IgG has both Fc-dependent and Fc-independent mechanisms that contribute to defense against infection<sup>64–66</sup> (Table 31.1). Fc-independent functions include neutralization of toxins, which are important virulence factors in several types of bacterial infection, agglutination and/or precipitation of infectious organisms, and neutralization of adhesion and attachment molecules. Similarly, neutralization of superantigens or toxins may explain the effects of IVIG in Kawasaki Disease and toxic shock syndromes. Fc-dependent functions include activating complement, facilitating phagocytosis (both locally at sites of tissue invasion and in bloodstream clearance by macrophages in the reticuloendothelial organs), and enhancing direct cell-mediated cytotoxicity. In general, all of these mechanisms involve stoichiometric interactions between the IgG and antigens and/or effector molecules such as C1q and Fcγ receptors. Therefore, it is not surprising that most studies comparing the efficacy of different doses of IgG replacement therapy in immune-deficient patients show fewer infections in groups that received higher doses. Pooled data from licensing studies of IVIG and SCIG clearly show that the incidence of pneumonia and other infections decreases as serum IgG levels increase.<sup>43,44</sup>

A broad array of mechanisms of action of IVIG of potential relevance to the use of high-dose therapy have been demonstrated in vitro and in animal models.<sup>64–66</sup> However, it is rarely clear which effects are most important in any given disease *in vivo*, partly because the pathogeneses of most autoimmune or inflammatory diseases are incompletely understood. Therefore, it is difficult to know whether any given effect demonstrated in vitro or in a model is really relevant in the diseased patient *per se*. One useful way to categorize mechanisms of action in these diseases is by considering whether they are likely to involve direct competition between normal molecules in therapeutic IgG and pathogenic autoantibodies.<sup>66</sup>

Clues suggesting that competitive effects are likely include strong dependency on the dose of therapeutic IgG or the amount of therapeutic IgG in the circulation at any point in time, “wearing off” of the IVIG effect as its concentration wanes, and efficacy of plasmapheresis or immunoadsorption as an effective alternative way of removing pathologic antibodies. Several mechanisms of this type are detailed below. In contrast, true “immunomodulatory effects” on the underlying disease process may be indirect, with more complex pharmacodynamics and dose-response characteristics. The effect of IVIG on the autoantibody concentration without modifying the underlying autoimmune diathesis is illustrated by a study in myasthenia gravis patients which showed that high-dose IVIG temporarily reduced the titer and ameliorated the effects of antiacetyl choline receptor antibodies but did not decrease their production and did not exert a “disease modifying effect” on the underlying immunopathogenesis.<sup>67</sup>

### Anti-idiotypic binding

Because each individual's immune repertoire arises randomly, it is readily understandable that some individuals respond to a given pathogen with antibodies that crossreact with self-antigens (e.g., *Campylobacter jejuni* and myelin gangliosides in Guillain–Barré syndrome [GBS]), whereas other individuals recognize different epitopes. Furthermore, it is easy to speculate that individuals who mount rigorous anti-id responses will rapidly bring a self-reactive response under control, whereas those whose anti-id response is weak or ineffective may continue to produce clinically significant amounts of autoantibodies.<sup>68</sup> Because IVIG contains the antibodies from tens of thousands of healthy donors, it follows that it likely contains many different anti-ids.

Shortly after its introduction, IVIG was found to neutralize “inhibitors” of the clotting protein factor VIII in hemophilia patients receiving replacement therapy.<sup>69</sup> These “inhibitors” are in fact antibodies against factor VIII (FVIII). Furthermore, F(ab') fragments of the IVIG neutralized the inhibitors, suggesting anti-id binding. Subsequent studies have shown that IVIG contains a wide variety of anti-ids,<sup>66</sup> consistent with Jerne's network theory of anti-id suppression of potential autoimmunity,<sup>8</sup> and suggest that this is actually quite common in normal physiology. The most important support for an anti-id mechanism of IVIG *in vivo* would be the observations that F(ab') or F(ab')<sub>2</sub> fragments from IVIG neutralize the autoantibody *in vitro* and/or can remove it by affinity chromatography, that the removal of the autoantibodies by plasmapheresis has a similar effect, and that autoantibodies recovered from patients reproduce the disease physiology *in vitro* or in animals and can be blocked by the therapeutic IgG preparation.

### FcRn saturation increases catabolism of endogenous antibodies

As noted above, FcRn on endothelial cells maintains the relatively high normal concentration and long half-life of IgG in the circulation.<sup>22–24,70</sup> In FcRn knockout mice and in patients with FcRn mutations, the half-life of IgG is very short, and its plasma concentration is quite low.<sup>71,72</sup> Furthermore, it is difficult to passively transfer IgG-mediated pathology into FcRn knockout mice because the half-life of the pathologic IgG is so short.<sup>72</sup> By analogy, if FcRn is saturated by high doses of *exogenous* IVIG, the catabolism of *endogenous* pathologic IgG is greatly increased. In wild-type mice, high-dose IgG dramatically increases the catabolism of pathogenic IgG, whereas, in FcRn knockout mice, high-dose IgG does not further enhance the already rapid catabolism of the exogenous pathologic IgG.<sup>24,72</sup>

Thus, by saturating FcRn with normal antibodies, IVIG increases the degradation of pathogenic IgG. This therapeutic effect of IVIG therefore requires that the total IgG concentration exceeds the binding capacity of FcRn and depends on the ratio of the serum concentration of normal IgG to the concentration of pathogenic autoantibodies. Targeting FcRn with engineered Fc fragments of IgG, monoclonal antibodies against its binding site, and other biologicals has been successful in clinical trials in myasthenia gravis, ITP, and other IgG-mediated autoimmune diseases.<sup>73,74</sup> Continued development of these agents should further define the role of FcRn in the mechanism of action of IgG therapy in autoimmune/inflammatory diseases and may actually reduce the use of plasma-derived IgG for this purpose.

### Complement scavenging

Complement components C4 and C3 contain a unique internal thioester bond that can transfer to the target during complement activation, forming a covalent bond.<sup>75</sup> Covalent binding of C4b and/or C3b increases the stability of convertases and the likelihood that the initial activation will be amplified. The C<sub>H</sub>1 domain in IgG has particularly good acceptors for this reaction, and high concentrations of soluble IgG can compete with surface-bound IgG for newly activated C3b. Inhibition of complement deposition by IVIG at concentrations readily achieved during high-dose therapy has been demonstrated in vitro and in animal models, and in humans being treated for dermatomyositis.<sup>76</sup> Clinical improvement following IVIG treatment in that condition is accompanied by decreased activation of C3 and decreased deposition of C3b and C5–9 on endomysial capillaries.<sup>76</sup> Basta *et al.* also showed that IgG could bind C3a and C5a noncovalently, thereby diminishing proinflammatory effects of complement activation.<sup>77</sup>

### Indirect actions of IVIG that do not involve competition per se

Many reviews of “the” mechanism of action of IVIG focus on laboratory data showing putative immunomodulatory effects involving networks of T cells, B cells, and cytokines.<sup>78–80</sup> However, consensus reports on uses of IgG suggest efficacy mainly in antibody-mediated diseases rather than in T-cell-mediated conditions like atopic dermatitis, graft vs. host disease, or cell-mediated allograft rejection.<sup>1</sup> Furthermore, many of these “immunomodulatory” effects of IVIG have prolonged time courses and are therefore not likely to be responsible for therapeutic effects that “wear off” before a dose of IVIG has reached its half-life.<sup>64–66,78</sup> Analysis of the pharmacodynamics of IgG therapy in any given disease may thus shed light on the mechanism by which the therapeutic IgG is acting and also on the immunopathogenesis of the disease.<sup>66</sup>

IVIG can interfere with maturation of dendritic cells in vitro and can inhibit expression of HLA-antigen complexes and the costimulatory molecules CD80 and CD86.<sup>64,79,80</sup> It certainly seems possible that decreasing or altering dendritic cell activity would decrease antigen presentation and alter the pattern of cytokine production, modulating the stimulation of different T-cell activities by the dendritic cells. IVIG can decrease the production of proinflammatory cytokines such as interleukin-1 (IL1), IL12, and interferon- $\gamma$ , and increase the production of regulatory molecules such as IL10 and IL1 RA.<sup>64,81</sup> In this way, IVIG could alter the balance between regulatory (CD25+) and effector (CD4+ or CD8+) T cells<sup>81</sup> and could also decrease the inflammatory activity of macrophages. However, when the pathology involves direct effects of antibodies and/or complement on target tissues, it is not clear that modulating T-cells

or macrophages results in significant beneficial effects. One report showed that IVIG decreased a B-cell-activating cytokine that was elevated in sera from chronic idiopathic demyelinating polyneuropathy (CIDP) patients, but the clinical correlation was poor, the time course of changes in cytokine levels was not reported, and the role of that cytokine (and autoantibodies, for that matter) in CIDP was not clear.<sup>82</sup> Reports that IVIG decreases the number of circulating “natural killer” (NK) cells; their expression of the low affinity Fc receptor (CD16) and their cytotoxic activity more likely represent in vitro blockade of CD16 than a genuine physiologic downregulation;<sup>83</sup> and the role(s) played by NK or other cells that can mediate antibody-dependent cellular cytotoxicity has not been established in the diverse autoimmune diseases for which IVIG is used.

Putative effects of IVIG in ameliorating autoimmune disease by modulating programmed cell death have been proposed, but remain controversial. Some studies suggest that anti-Fas antibodies in IVIG induce apoptosis in B cells.<sup>84</sup> However, other results suggesting that IVIG has limited or only transient effects on autoantibody production (or alloantibody, in the case of transplant rejection) would not be consistent with induction of apoptosis as a major mechanism by which IVIG acts in autoimmune disease. Because the level of Fas expression and the sensitivity of cells to proapoptotic signals vary with the degree of activation and physiologic state of the cells in question, it is not difficult to see how different results could be obtained in different experimental systems. Further compounding the issues are observations suggesting not only that IVIG preparations may contain antibodies against Fas and another important family of proteins that regulate cell death called *Siglecs*, but also that dimers in IVIG preparations may contain anti-idiotypic antibodies that can complex with and neutralize these autoantibodies.<sup>85</sup> Thus, a number of factors such as low-pH treatment during preparation and storage (which tends to dissociate dimers), stabilizers, and the percentage of dimers in any IgG preparation may also influence the results of laboratory studies, and perhaps the results with different preparations *in vivo*.

Research in animal models has focused on increased expression of the inhibitory receptor FcRIIB as a mechanism of action of a small subset of molecules in IVIG that have fully sialylated carbohydrate side chains.<sup>86,87</sup> These heavily sialylated IgG molecules putatively bind to a distinct receptor termed DC-SIGN, inducing the cytokine IL32, which increases FcRIIB expression and inhibits the activity of inflammatory macrophages.<sup>86</sup> This mechanism could potentially explain why high doses of IVIG are necessary for anti-inflammatory effects because only a small percentage of the IgG molecules are fully sialylated. Although a mouse model showed that merely 33 mg/kg of a highly sialylated Fc analog could replicate the effects of 1 g/kg of standard IVIG,<sup>87</sup> these effects appear to depend on the mouse strain and model used.<sup>88,89</sup> Thus, their relevance to therapy of human diseases is not clear.

### Dosing and scheduling IgG treatment regimens

#### Primary immune deficiencies

Antibody replacement therapy in immune deficiencies is typically initiated at doses of 400–600 mg/kg of IVIG every 3–4 weeks or 100–200 mg/kg/week subcutaneously. Doses in this range usually yield trough (in the case of IVIG) or steady-state (in the case of SCIG) serum IgG levels toward the low end of the normal range and

are quite effective in preventing sepsis or other serious bacterial infections.<sup>43,44</sup> However, based on results of clinical observations and a few controlled studies,<sup>90,91</sup> patients with chronic lung and/or sinus disease, and those suffering frequent breakthrough infections, are usually given higher doses. Several lines of evidence suggest that the resistance to acute infections is directly related to the serum (and tissue) IgG level at any point in time.<sup>43,44</sup> Analyses of large pooled data sets suggest that patients receiving IVIG every four weeks are more likely to experience infections and hospitalizations in the last week of their dosing cycle,<sup>92,93</sup> before their next dose is due. In a survey performed by the US Immune Deficiency Foundation before the use of SCIG was common, two-thirds of respondents indicated that they could feel their IVIG “wearing off” before the next dose was due.<sup>94</sup> Smoothing out of the “peaks” and “troughs” of every 3–4 weekly IVIG regimens is likely one reason why many patients prefer subcutaneous regimens in which frequent dosing achieves steady-state IgG levels. Combined studies of 88 Italian patients showed that the steady-state serum IgG level was proportional to the total monthly dose of SCIG per kg body weight regardless of the BMI.<sup>95</sup> A small case series illustrated that different patients require different “biologic IgG trough levels” to remain infection free,<sup>96</sup> and results from a cohort of 90 patients with primary antibody deficiency followed at a single center in the UK for over 20 years showed that the range of IgG doses needed to keep individual patients free from breakthrough infections varied widely: from 0.2 to 1.2 g/kg/month, resulting in trough serum IgG levels varying from 500 to 1700 mg/dL (5–17 g/L).<sup>97</sup> Thus, although guidelines can be used to recommend starting doses in previously untreated patients, dose, dosing interval, and route of administration should be individualized based on the clinical results for each patient.<sup>37,96,97</sup>

### **Secondary immune deficiencies (SID)**

A growing armamentarium of immunotherapies and other agents, such as kinase inhibitors, proteosome inhibitors, and antimetabolites that target B-cells, plasma cells, and malignancies derived from these lineages, is being used not only for hematologic malignancies but also for autoimmune diseases and antibody-mediated transplant rejection.<sup>98–100</sup> In addition to rituximab (anti-CD-20), newer antibodies against CD-20, and antibodies against CD-19, CD-22, B-cell maturation antigen, and CD-38, have completed late-stage clinical trials and/or have recently been approved. These antibodies, as well as alemtuzumab and some antilymphocyte globulins, and anti-CD19 chimeric antigen receptor (CAR-) T-cells deplete B-cells and/or plasma cells and may lead directly to secondary antibody deficiency (SAD) and/or frank hypogammaglobulinemia.<sup>101,102</sup> Other agents, such as cytokine and costimulation blockers, antimetabolites (especially fludarabine), and inhibitors of Bruton’s tyrosine kinase (the enzyme whose mutations cause X-linked agammaglobulinemia), other intracellular signaling inhibitors, and proteosome inhibitors such as bortezomib, alone or in combination, may also contribute to clinically significant antibody deficiency.<sup>99–101</sup> With increased efficacy of targeted therapies, and advances in supportive care, the survival of patients with hematologic malignancies and those with solid organ transplants is improving. Infection is a major cause of morbidity and mortality in these patients, and SIDs are likely major contributors.

Because of the heterogeneity of underlying conditions and complications of therapy for the primary diseases, there have been few large randomized controlled trials of IgG replacement in patients

with SID. Nevertheless, reviews in the United States,<sup>101,102</sup> a consensus study in the EU,<sup>103</sup> and the EMA core SmPC for IVIG<sup>2</sup> all suggest similar algorithms and criteria for considering IgG replacement in these patients for SID: 1). occurrence of severe or recurrent infections, especially if unresponsive to antimicrobial therapy, and 2). failure to mount at least a twofold increase in specific antibody titer in response to immunization, or frank hypogammaglobulinemia (serum IgG < 400 mg/dL [4 g/L]).

As with primary immune deficiencies, starting doses should be in the range of 400–600 mg/kg every 3–4 weeks for IVIG and 100–200 mg/kg/week for SCIG. Monitoring of the patient’s IgG infection status and IgG levels should actually begin at the time of diagnosis of the primary disease since many patients with chronic lymphocytic leukemia, other B-lineage malignancies, and/or autoimmune disease may actually have hypogammaglobulinemia or antibody deficiency even before beginning treatment. IgG dose adjustments and duration of therapy should be based on the individual patient’s clinical response.

### **Acute autoimmune or inflammatory diseases**

In contrast to immune deficiencies, in which the frequency of infection can be used to monitor and individualize IgG treatment, there are few such metrics available for guiding therapy in most acute inflammatory or autoimmune diseases treated with IVIG, so the regimen of 2 g of IVIG per kg is usually used. The core SmPC for IVIG in the EU includes class labeling for ITP, Guillain–Barré syndrome (GBS), multifocal motor neuropathy (MMN), chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), secondary immunodeficiencies, and Kawasaki disease.<sup>2</sup> In contrast, GBS, and secondary immune deficiencies are not FDA-approved indications for IVIg in the United States, even though IVIG is considered “standard of care” for these conditions. In the United States, labeling for CIDP and MMN has been granted only to those individual products for which efficacy has been demonstrated. One brand each is labelled for Kawasaki disease and Dermatomyositis in adults.

*Kawasaki disease* is an acute, severe, and potentially fatal inflammatory vasculitis syndrome of uncertain etiology that is most common in young children.<sup>104</sup> IVIG is the major treatment used, and a meta-analysis of studies in which different doses of IVIG were coadministered with aspirin showed a correlation between the dose of IVIG and its efficacy in preventing coronary artery aneurysms, which occurred in only 3.8% of patients who received the highest dose studied: 2 g/kg.<sup>105</sup> Furthermore, a randomized trial in 549 subjects<sup>106</sup> and the meta-analysis cited above both reported that administering the IVIG as a single infusion over 8–12 hours led to more rapid resolution of symptoms and was more effective than giving it as five consecutive daily doses of 400 mg each. Thus, the commonly used first-line treatment for Kawasaki disease is 2 g/kg of IVIG given as a single large bolus over 8–12 hours. The observation that more rapid administration of the large infusion increases its efficacy suggests that the peak IgG level achieved—rather than the total dose, AUC, or trough level—may be the most important determinant of efficacy in this particular situation. This conclusion, in turn, is consistent with the hypothesis that the target of IVIG in Kawasaki syndrome is intravascular per se, perhaps blocking the effects of a superantigen or toxin on endothelial cells and/or circulating leukocytes.

*Guillain–Barré syndrome* (GBS) is an acute autoimmune polyneuropathy causing flaccid paralysis that frequently follows resolution of an infectious disease, most notably gastroenteritis due to *C. jejuni*.<sup>107</sup> The leading hypothesis for the pathogenesis of GBS is

that antibodies produced by the host's immune system in response to the lipo-oligosaccharide of the infectious agent crossreact with ganglioside antigens on the patient's myelin, activating complement and causing dysfunction and demyelination of peripheral nerves.<sup>107,108</sup> As such, GBS is frequently cited as a leading example of the *molecular mimicry* theory of autoimmune disease. Although GBS is generally considered an acute, monophasic disease, as many as 5% of patients succumb during the acute episode, and up to 20% may have slow recovery and/or prolonged disability.<sup>107-110</sup> First-line treatments for GBS include high-dose IVIG and/or plasma exchange. Laboratory evidence supports hypotheses that IVIG acts predominantly by blocking the binding of autoantibodies to the nerves, presumably due to the presence of anti-idiotypes, and/or by blocking complement deposition.<sup>66,109,111,112</sup> It is likely that plasmapheresis also acts primarily by removing autoantibodies. However, different antibodies targeting different epitopes may be involved in different patients and different clinical variants, and neither measurements of autoantibodies nor in vitro determinations of the ability of IVIG to neutralize them are used to select or adjust the dose or schedule of IVIG treatment. Practice parameters of the American Academy of Neurology consider plasma exchange and IVIG equally effective first-line treatments.<sup>113</sup> A *Cochrane Review* reached the same conclusion but noted that the full course of IVIG treatments was more likely to be completed than the series of plasma exchanges, and that there was little additional benefit of combining the two modalities.<sup>114</sup> The most common dose of IVIG is 2 g/kg, usually given over 2–5 days. One study of 39 subjects suggested that six days of 0.4 g/kg (total dose = 2.4 g/kg) was preferable to three days of 0.4 g/kg (total dose = 1.2 g/kg) in terms of the number of days until subjects could walk with assistance, but the difference did not reach significance except in a smaller subgroup.<sup>115</sup> Although serum IgG levels achieved by patients receiving 0.4 g/kg/day for five days were quite variable, patients with the highest increments in IgG level from baseline to day 14 showed the best response in terms of the percentage able to walk unaided six months after the acute episode and vice versa.<sup>116</sup>

These results suggest that caution should be taken when the maximum dose of IVIG is limited to a preset total number of grams, or in which dosing is based on lean or ideal body mass rather than actual body mass. Such rules may result in underdosing some GBS patients, and the efficacy of lower doses in this acute situation has not been established. The International GBS Outcomes Study (IGOS) is being carried out to determine how to identify patients at high risk of death or long-term disability and who might benefit from more rigorous treatment.

*Immune thrombocytopenic purpura* (ITP), as noted in this chapter, was the first condition in which beneficial effects of IVIG in an autoimmune disease were reported (in ITP, autoantibodies mediate destruction of the patient's own platelets). ITP patients may suffer or be at risk for clinically important bleeding episodes, including acute severe blood loss and intracerebral hemorrhage. Corticosteroid therapy is frequently sufficient to increase the platelet count enough to control symptoms such as nosebleeds and menorrhagia. However, when more severe and/or acute bleeding requires a faster increase in the platelet count, IVIG is often used at a dose of 1–2 g/kg given over several consecutive days.<sup>117,118</sup> This increases the platelet count to >50,000 within seven days of beginning a course of therapy in >80% of patients. IVIG may also be used preoperatively to raise the platelet count and decrease the risk of bleeding in ITP patients who require urgent surgery. In patients with Rh<sup>+</sup> red cells, anti-Rh(D) immune globulin (Rhophylac<sup>®</sup> and WinRho<sup>®</sup>SDF) may be used as

an alternative to IVIG, obviating many of the potential adverse effects of high-dose IVIG.<sup>119</sup> The Rh(D) immune globulin is believed to act by creating immune complexes with the recipient's red cells, which then saturate phagocytic receptors in the reticuloendothelial organs, sparing the platelets. This, in turn, is associated with some destruction of the antibody-coated red cells, but the resulting hemolysis is rarely clinically significant. IVIG is repeated at monthly intervals in some patients with chronic ITP, but many such individuals are managed with corticosteroids, splenectomy, rituximab, and/or thrombopoietin receptor agonists.

IVIG may be expected to have effects in autoimmune neutropenia, autoimmune hemolytic anemia, and alloimmune thrombocytopenia (sensitization of baby's platelets with maternal IgG transferred across the placenta) similar to those in ITP, but these disorders are less common than ITP. Furthermore, if IVIG is used, it would frequently be given together with corticosteroids, with which it should have synergistic effects. High-dose IVIG is used as a treatment for pure red cell aplasia secondary to parvovirus B19 infection.<sup>120</sup> In that situation, the IVIG likely helps the host control the infection.

### Chronic autoimmune or inflammatory diseases

*Chronic inflammatory demyelinating polyneuropathy*: In many ways, CIDP resembles a chronic form of GBS.<sup>121,122</sup> CIDP differs in that few patients recall preceding infections or other triggering events. CIDP is considered by many to be an autoantibody-mediated disease, and plasma exchange is very effective. However, unlike the putative role of antiganglioside antibodies in GBS, no single major target antigen(s) has been identified in CIDP.<sup>66,120-122</sup> Based upon results of a randomized, placebo-controlled trial of IVIG in 117 CIDP patients (the ICE study), the FDA approved IVIG for CIDP using a loading dose of 2 g/kg followed by maintenance dosing of 1 g/kg every three weeks.<sup>123</sup> In many CIDP patients, the effects of IVIG are transient, suggesting a mechanism of action involving competition with autoantibodies rather than inhibition of their production. End of dosing-interval "wear-off" effects are common with every 3–4 week IV treatment regimens,<sup>66</sup> and doses and intervals other than those used in the ICE trial are prevalent.<sup>124-126</sup> A prospective study reported that 60% of CIDP patients required IVIG more often than once every two weeks to maintain optimal strength.<sup>126</sup> A large, randomized, controlled multicenter study showed that SCIG was also effective in CIDP at doses of 0.2 g/kg/week and 0.4 g/kg/week,<sup>127</sup> and this efficacy was confirmed in a 48-week open-label follow-up study.<sup>128</sup> Hizentra<sup>®</sup>, the 20% SCIG which was used in that study, is labeled for use in CIDP in the United States. Anecdotal reports and small series suggest that continuously maintaining high serum IgG levels by the use of SCIG may result in more stable maintenance of strength, and guidelines and study results suggest that long-term dosing should be individualized for each patient.<sup>125,129</sup>

*Multifocal motor neuropathy (MMN)*: MMN is characterized by multiple motor nerve conduction blocks with sparing of sensory nerves.<sup>130,131</sup> The electrophysiology is consistent with segmental demyelination, but several studies suggest immunologic target(s) on axons rather than, or in addition to, Schwann cells or myelin. Unlike GBS and CIDP, corticosteroids and plasma exchange are usually not effective in MMN,<sup>132,133</sup> raising questions about its immunopathogenesis. About half of MMN patients have IgM antibodies against the ganglioside GM1, and these seropositive patients tend to have more severe weakness, disability, and eventual axon loss than seronegative patients.<sup>134</sup> Efficacy of IVIG was demonstrated

in multiple anecdotal and case series reports in the mid-1990s. Small controlled studies soon followed, and the results of a 44-subject, randomized, double-blinded, placebo-controlled crossover trial were reported by Hahn *et al.* in 2013, and led to labeling of Gammagard® in the United States for improving muscle strength and decreasing disability.<sup>135</sup> The mean maximal grip strength declined 31% during placebo treatment and increased 3.75% during IVIG treatment ( $p = 0.005$ ).<sup>121</sup> IVIG has also been recommended as first-line treatment by a European Federation of Neurological Sciences/Peripheral Nerve Society task force,<sup>136,137</sup> and it is usually given in doses of 1–2 g/kg every 3–4 weeks. Interestingly, even early reports noted that improvement in strength and conduction began within a few days after the IVIG, but lasted only 1–2 months, at best.<sup>138–140</sup> As with CIDP, many patients complain that their strength deteriorates in the third or fourth week after an IVIG dose. Small case series suggest that SCIG may help to ameliorate these “wear-off effects” and promote more constant activity, but long-term follow-up studies of SCIG are needed to determine if this will prevent the eventual deterioration that now characterizes most MMN patients.

**Autoimmune mucocutaneous bullous (blistering) diseases:** Autoimmune mucocutaneous bullous (blistering) diseases are a family of conditions including multiple subtypes of pemphigus and pemphigoid in which the separation of intraepidermal or subepidermal layers of skin occurs because of antibodies against intercellular adhesion molecules such as desmoglein.<sup>141</sup> Most of these disorders have relapsing-remitting courses, and subtypes are characterized by differences in the locations and depth of the blisters, which in turn are probably related to differences in the specific targets of the autoantibodies. In general, corticosteroids are first-line therapies, and most patients are also given cytotoxic drugs such as cyclophosphamide or azathioprine. “High-dose” IVIG is often added as an alternative or addition to steroids in patients who develop complications of steroid treatment and is regarded as a “steroid-sparing” therapy.<sup>141–143</sup> IVIG may also be preferentially used in patients with poor tolerance of cytotoxic agents. A major effect of IVIG seems to be reduction of autoantibody titer, although this has been reported to take several months,<sup>142</sup> so it is not clear whether the mechanism is competitive or mediated by other pathways. In cases of severe mucosal and/or ocular involvement, high-dose IVIG may be used to achieve a more rapid remission of acute attacks or exacerbations.

### IgG in transplantation

IgG therapy has three main uses in solid organ transplantation. High-dose IVIG is employed along with plasmapheresis and rituximab in regimens designed to “desensitize” or remove preformed anti-HLA antibodies (“panel reactive antibodies” [PRA]) before transplantation in patients who have developed these antibodies in response to exposure to alloantigens in a previous transplant and/or in the fetuses of multiparous women.<sup>144</sup> In this situation, the IVIG is likely acting by anti-idiotype blocking, exchanging with endogenous IgG in the extravascular spaces, so the latter can be removed by plasmapheresis, and/or saturating FcRn to increase the catabolism of the endogenous anti-HLA antibodies. Particularly with kidney transplant patients, caution must be taken in selecting the IVIG product and scheduling the infusions to avoid adverse effects due to isoagglutinins or sucrose. The newer IVIG preparations with non-sugar stabilizers and those with reduced isoagglutinin content should ameliorate these concerns. The second major use also involves high-dose IVIG, which is used to treat acute antibody-

mediated rejection.<sup>145</sup> In this situation, part of the effect of the IVIG is undoubtedly to neutralize and/or accelerate the catabolism of the antibodies against the graft that are causing the rejection. However, immunomodulatory and inflammatory activities, including inhibiting complement, blocking Fc receptors, and altering the cytokine milieu, are also likely important. Many recipients of solid organ transplants become at least transiently hypogammaglobulinemic as a result of their immunosuppressive regimen, because of GI losses in visceral transplants<sup>146</sup> and/or because of preexisting hypogammaglobulinemia or specific antibody deficiency that may have been undiagnosed before the transplant (particularly in lung transplant recipients).<sup>147</sup> Such patients may benefit from antibody replacement, which may be given by the IV or subcutaneous routes, using regimens like those used for patients with primary antibody deficiency. Formerly, cytomegalovirus (CMV) hyperimmune globulin was used prophylactically after transplants, especially in antibody-negative recipients of organs from CMV+ donors (so-called D+/R– transplants). This has become much less common in the current era in which antiviral chemotherapy with gancyclovir and valgancyclovir is available, but it may still be used in patients who do not tolerate those agents and/or who develop active CMV disease.

In recipients of hematopoietic stem cell transplantations (HSCTs) for severe combined immune deficiency (SCID), particularly the X-linked form due to mutations in the cytokine receptor common  $\gamma$  chain, B-cell reconstitution frequently occurs much slower than hematopoietic and T-cell reconstitution.<sup>148</sup> Most SCID patients are given IgG replacement for at least a year after transplantation, and some require it for life.

Based on the results of a large, randomized, double-blind, placebo controlled study in France,<sup>149</sup> an independent meta-analysis in Canada,<sup>150</sup> and a *Cochrane Database Review*,<sup>151</sup> IVIG is not recommended for routine prophylaxis of infection after allogeneic HSCT, and has not been shown to be effective for prophylaxis or the treatment of graft vs. host disease.<sup>101</sup> However, in some malignant lymphoproliferative diseases, especially when rituximab is used in combination with conventional chemotherapy (e.g., cyclophosphamide, hydroxydaunorubicin, oncovin, and prednisone or prednisolone [CHOP]) or fludarabine, and in some cases in which rituximab is used (with or without cytotoxic agents) for nonmalignant antibody-mediated disorders, prolonged depletion of circulating B cells and significant hypogammaglobulinemia may occur, resulting in severe and/or recurrent infections. This is also likely in patients receiving CAR-T cells targeting CD19 or other B-cell lineage antigens. Such patients should be evaluated for IgG and/or specific antibody deficiency, and IgG replacement therapy using regimens similar to those used for primary immune deficiency should be considered.<sup>101,103,151,152</sup>

### Hyperimmune globulins

Hyperimmune globulins are made from plasma obtained from normal subjects with high titers of antibodies to the desired microbe or antigen detected by screening or because they are convalescing or have been repeatedly immunized.<sup>142,143</sup> Plasma is processed as for regular (IM) ISG or IVIG, and the final product is tested to ensure an adequate antibody titer to the microbe or other antigen. In general, hyperimmunes contain about fivefold higher titers of specific antibodies to the microbe or antigen for which they are labeled than standard IVIG preparations (on the basis of a unit of specific antibody per gram of IgG).<sup>153,154</sup> Thus, to get the same amount of specific antibody, fivefold higher doses of standard IVIG would have to

be given, constituting an extremely high dose of the latter. For example, to get the recommended amount of specific IgG for protection against respiratory syncytial virus required 750 mg/kg of the hyperimmune RespiGam® but would require 3750 mg/kg of “standard” IVIG. To put this in a current perspective, the same amount of specific IgG is contained in 15 mg/kg of the monoclonal anti-RSV antibody palivizumab (Synagis®), which can be given as a simple IM injection.<sup>143</sup> Other hyperimmunes target the Rh(D) red cell antigen (RhoGAM®, Rhophylac®, etc.) to prevent sensitization of Rh(D)-negative women to Rh(D)+ fetal erythrocytes and also for ITP in Rh(D)+ individuals. Hyperimmune globulins are also available for CMV (CytoGam® and Cytotect®), botulism toxins (Human Botulism Immune Globulin-IV® and Baby-BIG®), hepatitis B virus (BayHep B® and HyperHepB S/D®), rabies virus (HyperRAB® and Imogam-Rabies HT), tetanus (HyperTet-SD®), and varicella-zoster virus (VariZIG®). The same adverse effects may occur with IV hyperimmunes as with standard IgG preparations. However, the doses of IV hyperimmunes are generally lower than the high doses of IVIG used for immunomodulatory effects, and so are less likely to produce serious adverse effects unless they are administered too rapidly. Antivenoms used for spider and snake bites<sup>155</sup> and antithymocyte globulin used for immunosuppression (i.e., in transplant recipients) are usually animal antisera and may be associated with anaphylaxis and/or serum sickness.

## Summary

Given the diversity of the immune repertoire and the multiple interactions of its Fc domains with receptors and other effector systems, it is not really surprising that polyclonal IgG, pooled from tens of thousands of individuals, has a broad multiplicity of uses. Modern preparations are highly purified and contain stabilizers designed to prevent aggregate formation, and thus can be given intravenously or subcutaneously with relative freedom from

severe systemic adverse reactions. Caution and monitoring are still necessary as occasional serious and/or life-threatening AEs still occur, especially in individuals with identifiable risk factors. Doses in the range of 600–1000 mg/kg/month are generally used for replacement therapy for immune-deficient patients. This may be given in IV boluses every 3–4 weeks, or fractionated into smaller increments given by the subcutaneous route weekly or even more often. Although the former require venous access and are frequently monitored by trained medical personnel, the latter are frequently self-administered in the home, greatly facilitating the convenience of long-term IgG therapy and the quality of life for patients and their families. High-dose IVIG therapy (1–2 g/kg, usually every 2–4 weeks) is used for a growing number of autoimmune/inflammatory diseases, generally in clinical settings, and accounts for a continuously increasing global demand for IgG products.

# **Apheresis**

## CHAPTER 24

# Basic principles of apheresis and the collection of blood components by apheresis

Edwin A. Burgstaler & Jeffrey L. Winters

Therapeutic Apheresis Treatment Unit, Mayo Clinic, Rochester, MN, USA

### Terminology and definitions

Apheresis is derived from a Greek word that means *separate* or *remove*, and it was first used in 1914 by Able, Rowntree, and Turner to describe a procedure where blood was withdrawn from dogs and separated into cells and plasma, with the plasma being discarded and the cells returned with a replacement fluid.<sup>1</sup> Apheresis procedures can be divided into two categories, *cytapheresis*, where the cellular elements are removed, and *plasmapheresis*, where plasma is removed.

### Basic concepts common to all apheresis procedures

#### Blood component separation

Separation of blood components is performed by centrifugation, filtration, or a combination.<sup>2,3</sup> Centrifugation uses centrifugal force and blood-component-specific gravity to separate the elements in the blood. The elements are then removed by siphoning off the desired component or spilling the lighter components over a barrier that retains the heavier components. In some systems, elutriation is also used. Two opposing forces—centrifugal force that pushes heavier elements away from the centrifuge center and pump withdrawal force that pulls the elements to the centrifuge center—separate based on size rather than specific gravity. Effective separation by centrifugation is dependent on the centrifuge *g*-force, determined by the rotations per minute and rotor radius, and the time that blood is exposed to the centrifugal force.<sup>3</sup> Filtration separates elements based upon size.<sup>3</sup> The filter can be a bundle of hollow fibers with pores in their walls or a membrane surface with pores.<sup>3</sup> The pore size determines what passes through the filter and what is retained. Cascade or double-membrane filtration systems can remove substances from the plasma by using two filters, a primary membrane plasma separator to separate the plasma from the cells and a plasma fractionator with smaller pores to remove proteins, such as immunoglobulins.<sup>4</sup>

The Autopheresis C and the Aurora (Fresenius-Kabi, Lake Zurich, IL, USA) combines centrifugation and filtration to increase

plasma collection efficiency. A grooved cylinder covered with a filter membrane is encased within a larger cylinder. Whole blood enters the larger cylinder and surrounds the rotating grooved cylinder. The rotation moves the cells away from the filter toward the inner wall of the larger cylinder while the plasma moves toward the rotating filter. Pressure causes the plasma to flow through the filter to a collection bag while cells exit the bottom of the larger cylinder and are returned. The rotation improves efficiency by keeping platelets and cells from plugging the membrane pores.<sup>3</sup>

#### Anticoagulation

Contact between the plastic disposables and the blood activates the coagulation cascade and clots the circuit in the absence of anticoagulation. To prevent this, blood is anticoagulated prior to extensive contact with the tubing. In the United States, citrate or heparin are the primary anticoagulants with additional medications available in other countries.<sup>5,6,7</sup> Citrate anticoagulants contain citric acid, which binds calcium so that it cannot participate in the coagulation cascade.<sup>5,7</sup> It is necessary to lower the ionized calcium concentration to 0.2–0.3 mmol/L to inhibit coagulation. This would be incompatible with life, yet citrate anticoagulation is safely used due to compensatory mechanisms that increase calcium through release from albumin, mobilization from bone stores, and resorption by the kidneys.<sup>6,7</sup> Citrate is also rapidly metabolized by the liver, kidneys, and skeletal muscle releasing the chelated calcium.<sup>6,7</sup> Citrate anticoagulation produces regional anticoagulation, anticoagulation of the blood within the apheresis device but not in the patient donor.

Heparin anticoagulates blood by increasing antithrombin activity.<sup>6</sup> It is not used as widely as citrate due to systemic anticoagulation and the risk of heparin-induced thrombocytopenia.<sup>6</sup> Heparin is used in procedures where citrate interferes with the mechanism of action of the apheresis device, and it is frequently used in therapeutic plasma exchange (TPE) performed with filtration-based devices. The use in filtration TPE is related to plasma removal efficiency. In a centrifugal device, the plasma extraction ratio is higher (80%), resulting in the removal of most of the administered anticoagulant. The lower plasma extraction ratio (30%) of filtration

devices means a large percentage of the anticoagulant is returned to the patient, causing a greater risk of toxicity.<sup>5</sup> Heparin is not used as sole anticoagulant for the collection of most blood components.

Heparin and citrate may be used in combination to minimize the side effects of both by reducing the amount of citrate needed and its electrolyte disturbances and reducing heparin dose to minimize the length of systemic anticoagulation.<sup>8</sup> This dual anticoagulation is used in procedures on low-weight patients, such as children, where the total volume of anticoagulant administered during the procedure may be large relative to the individual's blood volume.<sup>8</sup> This combination of anticoagulants is commonly used for hematopoietic progenitor cell collections in pediatric patients and may be used for hematopoietic progenitor cell collection in adults by some centers as well.

### Vascular access

In donor apheresis, vascular access is obtained through peripheral venipuncture. A large-bore steel needle (17 gauge or greater) is inserted into an antecubital vein as the draw while an intravenous catheter (18 gauge or larger) is inserted into a peripheral vein of the opposite arm to serve as the return.<sup>9</sup> In blood donors, this is effective and safe.

Underlying disease, previous medical treatment, previous IV insertion, hypovolemia, and multiple apheresis procedures may make peripheral access difficult in patients, and it may be necessary to insert a central venous catheter. Central venous catheters capable of supporting apheresis must have a large diameter and short length to minimize resistance to flow and have rigid walls to prevent collapse under negative pressure in order to allow adequate flow rates.<sup>9</sup> Such catheters are almost always dual lumen catheters to allow a single line to be utilized for both the draw and return. The use of triple lumen catheters is uncommon as the presence of the third lumen frequently results in too small of a diameter of the draw and return causing increased resistance with pressure alarms from the apheresis device. Catheters used for dialysis are acceptable for apheresis. The size of the catheters used varies according to the size of the patient undergoing therapy with 8 French dual lumen catheters utilized for patients 10–20 kg, 7–10 French catheters for patients 20–40 kg, and 10–12.5 French diameter twin or dual lumen catheters for those >40 kg.<sup>10</sup>

Central venous catheter placement represents the greatest risk for apheresis complications,<sup>11</sup> with complications including pneumothorax, bleeding, thrombosis, and infection.<sup>5</sup> Deaths due to these complications have been reported.<sup>12</sup> Studies have found that adequate access can be obtained in patients using peripheral veins. One TPE study involving multiple sclerosis patients found inadequate peripheral access in only 4.5% of patients.<sup>13</sup> An additional, more recent, single center study found that peripheral venous access was successful in 72% of therapeutic procedures but only 29% of TPE.<sup>14</sup> More recent studies examining vascular access for apheresis procedures globally have demonstrated a variation in practice with Europe demonstrating predominantly peripheral access (63% in 2003 and 71% in the period from 2003 to 2007) while North America, South America, and Asia demonstrated predominantly the use of central venous catheters.<sup>15,16</sup>

To minimize risks, each patient should have their peripheral access evaluated and used, if possible. Transitioning to such a practice, however, may be difficult. Recent studies have demonstrated that utilizing ultrasound guidance to obtain peripheral access can successfully reduce central venous catheter use in both adult and pediatric patients.<sup>17,18</sup> In adults, Salazar *et al.* demonstrated a

reduction in the need for such catheters in 20% of their patients where peripheral access could not initially be obtained.<sup>17</sup> Mahon and colleagues found that the use of ultrasound guidance in difficult peripheral venous access pediatric patients resulted in a “small amount of time gained” but a significant improvement in patient and parent satisfaction.<sup>18</sup>

Beyond peripheral venous access and central venous catheters, other forms of access can include peripheral arterial access in the form of arterial lines, use of subcutaneous implantable ports, use of AV fistulae, and the use of AV grafts. These last three forms of access are predominantly utilized for long-term chronic apheresis treatment as they may require weeks to months to “mature” following surgical placement. Peripheral arterial access is used acutely and short term but is relatively uncommon and used predominantly in very small pediatric patients.<sup>19</sup>

### Blood donor apheresis

The 2017 National Blood Collection and Utilization Survey demonstrated a continued shift from whole blood to apheresis donation.<sup>20</sup> This preference in the use of apheresis-derived blood products has been driven by the ability to optimize the products collected based upon the donor's characteristics and inventory needs. For example, although AB plasma is in high demand as the universal plasma product, AB red blood cells are only compatible with 4% of the population and are therefore of limited use. Collecting only plasma from an AB donor allows that donor to donate plasma more frequently and does not generate a low-demand product likely to outdated. Similarly, by not collecting red blood cells from donors donating COVID-19 convalescent plasma, the deferral between donations is shorter allowing for the collection of more product. Multicomponent collections (e.g., a platelet collection with a concurrent collection of plasma) can also be performed, allowing even greater optimization. Table 24.1 lists the various blood components and their combinations that can be collected. Table 24.2 lists advantages of collecting blood components by apheresis.

Compared to 2015, in 2017 there was a decrease in red blood cell (RBC) units produced from whole blood donation by 3.2% and units collected by apheresis of 0.6%. There was a decline in the number of RBC units transfused by 6.1%. While there was an overall decrease in both RBC sources and an overall decrease in RBC transfusions, the greater decline in RBCs derived from whole blood demonstrates a preference for apheresis-derived RBCs, driven by the ability to optimize product collections.

The total number of apheresis platelets collected in 2017 compared to 2015 increased by 4.6%. There was also an increase in whole-blood-derived platelets distributed by 10.3%. However, there was a substantial decline in the number of whole-blood-derived

**Table 24.1** Blood Components Collected by Apheresis

Granulocytes
Hematopoietic progenitor cells
Plasma: multiple doses may be collected depending upon donor characteristics
Platelet: single, double, or triple
Double platelet and single plasma
Platelet and single or double plasma
Red blood cell: single or double
Red blood cell and plasma
Red blood cell and platelet
Red blood cell, platelet, and plasma

platelets transfused by 52.3% with an accompanying increase in apheresis platelets transfused of 2.3%. These numbers indicate that there was the preferential use of apheresis platelets compared to whole-blood-derived platelets, as has been seen in previous National Blood Collection Utilization Surveys. In 2017, 91.3% of platelets distributed were collected by apheresis. This trend could be influenced by the availability of pathogen-reduced platelet products, reduced manipulation of the platelet product by the transfusing facility (no need for pooling of whole-blood-derived platelets), decreased donor exposure, and other factors. Given pending deadline for implementation FDA requirements concerning bacterial detection for platelet products, this trend may continue in the future.

### Donor apheresis instrumentation

Devices cleared by the US Food and Drug Administration (FDA) and currently available in the United States will be briefly described. Table 24.3 lists the different products that each of these devices can collect.

#### Alyx (Fresenius-Kabi, Lake Zurich, IL, USA)

The Alyx is a single-needle instrument designed for double red cell and multicomponent collection (Table 24.3). Blood is pumped by the donor pump into an "in-process" bag. Blood is then pumped by the in-process pump into the centrifuge. Because the in-process pump is slower than the donor pump, unprocessed blood accumulates in the in-process bag. Plasma is drawn from the centrifuge by the plasma pump and delivered to the plasma bag to be returned to the donor or saved for plasma collection. The packed RBCs are pumped into the RBC bag for collection (or returned during a plasma collection). In RBC collection, when a predetermined

amount of blood has been processed, the plasma and saline are returned to the donor by the donor pump. Simultaneously, the in-process pump delivers unprocessed blood from the in-process bag, so the centrifuge is continuously processing blood. During RBC collection, when the appropriate amount of RBCs is collected, the extra blood components are returned to the donor. A preservative solution is added to the RBCs, which are pumped through a leukoreduction filter into final storage bags. The extracorporeal volume (ECV) is 110 mL plus the volume of the products. The Alyx is a compact device that can be utilized on mobile blood drives.<sup>3</sup>

#### Fenwal Amicus (Fresenius-Kabi, Lake Zurich, IL, USA)

The Amicus can perform single- and multicomponent collections (Table 24.3). Blood is pumped into a double chamber belt wrapped around a spool. Prior to entering the centrifuge, plasma is added to the whole blood to adjust the hematocrit (HCT). When blood enters the centrifuge, the lighter platelets quickly migrate toward the center of the centrifuge and are withdrawn by the platelet-rich pump (PRP) from the inlet side of the separation chamber. As blood flows through the separation chamber, the HCT increases, and mononuclear cells flow to the center of the centrifuge and are drawn by the PRP pump toward the platelet outlet. However, when they encounter the lower HCT of the entering diluted blood, they fall to the outside of the chamber. They continue to circulate in the center of the separation chamber until they are returned to the donor during reinfusion. The packed RBC and granulocytes flow to the far end of the separation chamber and are returned to the donor. The PRP is pumped into the second chamber (collection chamber), where the platelets concentrate and the platelet-poor plasma is directed into a collection bag or returned to the donor.<sup>3</sup> When the procedure is complete, the platelets are manually resuspended and then pumped into the platelet storage bags.

The interface between the blood components in the separation chamber is monitored by an interface detector and maintained by a microprocessor. The Amicus can perform double- or single-needle procedures, with the later used for multicomponent collections (Table 24.3). RBC leukoreduction is done off-line by manually filtering the product. The ECV without products is 205 mL for double-needle procedures and up to 329 mL for single-needle procedures.<sup>3</sup>

#### Autopheresis-C and Aurora (Fresenius-Kabi, Lake Zurich, IL, USA)

The Autopheresis-C and Aurora perform plasma collection (Table 24.3). The centrifugal filtration system described under blood component separation is used by both. The devices are single-needle systems using citrate anticoagulation. Both have ECVs of 200 mL, not including the volume of the products being collected.<sup>3</sup>

**Table 24.2** Advantages of Apheresis Collected Blood Components

- Reduced donor exposure: full transfusion dose collected from one donor
- Frequent repeat donors: "pedigreed" donors with repeated screening and testing
- Higher quality products: more quality control per component collected
- Consistent and standardized product volumes and yields
- Ability to match donors to patients: HLA matching for platelet transfusions
- Ability to collect only the product of interest from donor: collect AB plasma or COVID convalescent plasma without collecting RBCs leading to longer donor deferral and unneeded product
- Double, triple, or multiple full-dose blood component collections
- Safety enhancement for the patient with reduced frequency of certain transfusion reactions
- Reduced frequency of donor reactions
- Ability to perform pathogen reduction

**Table 24.3** Products Collected by Donor Apheresis Devices Available in the United States

### **Trima Accel (Terumo Blood and Cell Technologies, Lakewood, CO, USA)**

The Trima Accel is capable of single- and multicomponent collections (Table 24.3). Blood is pumped into a rotating single-stage circular channel. The collect line from the centrifuge is attached to a conical leukocyte reduction chamber. The “collect pump” pumps the product into collection bags. The plasma is collected in the plasma collection bags or is returned to the donor, depending upon the procedure being performed. The packed cells go to the return reservoir or RBC collection bag, again depending upon the procedure being performed. A microprocessor directs component flow from the centrifuge through a valve system to the proper collection bags. The plasma-cell interface is maintained by algorithms that utilize donor data entered at the procedure beginning. Because of this, there is no interface detector, but there is an RBC detector that will monitor RBC spillover during the collection. The Trima Accel is a single-needle system. Double RBC units can be collected, filtered, and additive solution added, all on-line. The ECV, without products, is 196 mL for the platelet kit and 182 mL for the RBC-plasma kit.<sup>3</sup>

### **Spectra Optia (Terumo Blood and Cell Technologies, Lakewood, CO, USA)**

The Spectra Optia, while predominantly used as for therapeutic apheresis (see Chapter 24), can be used for granulocyte collection. It uses a circular separation channel with ports positioned at different distances from the outside wall. The Spectra Optia is automated with an interface detector that monitors the position of the plasma/cell interface, at the port of the collect line. The operator can fine tune the product content by monitoring the collect line color and adjusting the plasma pump. The Spectra Optia typical ECV during granulocyte collection is 253 mL while the maximum is 297 mL, not including the product volume.<sup>3</sup>

### **Haemonetics MCS+ 9000 and 8150 (Haemonetics Corporation, Braintree, MA, USA)**

MCS stands for *mobile collection system*. The MCS+ 9000 is used for platelet collection and concurrent plasma, and the MCS+ 8150 is used for double RBC collection and RBC with concurrent plasma (Table 24.3). The MCS+ 9000 uses a conical-shaped Latham bowl, and the MCS+ 8150 uses a bowl with vertical walls.<sup>3</sup>

With the MCS+ 9000, blood fills the spinning conical bowl from the bottom, with the RBCs migrating to the outside wall and plasma staying on the inside wall with the buffy coat (white blood cells [WBCs] and platelets) lying between. The cell/plasma interface is monitored by a light beam reflected off the inside of the top of the bowl. Plasma exits the bowl by first passing through an optical-based line sensor. When the plasma-buffy coat interface is detected in the bowl, plasma is rapidly pumped into the bowl from the bottom, flushing the lighter platelets from the bowl. When the platelets are detected by the line sensor, a valve opens to the collect bag, which then closes when WBCs are detected. At that point, the bowl contains only RBCs, which are returned to the donor along with the plasma. The cycle is then repeated. WBC removal occurs through an on-line leukoreduction filter. When concurrent plasma is collected, the desired volume of plasma is retained during the last reinfusion.<sup>3</sup>

In the MCS+ 8150, the vertical-wall centrifuge bowl (blow-molded bowl) also fills from the bottom. Instead of a light-beam-based sensor at the top of the bowl, the line sensor detects the presence of RBCs in the bowl effluent line and stops the cycle. A

small amount of saline is pumped to the donor, and then a predetermined amount of RBCs is transferred to the RBC reservoir bag. The remaining RBCs, plasma, and additional saline are returned to the donor. The cycle is repeated until the programmed RBC volume is collected. The donor is disconnected when all remaining plasma and RBCs have been returned. Additive solution is pumped to the reservoir bag, and the set is disconnected. Leukoreduction is performed by gravity through preattached filters as blood drains into two RBC product bags.<sup>3</sup>

The MCS+ 9000 and MCS+ 8150 ECV are dependent on the size of bowl used, donor HCT, and phase of the cycle. The range is 542 mL (38% HCT) to 391 mL (54% HCT). The instruments are designed to be portable and can be used for mobile blood drives.<sup>3</sup>

### **Haemonetics PCS-2 (Haemonetics Corporation, Braintree, MA, USA)**

The Haemonetics PCS-2 is used for plasma collection (Table 32.4). The MCS+ 8150 vertical wall bowl is used with plasma diverted to a collection bag until the bowl fills with RBCs. The bowl contents are then returned to the donor. Cycles are repeated until the target plasma volume is collected. The ECV depends upon the donor hematocrit ranging from 480 mL (38% HCT) to 359 mL (52% HCT). The device is portable.<sup>3</sup>

## **Product and procedure requirements**

### **Granulocytes**

Chapter 19, “Granulocyte collection and transfusion,” discusses granulocyte collection and clinical use, and the reader is referred to this chapter for procedure and product requirements.

### **Hematopoietic progenitor cells**

Chapter 53, “Hematopoietic stem cells and transplantation,” discusses the collection and processing of hematopoietic progenitor cells, including procedure and product requirements. The reader is referred to this chapter.

### **Plasma**

In 2017, 564,000 plasma units were collected by apheresis in the United States. These apheresis units, however, represent only 8.7% of the plasma collected for transfusion with the majority collected from whole blood donation.<sup>21</sup> Between 2015 and 2017, there was a decline in plasma units transfused by 13.6% with an accompanying decline in the production of plasma units from both whole blood (13%) and apheresis (46.3%). The increased cost and complexity of apheresis plasma collections in the presence of shrinking demand resulted in this change. Plasma is also collected as *source plasma*, plasma to be fractionated and manufactured into products such as albumin, intravenous immune globulin, and coagulation factor concentrates (see Chapter 22, The purification of plasma proteins for therapeutic use).

The regulatory and accreditation requirements for plasma collection depend upon donation frequency. Donors may donate more frequently than every four weeks (*frequent*) or less frequently than every four weeks (*infrequent*). In general, frequent donors donate “source plasma” and infrequent donors donate plasma for transfusion. Infrequent plasma donors must fulfill whole blood donor requirements.<sup>22</sup> AABB Standards for Blood Banks and Transfusion Services also require that donors taking warfarin be deferred for one week following their last dose to allow for vitamin-K-dependent

coagulation factor regeneration.<sup>23</sup> Frequent plasma donors must fulfill criteria outlined in the US Code of Federal Regulations (CFR).<sup>23,24</sup> These require that total serum protein is greater than 6.0 g/dL prior to each donation, a serum protein electrophoresis or quantitative immunodiffusion be performed every four months, and a physical examination performed by a physician be performed annually.<sup>24</sup> This ensures that “frequent” plasma donation does not deplete plasma proteins that could harm the donor and affect the potency and efficacy of the products.

Both frequent and infrequent plasma donors are limited to the total plasma volume that can be donated in 12 months. Donors weighing 110–175 lbs. can donate up to 12 L, and those weighing >175 lbs. can donate up to 14.4 L.<sup>22</sup> Frequent plasma donors are limited to two donations within a seven-day period, with at least two days between the donations.<sup>24</sup>

The SARS-CoV-2 pandemic has resulted in a development in renewed interest of utilizing convalescent plasma from individuals who have recovered from infection.<sup>25</sup> Donors donating such plasma may be either frequent or infrequent plasma donors. Donor criteria for the collection of COVID-19 Convalescent Plasma (CCP) have been issued by the FDA with numerous updates.<sup>26</sup> At the time of writing of this chapter, donors donating CCP must fulfill the criteria outlined in Table 24.4. Indications for the appropriate use of CCP are discussed in Chapter 3, Responding to the regulatory challenges during emergencies and epidemics, and Chapter 21, Plasma and cryoprecipitate for transfusion.

## Platelets

Donor requirements for apheresis platelet donation are the same as whole blood donation.<sup>23,27</sup> Both the AABB and FDA have requirements that address a donor’s exposure to antiplatelet medications.

The FDA requires deferral of apheresis platelet donors who have ingested aspirin or piroxicam within two days prior to collection.<sup>27</sup> Apheresis platelet donors who have taken clopidogrel or ticlopidine, drugs whose metabolites inhibit platelet function and have a longer antiplatelet effect, are deferred for 14 days.<sup>27</sup> AABB Standards require that apheresis platelet donors taking “medications known to irreversibly inhibit platelet function” be evaluated prior to donation.<sup>23</sup> These criteria do not apply to whole blood donors whose donations are used to manufacture platelets unless they represent the single source of platelets to the patient (e.g., transfusing an aliquot from a single whole-blood-derived platelet to a pediatric patient).

**Table 24.4 Donor Criteria for the Collection of COVID-19 Convalescent Plasma.** Source: Based on Food and Drug Administration.<sup>26</sup>

- Evidence of COVID-19 infection as defined by either 1 or 2
- 1. Symptoms of COVID-19 and positive results on a diagnostic test approved, cleared, or authorized by the FDA
- 2. No prior symptoms or positive diagnostic test but reactive results on two different FDA approved, cleared, or authorized tests for SARS-CoV-2 antibodies
- Resolution of symptoms at least 14 days before donating
- Male donors or female donors who have never been pregnant or for female donors who have been pregnant with a negative test for HLA antibodies since the most recent pregnancy
- Donors who have received a COVID-19 vaccine may donate if they had symptoms of COVID-19 infection and a positive diagnostic test, received the vaccination after diagnosis, and are within six months of resolution of COVID-19 symptoms
- Donors who have received monoclonal antibodies may donate three months after the administration of the monoclonal antibody

Platelet donors must have a minimum 150,000/ $\mu$ L platelet count. A predonation count must be used to program the apheresis instrument and can be a post collection count from the donor’s previous donation or a count on a sample drawn immediately prior to the current donation. If the count is not available prior to the start of collection, the procedure can begin but the count must be entered when available. If a preprocedure count cannot be obtained, an average of the donor’s previous platelet counts, a default count recommended by the instrument manufacturer, or a default count determined by the collection center may be used.<sup>27</sup> When a preprocedure platelet count cannot be determined on a first-time donor, a triple-platelet product cannot be collected.<sup>23</sup> If capable, the instrument must be programmed to ensure that the donor’s platelet count does not fall below 100,000/ $\mu$ L.<sup>27</sup>

Platelet donors have restrictions on donation frequency and the total number of donations that can occur within a 12-month period.<sup>23,27</sup>

Donors cannot donate more than 24 times in a rolling 12-month period.<sup>27</sup> This limit arose from the observation that donors collected on early apheresis devices experienced declines in total lymphocyte numbers, T-lymphocyte numbers, and immunoglobulin G (IgG) levels for up to eight months.<sup>28</sup> It had been suggested that with newer devices, this was no longer a problem.<sup>28</sup> However, a recent study examining donors donating using the Trima Accel demonstrated statistically significant declines in CD4 and CD8+ T-cells with a dose response to the number of donations in two donor groups (3–19 donations per year or 20–24 donations per year) compared to a control group of 1–2 donations per year.<sup>29</sup> The authors of this study could not demonstrate any effect lymphopenia on donor health.<sup>29</sup> An additional study by the same authors examined 30 platelet donors who had undergone 20–24 platelet donations in the prior year with the Amicus.<sup>30</sup> This group of donors did not show the same reduction in CD4 and CD8+ T-cells. The leukocyte reduction method of the Trima Accel and Amicus is substantially different and therefore the authors concluded that lymphopenia due to platelet donation is likely device dependent.<sup>30</sup> A nationwide cohort study from Sweden examining 74,408 apheresis platelet donors and comparing the risk of infections in donors donating on devices using the leukocyte reduction chamber used in the Trima Accel to those who had donated platelets at a time when such chambers were not in use has been published.<sup>31</sup> The authors found an increased risk of immune-suppression-related infections, mostly reactivation of varicella-zoster, and an increased risk of bacterial infections in donors donating on devices with leukocyte reduction chambers when matched for the same donation frequency.<sup>31</sup> These findings support continued limitations on the number of apheresis platelet donations if certain leukocyte reduction methods are used.

In addition to lymphopenia, a study has suggested that long-term platelet donation could result in baseline platelet count decline and a delay in platelet recovery.<sup>32</sup> This study resulted in the addition of the limitations on the number of times a donor can donate in a week and the requirement for a longer period of deferral between donations when double or triple products are donated.<sup>27</sup> Donors can donate twice per week but must have two days between donations if they are donating a single dose of platelets. If donating a double or triple product, they are deferred for one week.<sup>23,27</sup> It should be noted, however, that declines in baseline platelet count and delayed recovery with increasing donation frequency have not been seen in other studies.<sup>33</sup>

The FDA has also placed limits on the total amount of plasma removed during a platelet donation and the total amount of RBCs lost within eight weeks.<sup>27</sup> Donors weighing <175 lbs. can have no

**Table 24.5** Impact of Red Cell Loss on Donor Eligibility. Source: Modified from Food and Drug Administration.<sup>27</sup>

First Red Cell Loss (mL)	Total of First and Subsequent Red Cell Loss in Preceding 8 Weeks (mL)	Eligibility
<200	<200	No deferral
<200	>200 but ≤300	Defer for 8 weeks from second loss
>200 but ≤300	NA	Defer for 8 weeks from first loss
<200	>300	Defer for 16 weeks from second loss
≥300	NA	Defer for 16 weeks from loss

NA: not applicable.

more than 500 mL of plasma removed, whereas those weighing ≥175 lbs. can have 600 mL removed.<sup>27</sup> RBC loss, from whole blood donation or loss during the apheresis donation, can result in prolonged donor deferral.<sup>21,23</sup> The loss of red blood cells during apheresis platelet collection, however, is usually minimal with significant red cell loss occurring only in the presence of instrument malfunctions that prevent the reinfusion of blood from the apheresis device. Even then, the extracorporeal red cell volume of most devices is less than 100 mL. These deferrals are listed in Table 24.5.

The FDA requires that 75% of the apheresis platelet products contain at least  $3.0 \times 10^{11}$  platelets,<sup>24</sup> whereas AABB requires that 90% contain  $3.0 \times 10^{11}$  platelets.<sup>23</sup> The products must also have a pH >6.2 at issue or the end of storage.<sup>23</sup> If products are leukocyte reduced, then 95% of the units sampled must have  $\leq 5 \times 10^6$  residual leukocytes.<sup>23</sup>

### Red blood cells

RBCs can be collected as a single or a double unit. Single units are usually collected as part of a multicomponent collection due to the costs associated with the collection. Advantages of apheresis RBC collections include fewer donor reactions, better inventory management, standardized RBC doses, and decreased donor exposure if both units of a double RBC are given to the same patient.<sup>34</sup> Disadvantages include stricter donor criteria that are dependent upon the apheresis device used, longer donation time, and potential apheresis-related complications.<sup>34</sup>

Apheresis RBC donors must meet whole blood donation criteria<sup>23,35</sup> and must also meet criteria defined by the device manufacturer. These criteria define height, weight, and hematocrit requirements based upon the donor's sex.<sup>35</sup> Of note, the hematocrit requirements of the manufacturer may differ from those defined by the FDA for whole blood donation (females Hgb 12.5 g/dL, Hct 38%; males Hgb 13 g/dL, Hct 39%). The FDA requires that the hemoglobin/hematocrit method used to qualify the donor be a quantitative method.<sup>35</sup>

The maximum allowed RBC volume removed during the collection is defined in the device operator's manual with no specific requirements from the FDA.<sup>35</sup> AABB standards require that the amount of RBC removed not reduce the donor's hemoglobin below 10 gm/dL or the hematocrit below 30%.<sup>23</sup>

Donation frequency is determined by the type of RBC product donated. Single-unit RBC donors are deferred for 8 weeks, whereas those donating two units are deferred for 16 weeks.<sup>35</sup> The deferral length may vary based upon the absolute RBC loss in cases where there is an incomplete procedure or there has been additional RBC

loss due to other donations (Table 24.5).<sup>27</sup> As with whole blood donation, iron deficiency among apheresis donors is a significant concern with the potential for significant health effects. See Chapter 7, Chronic effects of blood and plasma donation, for further discussion concerning these issues.

The FDA requires that 95% of the products collected meet the "expected or target RBC volume" and "any other target parameters" defined in the device operator's manual. The FDA defines how the testing to validate and monitor the apheresis RBC collections is performed.<sup>35</sup> For validation, the FDA requires testing 100 consecutively collected units. For monitoring, at least 50 units, consisting of single and double RBCs, must be monitored each month. When a center collects fewer than 50 units, all of the units must be tested.<sup>35</sup> AABB standards require that the method used results in a mean hemoglobin of ≥60 g or 180 mL RBCs. At least 95% of the units must have >50 g of hemoglobin or 150 mL RBCs. If the RBC unit is leukocyte reduced, the method must have a mean hemoglobin ≥51 g or a 153 mL RBC volume and a residual leukocyte count ≤5 × 10<sup>6</sup>. Ninety-five percent of units must have >42.5 g of hemoglobin or 128 mL RBCs.<sup>23</sup>

### Multicomponent collections

Multiple different components can be collected by apheresis from a single donor (Table 24.2). With multicomponent collections, the donor and product requirements that apply to the individual products apply to the procedure. Donation frequency requirements seen with plasma donation apply when plasma is collected concurrently with a platelet or RBC product. Red cell loss deferrals given in Table 24.5 and the plasma volume limits described with plasma and platelet donation also apply.

### Apheresis complications

#### Donor reaction overview

Among American Red Cross apheresis donors, the reaction frequencies were 577.5/10,000 for platelet donation and 538.3/10,000 for double red cell donation, compared to 348.9/10,000 for whole blood donation.<sup>36</sup> Severe reactions, requiring outside medical management, occurred in 3.2/10,000 whole blood, 2.9/10,000 platelet, and 2.9/10,000 double red cell donations. The differences were not statistically significant, although the reaction types with severe reactions to whole blood donation were predominantly vasovagal reactions, whereas those due to apheresis donation were phlebotomy related.<sup>36</sup> One study found severe reactions in 0.01% of apheresis platelet donations,<sup>37</sup> a rate 20 times that seen with whole blood donation (0.0005%).<sup>38</sup> Reaction types and frequencies in apheresis and whole blood donors are listed in Table 24.6. Venipuncture-related complications are most frequent with apheresis donation, with first-time donation being the most common risk factor.<sup>36,39</sup>

**Table 24.6** Frequency of Reactions among Apheresis and Whole Blood Donors

Reaction	Apheresis (%) <sup>39</sup>	Whole Blood (%) <sup>40</sup>
Hematoma	1.15	9–16
Citrate toxicity	0.4	Not applicable
Vasovagal	0.05	2–5
Vasovagal with loss of consciousness	0.08	0.1–0.3

## Therapeutic apheresis reaction overview

Reaction frequencies among patients undergoing therapeutic apheresis vary among studies. McLeod observed reactions in 4.75% of procedures, and Couriel and Weinstein observed reactions in 17%.<sup>12,41</sup> A difference between these studies was that Couriel and Weinstein considered central line complications as an apheresis complication, whereas McLeod did not. In the study by Couriel and Weinstein, all severe reactions, including one patient death, were associated with central line placement.<sup>12</sup> Shemin *et al.* observed reactions in 36% of TPE procedures.<sup>42</sup> The reactions observed by McLeod were transfusion reactions related to replacement fluids (1.6%), citrate toxicity (1.2%), hypotension (1.0%), vasovagal reactions (1.0%), tachycardia (0.4%), respiratory distress (0.3%), tetany and seizure (0.2%), and chills and rigors (0.2%).<sup>41</sup>

## Common apheresis complications

### Citrate toxicity

Citrate chelates calcium, making it unavailable for the coagulation cascade. Ionized calcium levels necessary for anticoagulation occur within the apheresis device, not in the patient donor, due to compensatory mechanisms. Despite this, levels of ionized calcium can reach a point whereby spontaneous neuron depolarization occurs, resulting in the signs and symptoms listed in Table 24.7.<sup>43</sup> The table

lists these in the order of appearance, so it is possible to avoid more severe reactions by identifying the early, mild symptoms.<sup>43</sup> Hypocalcemia can also suppress myocardial function, induce arrhythmias, and prolong the QT interval.<sup>36</sup> Treatments of hypocalcemia are listed in Table 24.8. Prevention of hypocalcemia includes continuous intravenous calcium administration during the procedure and correction of low levels prior to the start of the procedure.<sup>43</sup>

Although hypocalcemia is commonly thought of as citrate toxicity, citrate anticoagulation results in a variety of electrolyte and acid–base disturbances. The second most common divalent cation in the blood is magnesium, which is also chelated by citric acid. Significant magnesium decline has been seen during apheresis procedures. Signs and symptoms of hypomagnesemia are similar to those of hypocalcemia, including muscle spasms, muscle weakness, decreased vascular tone, and impaired cardiac contractility, and therefore may present as hypocalcemia that fails to respond to calcium supplementation.<sup>43</sup> Treatment consists of procedure discontinuation with magnesium supplementation.

Citrate metabolism generates bicarbonate, producing a metabolic alkalosis.<sup>43</sup> In most circumstances, this is not significant but in the presence of renal impairment and/or increased citrate load when plasma is used as the replacement fluid, severe metabolic alkalosis may occur. Symptoms are nonspecific and present as

worsening hypocalcemia, although suppressed respiratory drive can occur as the body tries to compensate. Metabolic alkalosis resolves with time, although in severe cases, dialysis may be necessary.<sup>44</sup>

Metabolic alkalosis can also produce hypokalemia. To buffer the generated bicarbonate, protons leave cells with a resulting net potassium influx to maintain a neutral charge. Significant potassium decline, up to 11% in a large-volume stem cell collection study, can occur.<sup>45</sup> Most patients are asymptomatic, but symptoms can include weakness, hypotonia, and cardiac arrhythmia. Treatment consists of oral or intravenous replacement.<sup>45</sup>

### Hypotension

Hypotension is a common reaction during apheresis and can result from numerous mechanisms. As indicated in Table 24.6, citrate-induced hypocalcemia can cause hypotension. Other causes include hypovolemia, vasovagal reactions, and the presence of angiotensin-converting enzyme inhibitors (ACEIs). In hypovolemia, the amount of blood within the extracorporeal circuit is greater than can be tolerated by the patient donor. It is characterized by hypotension and tachycardia.<sup>43</sup> Hypovolemia is relatively uncommon among healthy apheresis donors because the total amount of blood withdrawn into the extracorporeal circuit and the collected products is limited to 10.5 mL/kg.<sup>23</sup> Hypovolemia is common among patients as they may be volume depleted due to underlying disease and poor oral intake. Vasovagal reactions are characterized by low blood pressure with an inappropriately low pulse. Increased parasympathetic output in response to sympathetic drive leads to vasodilation and bradycardia.<sup>46</sup> Both hypovolemia and vasovagal reactions are treated by pausing the procedure, placing the patient donor in the Trendelenburg position, and infusing fluids.<sup>46</sup>

An uncommon but important cause of hypotension, in patients undergoing TPE with albumin replacement fluid and lipid apheresis with the Kaneka MA-03 Liposorber system, is the use of ACEIs. This reaction is characterized by flushing, hypotension, bradycardia, and dyspnea occurring after a few milliliters of blood is returned to the patient due to bradykinin generation in the apheresis device. Bradykinin may be generated by prekallikrein activating factor that is present in some albumin lots.<sup>47</sup> In the Liposorber system, bradykinin is generated when blood comes into contact with the negatively charged dextran sulfate beads within the Liposorber columns.<sup>48</sup> Normally, bradykinin has a short half-life, metabolized by kinase I and kinase II. ACEIs inhibit these, resulting in unopposed bradykinin effects. Treatment options are limited, and when severe reactions occur, procedures must be terminated. Avoiding ACEI administration for 24–48 hours before the procedures can prevent these reactions. ACEIs can be safely administered immediately following the procedures.

### Allergic and anaphylactic reactions

In therapeutic apheresis, allergic and anaphylactic reactions are most often triggered by the replacement fluid. Allergic and anaphylactic reactions can occur when either plasma-containing blood products or albumin is used. They can also occur in donor apheresis.<sup>43</sup> In donors, substances present in the disposables or substances used in the procedure trigger histamine release. For example, there have been reports of apheresis platelet donors developing allergic and anaphylactic reactions to residual ethylene oxide present from sterilizing the disposables.<sup>49</sup> In granulocyte collections, hydroxyethyl starch (HES) is used as a sedimenting agent to enhance the product yield. HES can activate the alternate complement pathway generating C3a and C5a, which can trigger mast cell release.<sup>50</sup> Simple allergic reactions can be treated with oral or intravenous antihistamines. In donors, procedures would be discontinued, whereas in patients, they could be resumed after ensuring that the symptoms are not progressing. In severe reactions, procedures should be discontinued but vascular access maintained. Treatment of severe reactions would include administration of epinephrine, fluids, and potentially aminophylline for bronchoconstriction. These patients may also require intubation to maintain their airway. At the end of an apheresis procedure, the contents of the centrifuge are returned to the patient donor. In the setting of severe allergic or anaphylactic reactions where procedures are stopped early, this should be avoided in order to prevent allergen infusion.

### Air embolism

Air embolism is a rare, but potentially fatal complication, of apheresis. This complication occurs when a volume of air greater than 3–8 mL/kg enters the venous circulation. It is rare as all modern apheresis instruments include air detectors that immediately stop the return of blood to the donor or patient when air is detected in the system. Air embolism is most likely to occur, therefore, in patients with central venous access. It occurs in this setting when connecting or disconnecting the apheresis device from the catheter without closing the clamp on the catheter and the patient taking a deep inspiration resulting in a negative intrathoracic pressure. Air embolism results in bronchoconstriction, pulmonary artery vasoconstriction, and right ventricular outflow obstruction producing

wheezing, hypotension, cyanosis, and cardiovascular collapse. Treatment consists of immediately placing the patient into Trendelenburg position on their left side so that the air moves from the right ventricular outflow track. With time the air will dissolve or if a large amount is present, it may be necessary to insert a catheter into the right ventricle and aspirate the air.<sup>43</sup>

### Summary

The term *apheresis* has been used to describe a family of medical procedures for more than 100 years. Both donor collections and therapeutic procedures have in common the basic mechanisms of blood separation, anticoagulation, and vascular access, and as a result, share some of the same complications. The use of apheresis to collect blood products for transfusion continues to expand despite an overall reduction in the total number of transfusions in the United States. The percentage of red blood cells and platelets collected by apheresis has grown between 2015 and 2017. While the collection of plasma products for transfusion decreased during that time period, the collection of COVID-19 convalescent plasma has recently become an important priority for blood collectors. Apheresis blood collections represents an important and effective way to tailor collections to maximize donations and provide products to meet the special needs of patients.

## CHAPTER 25

# Therapeutic apheresis: plasma processing

Patricia A. R. Brunker<sup>1</sup> & Monica B. Pagano<sup>2</sup>

<sup>1</sup>Blood Transfusion Service, Department of Pathology, Massachusetts General Hospital, Boston, MA, USA

<sup>2</sup>Department of Laboratory Medicine and Pathology, University of Washington, Seattle, WA, USA

## Introduction

The pathophysiology or symptoms of some diseases are due to the excessive accumulation of blood cells or plasma constituents. When medical options to address the core pathophysiology in these conditions is limited or ineffective, blood cell separators can be used therapeutically.<sup>1</sup> Therapeutic apheresis includes plasma exchange, red blood cell exchange, therapeutic cytoreduction, photopheresis, and specific selective adsorption. In the United States, in 2006 approximately 112,109 therapeutic apheresis procedures were performed. Subsequent summary data are not available, but therapeutic apheresis is projected to be a \$120,000,000 business as of 2015. From an estimated \$178 million industry in 2020, the therapeutic plasma exchange market is projected to increase to \$243 million by 2025.<sup>2</sup>

## Therapeutic plasma exchange (TPE)

John J. Abel of the Johns Hopkins University used the term “plasmapheresis” to describe a method for removing large quantities of plasma from experimental animals.<sup>3</sup> Therapeutic possibilities in humans have been driven by advances in centrifugal blood separation technologies, starting with collection chambers filled by intermittent blood flow, such as the Cohn and Latham bowls in the 1950s, through challenges of rotating seals to modern, fully automated continuous flow systems. Commercially available apheresis devices range from tabletop platforms optimized for component collection to portable yet highly customizable systems that can interface with other extracorporeal technologies at an ICU bedside.<sup>4</sup>

## Techniques of plasma exchange

### Instruments

Collection of plasma for the purposes of blood product manufacture or further processing into plasma derivatives is discussed in Chapter 22. Medical devices require review by different regulatory agencies around the world. We focus on the procedure as it occurs in the United States, which is regulated by the Food and Drug Administration (FDA); therefore, it is required to consult local authorities for instruments that may be approved in other jurisdictions. For therapeutic applications, plasma is separated either by

centrifugation or membrane separation, using distinct instruments. Centrifuge-based methods are commonplace in the United States, whereas membrane-based methods have gained popularity in Japan and Germany. In plasma exchange using centrifugal blood cell separators, the whole blood enters the instrument, where an anticoagulant is added to allow for smooth flow through the tubing and most of the red cells, leukocytes, and platelets are separated from the cell-poor plasma. Separated plasma from the patient is diverted into a waste bag and is replaced with one or more of several available fluids according to the indication for the exchange and patient-specific factors. Membrane filtration plasma exchange is similar to ultrafiltration performed on dialysis machines and employs a filter with pores between 0.3 and 0.5 mm which allow even large plasma proteins to pass through, while all cellular components remain.<sup>5</sup> Since centrifuge-based instruments allow the flexibility to remove (or collect) blood's cellular components as well as plasma, transfusion medicine practitioners and services primarily employ this technology, and we restrict this chapter to centrifugal therapeutic apheresis.

Several instruments can be used for TPE, including the Terumo Optia (which replaced the Spectra instrument and is the most common device), Fresenius Kabi Amicus, Fresenius COM.TEC (including AS104 as a predicate device), and Haemonetics MCS. Due to the risks associated with apheresis, the FDA regulates new devices under the 510(k) pathway and maintains a list of approved devices online.<sup>6</sup> Membrane-based separation systems are regulated by the FDA under a distinct classification from centrifuge-based systems used for therapeutic purposes (“MDP” vs. “LKN” product codes). The Terumo and Fresenius instruments are continuous-flow systems that make it easier to control the patient's fluid volume, and the Haemonetics instrument uses repeated cycles of filling and emptying the blood cell separator. In the United States, the Spectra has been the most widely used, with most centers moving to the Optia when the Spectra became obsolete. The extent of use of Amicus instruments for therapeutic apheresis is not clear, although they are widely used in collections. Details of operating these instruments are not included here. The manufacturer's operating manuals must be used because of the complexity of these procedures. Thorough quality control programs are essential to be sure staff are properly trained, fluids monitored, alarms tested, lines and

fluid attachments secured, and medications and replacement solutions used correctly. Particularly important clinical parameters include understanding the extracorporeal blood volume, inlet:anticoagulant ratio, and pump pressures, which can help diagnose midprocedure clinical changes as well as overall suitability for a patient to undergo a plasma exchange. The plasma removed must be discarded as biohazardous waste.

### Vascular access

The majority of therapeutic plasma exchanges (TPEs) will have a withdrawal rate between 60 and 150 mL/minute using centrifugal systems, allowing most procedures to process one plasma volume in approximately one and a half to three hours. Vascular access for TPE is most commonly via peripheral veins or central venous catheters (CVCs) that can be tunneled or nontunneled, although arteriovenous fistulas, grafts, or power-injectable (a.k.a. "vortex") ports are possible options for long-term use as well. Membrane-based systems require higher flow rates that prohibit peripheral venous access. Factors such as the desired flow rate; the vascular anatomy; patients' mobility and ability to care for a catheter; the urgency, frequency, and anticipated duration of TPE; or whether other treatments that require venous access are needed all help determine the selection of vascular access.<sup>7-9</sup>

Peripheral venous access is desirable because it can be done immediately and is without the potentially serious risks associated with the use of CVCs. Steel dialysis-type needles, typically inserted under aseptic conditions in the antecubital veins, are required to maintain adequate negative pressure on the draw line for continuous flow procedures. For adults, 17 gauge needles can accommodate 80 mL/minute and greater flow rates.<sup>10</sup> Forced-air warming blankets, warm compresses, and arm exercises can increase venous blood flow, making venipuncture more successful in the cooperative patient. A vein assessment by an apheresis nurse is an important step in the planning of appropriate vascular access for elective procedures. A small study of neurological patients receiving TPE showed only 50% of patients were able to complete a planned course of therapy with only peripheral access.<sup>7</sup> According to the 2007 International Apheresis Registry, peripheral access is more common in Europe and Australia (66–70%) than in Asia and the Americas (2–15%).<sup>11</sup> Ultrasound-assisted peripheral venous access has increased, thanks to small devices with intuitive interfaces optimized for vascular access, such as the Sonosite SII, which can be used by apheresis clinic staff.<sup>12</sup> CVC use was reduced to only 1–3% at an academic apheresis clinic in Toronto after they initiated an ultrasound-guided program for both therapeutic apheresis and cellular therapy collections.<sup>13,14</sup> The use of single-arm needle attachments has improved the ability to complete an apheresis course peripherally if a patient can tolerate the longer time required to perform a discontinuous flow procedure. Unfortunately, CVCs are often required due to small vein caliber, poor vascular tone, altered mental status, or the need for several procedures.<sup>15</sup> Patients with seizure disorders may also be better suited to CVC access over peripheral to protect against serious antecubital fossa trauma from the steel needles in the event of a seizure during the procedure. In children, peripheral venous access is not recommended given their small venous caliber and inability to tolerate immobility as required to complete a procedure.<sup>9,16</sup>

If CVC placement is necessary, the apheresis personnel should be involved to ensure appropriate catheter selection. Poiseuille's equation (in which  $R$  is proportional to viscosity  $\times$  length/radius) states that there are primarily three determinants of resistance to flow in a

catheter: radius, length, and viscosity.<sup>17</sup> Shorter catheters allow for less resistance to flow with the added benefit of allowing the anticoagulant to reach the blood sooner. A larger diameter offers less resistance and also ensures that a small clot or fibrous sheath will not block the lumen.<sup>17,18</sup>

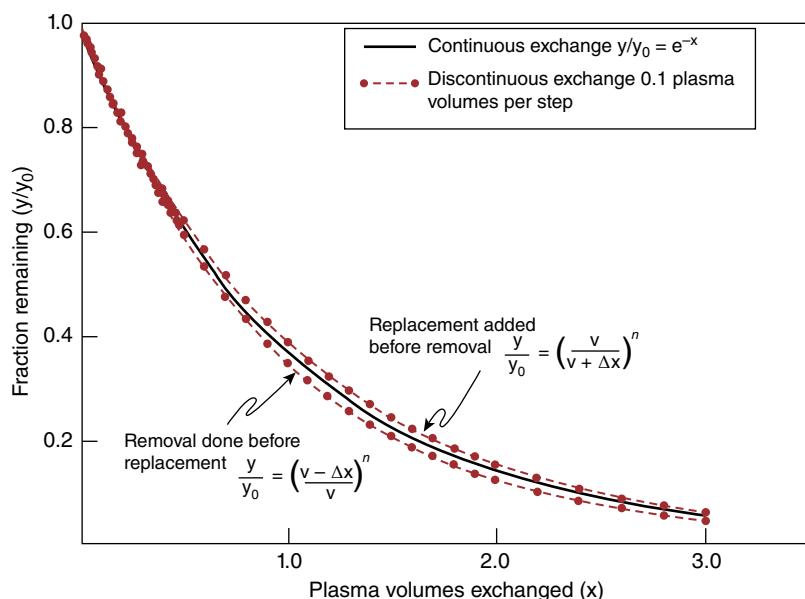

Shorter catheters allow for less resistance to flow with the added benefit of allowing the anticoagulant to reach the blood sooner. A larger diameter offers less resistance and also ensures that a small clot or fibrous sheath will not block the lumen.<sup>17</sup> The catheters must have sufficient rigidity so as not to collapse under negative pressure during blood removal.<sup>17,19</sup> In general, if a CVC can support hemodialysis, it will be sufficient for TPE. Double-lumen catheters are most commonly color coded with red for the draw line and blue as the return line. There are potential risks with all catheter tip positions, but it is generally accepted that the tip should be preferentially in the superior vena cava (SVC) or inferior vena cava (IVC), outside the pericardial sac, and should not touch the vein or heart wall at a sharp angle.<sup>20</sup> Radiographic confirmation of the catheter position is typically necessary prior to use. Recent advances in vascular access technology, including devices such as the Arrow vascular positioning system (VPS), which combine Doppler ultrasound, electrocardiography, and algorithmic logic, allow catheter use immediately after placement.<sup>19,21</sup> The majority of evidence-based guidelines on CVC care have been inferred from hemodialysis literature. In order to prevent fibrin sheaths and thrombosis, CVCs must be flushed with saline and locked with an anticoagulant after each use and at regular intervals when not in use. Catheter-locking solutions include heparin and sodium citrate (4%), with use of tissue plasminogen activator (tPA) instillation if a catheter used for regular procedures becomes problematic.<sup>10</sup> To reduce the risk of bleeding, the solution should be aspirated if the heparin dose is 1000 units per mL or greater.<sup>10</sup>

The average plasmapheresis treatment course for TTP is 13 procedures, but can extend up to several weeks.<sup>22</sup> Most other indications require 5–7 procedures for an urgent course of treatments, but chronic schedules may be preferred in some circumstances. For patients with renal disease who also require hemodialysis, the use of a pre-existing arteriovenous fistulae or grafts may be convenient, but these approaches are not typically taken if the patient requires access for apheresis alone. Rather, the use of subcutaneous port-CVC systems has gained in popularity due to their low rates of infection, long-term use, and patient satisfaction. Cost-savings and convenience have also been reported.<sup>10,23</sup>

### Exchange volume

The volume of plasma to be exchanged is usually based on the estimated plasma volume of the patient. The fraction of the unwanted compound that remains in patient's plasma volume decreases as an exponential decay due to the continuous mixing of the replacement solution with the patient's plasma during the plasmapheresis (Figure 25.1). After an exchange equal to the patient's plasma volume, the unwanted component will be reduced to approximately 35% of the initial value. Exchanging two times the patient's plasma volume further reduces the unwanted component only to approximately 15% of the initial value. A plasma exchange is therefore the most efficient at the beginning, and due to its diminishing effectiveness and increasing likelihood of possible adverse effects from the anticoagulant, the procedure is usually limited to between two and four hours.

The molecule targeted for removal by TPE is often an immunoglobulin G (IgG) antibody, which is approximately 50% extravascular.

**Figure 25.1** Calculated fraction of intravascular substance remaining during a plasma exchange, assuming no equilibration with extravascular material. Source: Chopek and McCullough (1980).<sup>31</sup> Reproduced with permission of American Association of Blood Banks.

Since the removal of accessible (i.e., intravascular) IgG becomes progressively less efficient during a TPE procedure, most practitioners limit an exchange to 1–1.5 times the patient's estimated plasma volume. An exchange of this magnitude will remove 60–75% of intravascular material while limiting side effects from depletion of normal plasma components. The intravascular IgG level will rise during the ensuing 1–2 days by equilibration with extravascular sources, and further removal by a subsequent exchange can then be undertaken more efficiently. It does not appear that a rebound overshoot in antibody levels occurs after plasma exchange, but rapid re-equilibration of IgG occurs because 50% of IgG is extravascular.<sup>24,25</sup> Because IgG removal is often the goal of TPE, it is worthwhile to consider certain aspects of IgG metabolism. The subclasses IgG1, IgG2, and IgG4 together constitute about 90% of total IgG. Their catabolic rates are proportional to total IgG level, and their half-lives are therefore inversely proportional to concentration. Animal studies concerning levels of specific antibody were interpreted to show that the synthetic rate for IgG exhibits negative feedback, increasing when IgG or specific antibody levels or both are lower.<sup>26</sup> However, Junghans<sup>27</sup> has shown that "knockout" mice genetically deficient for the FcRn receptor catabolize IgG quite rapidly and maintain very low IgG levels, but they have the same IgG synthetic rate as normal mice. This argues against negative feedback regulation of IgG synthesis and suggests that a reduction in antibody levels induced by TPE would not produce a meaningful "rebound" increase in IgG synthesis. Moreover, serial monitoring of pathologic as well as post-vaccination antibodies in myasthenic patients failed to demonstrate any rebound phenomenon.<sup>28</sup>

A reduction of 80–90% can be obtained with four to six exchanges in 14 days. A typical treatment series for IgG removal consists of five procedures approximately every other day. The effects of a series of TPEs on extravascular, intravascular, and total IgG are shown schematically in Figure 25.2. Treatment of some patients such as those with TTP or acute Guillain–Barré disease might involve plasma exchange daily for several days. There appears to be a limit of the linear removal of antibodies in

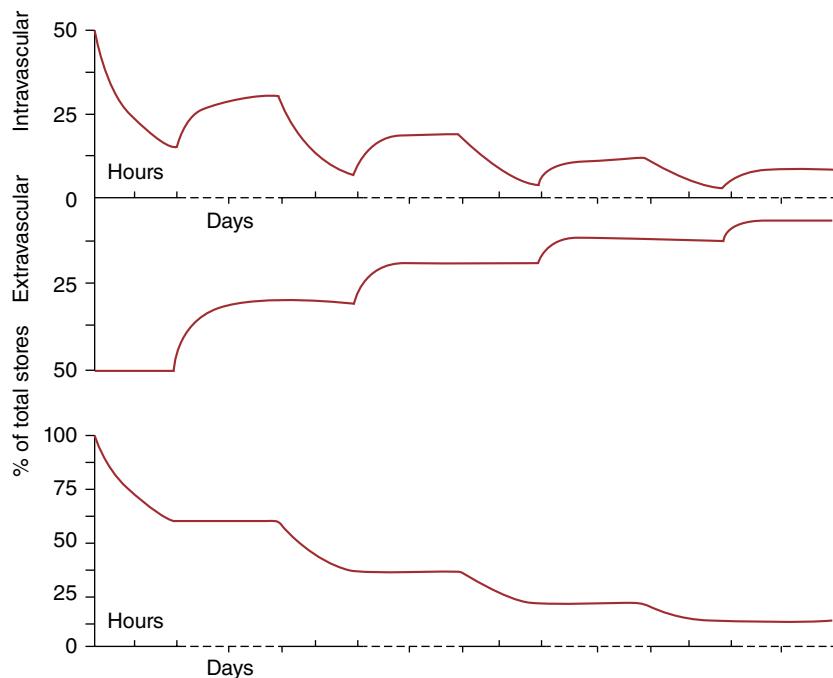

patients undergoing peri-transplant desensitization with TPE and IVIg,<sup>29</sup> likely attributable to a component of maintained antibody synthesis.

A model that takes into account the size of the exchange relative to the patient's blood volume, the amount of material available to exchange, the amount of material in both the intravascular and extravascular compartments, the mobility of the material between the pools, and the production and catabolic rate of the material showed good agreement with in vivo observations in patients with hyperbilirubinemia and hypercholesterolemia.<sup>25</sup> Many of these parameters cannot be measured in vivo. Efforts to estimate them do not fit clinical observations, which is likely due to the dynamic clinical state of patients experiencing disease processes that require therapeutic apheresis.<sup>30</sup>

### Replacement solutions

The goal of plasma exchange is to remove a pathologic material in an euvolemic manner, with minimal perturbation of homeostatic volume status. Saline replacement alone can suffice when only 500–1000 mL of plasma is removed in a manual plasmapheresis, but in order to maintain intravascular volume, a replacement volume of colloid solutions (Table 25.1) equivalent to the removed plasma volume is given during the dynamic fluid exchange. If a patient is hemodynamically unstable, the management of replacement fluids can be adjusted to compensate. This can be done by infusing the replacement solutions at either (1) less than 100% fluid balance (volume replaced is less than volume removed) if the patient is fluid overloaded, or (2) greater than 100% fluid balance (volume replaced is greater than volume removed) if the patient is in need of extra fluids.

For the majority of indications, the standard replacement medium is 5% human serum albumin in normal saline;<sup>32</sup> however, substitution of 25–50% of the total with saline has been shown to be well tolerated in certain patient groups.<sup>33</sup> Although it is a pooled product, 5% albumin is preferred over plasma as a source of replacement colloid because (1) it is treated to inactivate bloodborne

**Figure 25.2** Computer-generated curve estimating amounts of intravascular and extravascular immunoglobulin (IgG; upper curves), and total IgG (lower curve) during a course of four one-plasma volume therapeutic plasma exchanges with an IgG-free replacement medium. Published formulas were used for rates of removal during exchanges and re-equilibration after exchanges. No correction was made for continuing synthesis.

**Table 25.1** Colloid Replacement Fluids for TPE

Fluid	Advantages	Disadvantages
5% Albumin	Virus inactivation Ease of use Reactions rare	High cost Most proteins not replaced
Single-donor plasma*	All proteins replaced	High cost Inconvenient <sup>b</sup> Citrate reactions Transfusion reactions possible Viral infection risk Depletes precious supply
Pooled solvent/detergent-treated plasma	All proteins partially replaced <sup>c</sup> Lipid-coated viruses inactivated Pooled plasma dilutes single donor allergens	Very high cost Inconvenient <sup>b</sup> Citrate reactions Transfusion reactions possible Depletes precious supply
6% Hetastarch	Low cost Viral safety Ease of use Slow catabolism	No proteins replaced Hypotensive reactions Dosage limit

\* Fresh-frozen plasma, plasma frozen in 24 hours, or plasma cryoprecipitate reduced.

<sup>b</sup>Must be thawed before use and must be ABO compatible.

<sup>c</sup>Coagulation factors  $\geq 80\%$  of normal levels.

TPE: therapeutic plasma exchange; US: United States.

pathogens, (2) it can be given without regard to blood type, and (3) it does not require thawing or other preparation before use. The transient depletion of coagulation factors and other plasma proteins that occurs with albumin solution replacement is mild enough that fresh-frozen plasma (FFP) replacement is not typically warranted in patients without known coagulation disorders. An exception to this might be during a series of several daily procedures when it may be prudent to monitor the fibrinogen level and platelet count to assess the need for platelets, FFP, or cryoprecipitate. When there is a need to replace essential plasma constituents, such as with TTP

or depleted coagulation factors, FFP should be used. The advantages of plasma include supplementation of immunoglobulins, antithrombin, and fibrinogen, along with other proteins. The disadvantages of plasma include a viral transmission risk, an increased citrate load, ABO incompatibility risk, allergic reactions, and the potential for sensitization. Partial replacement with saline (crystalloid) can be used; however, this should not exceed 25–30% of the replacement volume.<sup>18</sup>

There are a few circumstances in which the replacement of patient plasma with donor plasma is used. Patients with ITP

customarily receive exchanges with FFP in light of abundant evidence that patients with TTP respond better to plasma than to albumin. Cryoprecipitate-reduced plasma is also effective for this purpose.<sup>19</sup> Some plasma may also be given toward the end of an exchange to patients with preexisting thrombocytopenia or humoral coagulopathy, who are considered to be at increased risk for bleeding complications when the dilutional coagulopathy of an albumin exchange is superimposed, or to patients with ongoing blood loss regardless of pretreatment coagulation status.

One group reported infusing a solution of hydroxyethyl starch (HES), a less costly volume expander, in the early part of an exchange.<sup>20</sup> They reason that recommended dosage limitations for HES will not actually be exceeded because much of the infused HES will be removed in exchange for albumin infused later. This group has seen successes, albeit with a higher incidence of side effects. HES is not recommended for patients with renal impairment, underlying coagulopathy, or a history of hypersensitivity to HES.

The apheresis physician should determine whether any combination of replacement fluids is used and, if so, the relative proportions of each fluid. This should be based upon the patient's cardiovascular stability, underlying disease, frequency of procedures, coagulation status, and cost.

### Complex circuits

Critically ill patients who may be candidates for therapeutic apheresis may have comorbidities that require other extracorporeal interventions. Extracorporeal membrane oxygenation (ECMO) and continuous renal replacement therapy (CRRT) are two common therapies that affect the circuit volume and access placements.<sup>34</sup> The total circuit volume must be added to the patient's total blood volume when performing procedure calculations. For concomitant ECMO procedures, anticoagulation is monitored and adjusted by the perfusionist and so the TPE protocol usually does not require supplemental anticoagulation. Apheresis machines can be directly connected to ECMO devices in various configurations so additional vascular access is not required.<sup>35,36</sup> When CRRT cannot be paused to allow TPE through the existing vascular access, membrane-based TPE or a second catheter may be considered.<sup>5</sup>

### Biochemical changes resulting from plasma exchange

Removal of such a large volume of plasma has several biochemical effects (Table 25.2).<sup>31,37,38</sup> Because some platelets are in the plasma being removed, there is about a 30% decrease in the platelet count, which takes about three days to return to baseline. The changes in the proteins IgG, IgM, IgA, factor V, ferritin, transferrin, lactic dehydrogenase, serum glutamic oxaloacetic transaminase, and alkaline phosphatase closely follow the decrease expected based on the volume of plasma removed. When no FFP is used for replacement, coagulation test results are abnormal at the end of the plasma exchange.<sup>39</sup> For instance, the prothrombin time is usually 20 seconds or more, the partial thromboplastin time is more than 180 seconds, and the fibrinogen is decreased by about 70%.<sup>31,38</sup> These test values return to baseline in about 24 hours, except fibrinogen, which normalizes in 72 hours (Figure 25.3).<sup>31</sup>

Complement components C3, C4, and CH50 can be depleted when albumin is used as the replacement fluid; however, this is unlikely unless plasma exchange is performed daily for several days due to its rapid rate of synthesis.<sup>37</sup>

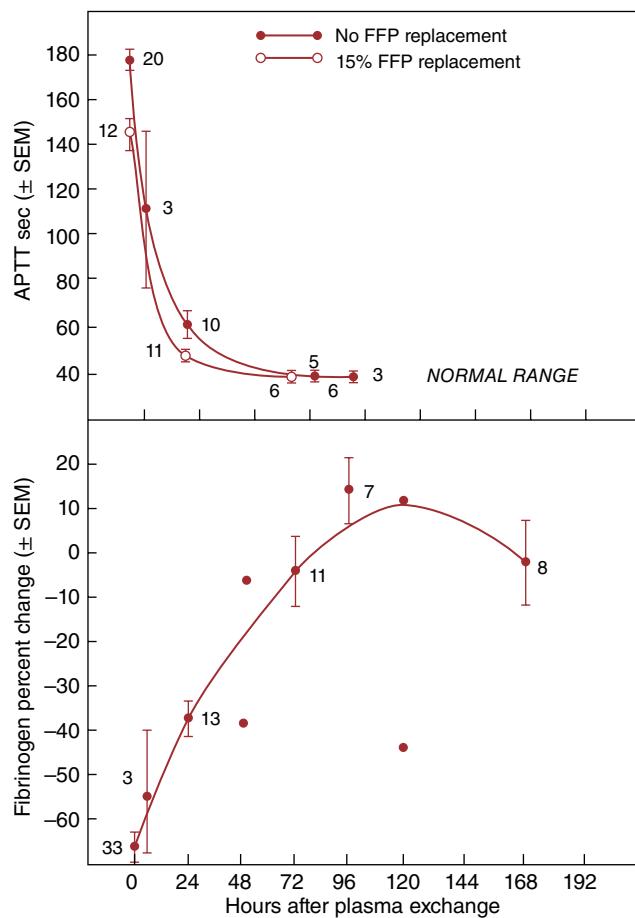

There are no clinically important changes in electrolytes as a result of plasma exchange (Table 25.2). The ionized calcium level is particularly important because citrate is often used as the procedural anticoagulant, exerting this effect by binding calcium. Citrate toxicity thus manifests through hypocalcemia, causing symptoms of paresthesia, muscle cramping, tremors, shivering, lightheadedness, and anxiety; when more severe, it can cause grand mal seizures, tetany, and, most dangerous of all, electrocardiographic abnormalities (Figure 25.4). These serious physiological disturbances occur far before potential bleeding due to a theoretical citrate-induced coagulopathy. If FFP is used for replacement, this provides additional citrate. Studies of citrate and calcium metabolism during normal-donor plateletpheresis have established that symptoms only begin to occur when the rate of citrate infusion exceeds 60 mg/kg/hour.<sup>40-43</sup> Although there is some reduction in ionized calcium levels even when albumin is used as the replacement solution,<sup>44</sup> the citrate infusion rates are below 60 mg/kg/hour and only approach this rate when FFP is used and the flow rates are substantial. Thus, supplementation with calcium during plasma exchange should be based on each patient's situation.

**Table 25.2** Comparison of Changes Induced by Plasma Exchange of 1.0–1.5 Plasma Volumes with Equal Volume Replacement

	Albumin Replacement	FFP Replacement
Hematology	↓ Platelets (30–50%) ↑ Granulocytes (2000–3000/mL) ↓ Hemoglobin (10–15%)	↓ Platelets (30–50%) ↑ Granulocytes (2000–3000/mL) No change in hemoglobin
Proteins	↓ Pathological antibodies (60–75%) (60–75%) ↓ All other proteins (60–75%) Long-term effects depend upon TER, FCR, and S (see text)	↓ Pathological antibodies All other proteins change to approximate levels present in FFP
Coagulation	↓ Individual factors (60–75%) Transient coagulopathy (24–48 hours)	All factors approximate levels in FFP
Electrolytes	Slight ↓ potassium Albumin: Ø Bicarbonate (6 mEq/L) ↑ Chloride (4 mEq/L) PPF: ↑ Bicarbonate ↓ Chloride	↓ Potassium (0.7 mEq/L) ↑ Bicarbonate (3 mEq/L) ↓ Chloride (6 mEq/L)
Citrate and calcium	Slight ↑ citrate (0.2 mM/L) ↓ Total calcium (1.4 mg/dL) ↓ Ionized calcium (0.5 mEq/L)	↑ Citrate (1.1 mM/L) Slight ↓ total calcium (0.3 mg/dL) ↓ Ionized calcium (0.6 mEq/L)

FCC: fractional catabolic rate; FFP: fresh-frozen plasma; PPF: plasma protein fraction; S: synthesis; TER: transcapillary escape rate.

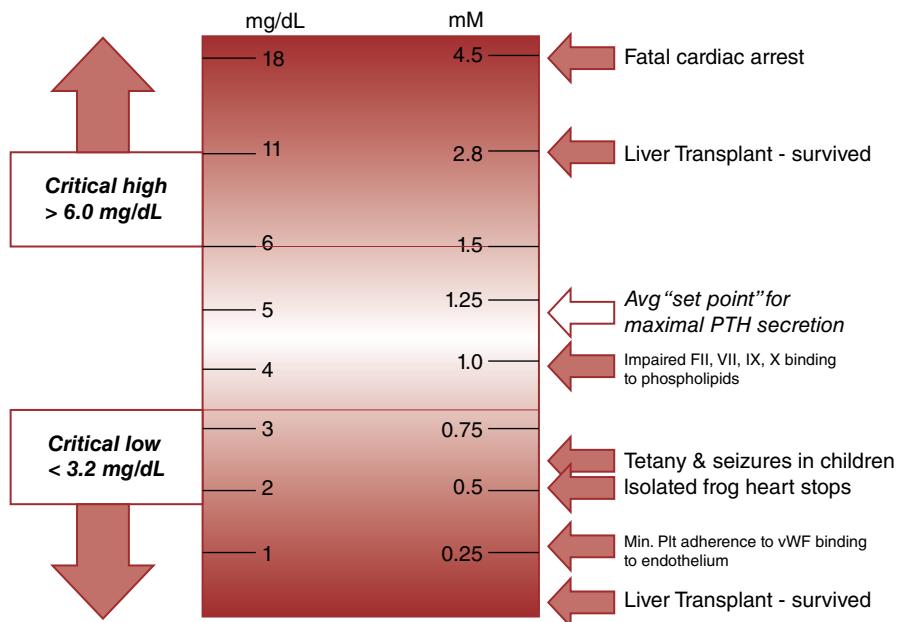

**Figure 25.3** Normalization of fibrinogen level and activated partial thromboplastin time after plasma exchange using albumin for replacement.<sup>31</sup>

The differences between albumin and FFP as replacement solutions are summarized in Table 25.2.

### Complications of plasma exchange

Apheresis of normal donors for the collection of blood components is well tolerated with few side effects and only very rare serious complications. However, therapeutic apheresis is carried out in ill patients who should not be expected to react the same as a healthy donor.<sup>45</sup> Deaths in patients undergoing TPE may be attributable to progression of their serious underlying medical condition.<sup>46,47</sup> The mortality rate is estimated to be three per 10,000 procedures.<sup>48</sup> Most deaths have resulted from cardiac or respiratory arrest, but deaths due to anaphylaxis, pulmonary embolus, and vascular perforation have also been reported.<sup>49</sup> The FDA receives an average of three medical device reports a year related to therapeutic apheresis devices, and in a review in 2015, none of the reports from the prior decade was attributable to the device, verifying the overall safety of this class of instruments.<sup>50,51</sup> The nature and incidence of complications will depend somewhat on the condition of the patient prior to plasma exchange. In one comprehensive report of complications of plasma exchange, side effects occurred during 12% of procedures and involved 40% of patients.<sup>52</sup> The incidence of severe complications was 0.5% of procedures. A national registry of therapeutic apheresis procedures in the former East Germany reported complications in 22% of 1945 procedures in 419 patients.<sup>53</sup> There were severe complications in 2%, including cardiac arrhythmia, bronchospasm, adult respiratory distress syndrome (ARDS), and thromboembolic problems. Of the 419 patients, 87 died; of these, 64 died of their underlying disease and 19 of related causes not thought to be due to the plasma exchange. Twelve patients died during or immediately after the plasma exchange, and four of these fatalities were thought to be due to the apheresis procedure. Two of these fatalities resulted from ARDS, one from myocardial infarction, and one from pulmonary embolus. The complication rate was almost twice as great when FFP was used as the replacement solution

**Figure 25.4** Relationship of clinical signs and symptoms to ionized calcium concentration.

compared to albumin, although the nature of the complications was not described. The Canadian Apheresis Study Group reported that adverse reactions occurred in about 9% of 58,000 procedures.<sup>54</sup> About two-thirds of these were mild, and only 8% were severe, resulting in a severe reaction rate of 7 per 1000 procedures. In a recent four-year series of pediatric ICU patients undergoing over 600 TPE procedures, adverse events were reported in 16.3% of procedures. The majority of complications were related to circuit clotting or vascular access malfunction (69%) without a significant impact to the patient.<sup>55</sup>

The complications of plasma exchange are due to vascular access, replacement solutions, or the procedure itself.

### Vascular access

Placement of vascular access devices is often required, although peripheral venous access should be used whenever possible. There are numerous complications associated with catheters, some of which can be fatal. Vascular access devices may cause either immediate or delayed adverse effects. Immediate adverse effects include bleeding, arterial puncture, arrhythmia, air embolism, thoracic duct injury, catheter malposition, pneumothorax, and hemothorax.<sup>20,56–58</sup> Delayed complications include infection, venous thrombosis, venous sclerosis, catheter migration, catheter embolization, myocardial perforation, and nerve injury.<sup>9,56,57,59–61</sup> Complications with CVCs differ with insertion sites and physician experience, with more than 15% of patients experiencing some type of complication.<sup>62–64</sup> In one study of 385 CVC procedures, there was an overall mechanical complications rate of 33%.<sup>56</sup> Another study showed that 11% (3 of 28) of CVCs placed in patients undergoing TPE procedures experienced life-threatening complications associated with catheter use. These complications were pneumothorax, air embolus upon removal, and catheter-related bloodstream infection.<sup>7</sup> Infectious complications range from 5% to 26%; however, the implementation of procedures such as checklists and care bundles has been shown to reduce catheter-related bloodstream infections.<sup>65–67</sup> The reported rate of vascular access complications associated with TPE procedures is lower when compared to hemodialysis procedures; however, this is likely explained by the longer duration of catheter use along with higher comorbidities in hemodialysis patients.

### Replacement solutions

Complications related to replacement solutions include citrate-induced hypocalcemia, coagulation factor depletion, depletion of other functional proteins, electrolyte abnormalities, and transfusion reactions or disease transmission when plasma is used. Adverse reactions to albumin are rare.<sup>68</sup> Exchanges of plasma for albumin produce temporary deficiencies of other plasma proteins, such as coagulation factors; however, these are usually subclinical, and levels are rapidly restored by ongoing synthesis and reequilibration.<sup>69</sup> Hypotonic replacement solutions should not be infused during the procedure as this can cause hemolysis.

Allergic reactions such as urticaria or mild fevers are rather common even when albumin is the replacement solution. Plasma replacement carries a higher risk of urticarial and hypocalcemic reactions.<sup>70</sup> Progenic reactions can occur to specific lots of albumin.<sup>68</sup> An unusual case of hemolysis due to infusion of hypotonic replacement solution has been reported.<sup>71</sup> The 25% albumin was diluted to 5% in sterile water rather than saline, resulting in the hypotonic solution. Depletion of coagulation factors leading to a bleeding diathesis should not occur because this can usually be

prevented by spacing out TPE procedures or judiciously using an FFP as part of the replacement solutions. The same is true for other functional proteins and electrolytes. If FFP is used, febrile or allergic reactions are more common because of the proteins in the plasma. Antibodies in the plasma may cause transfusion-related acute lung injury (TRALI),<sup>72</sup> and ABO-incompatible plasma can cause hemolysis. When reactions occur during plasma replacement, it may be difficult to identify the offending unit because of the timing or the reaction in relation to the infusion rate.

Inclusion of some proportion of saline in replacement fluids is particularly desirable for the treatment of hyperviscosity syndromes to promote rapid correction of either plasma or whole blood viscosity. There is an economic incentive to substitute some saline for albumin as well. In a study of 3642 procedures, 67% of which used 20% saline and with 105% fluid replacement, the incidence of hypotension increased from 1.5% to 3% in partial-saline procedures compared to all-albumin procedures.<sup>73</sup> Increasing the fluid replacement to 110% can be well tolerated even with up to 50% saline in appropriate patients without vasomotor, renal, or cardiopulmonary comorbidities.

### Apheresis procedure

Mild reactions are rather common during plasma exchange; they are usually chills (possibly due to infusion of room-temperature replacement solutions) or lightheadedness (possibly due to a vagal reaction). These can also be symptoms of hypocalcemia due to citrate infusion, and so when the symptoms begin the operator often slows the blood flow rate and the symptoms subside. Fluid shifts can also contribute to procedural hypotension or hypertension that are usually well tolerated but may be problematic for patients with baseline fluid overload, congestive heart failure, or arrhythmias. Transient hypotension can be caused by hypovolemia resulting from the blood required to fill the extracorporeal circuit. Thus, the volume of the circuit in relation to the patient's blood volume must be considered, and for smaller patients it may be desirable to prime the circuit with albumin. If this is done, the dilutional effect of the priming solution must also be considered. Hypertension can occur if the volume of fluid returned exceeds that removed. Thus, it is important that the operator closely monitor the fluid balance during the procedure.

Anaphylactoid reactions consisting of flushing, hypotension, bradycardia, and dyspnea have occurred in patients taking angiotensin-converting enzyme (ACE) inhibitors for hypertension.<sup>74–76</sup> Bradykinin (BK) causes vasodilation and smooth muscle contraction in some tissues. ACE is the major peptidase that inactivates BK.<sup>76</sup> Patients receiving ACE inhibitor drugs have less ability to inactivate BK and can experience serious hypotension and may not be responsive to fluids.<sup>77</sup> Thus, situations that promote BK release may lead to hypotensive reactions in patients taking ACE inhibitors. This is thought to occur during therapeutic apheresis, possibly due to contact between the patient's blood and the foreign surfaces of plastic bags, tubing, centrifuge systems, and blood filters. Discontinuation of the ACE inhibitor for 24–48 hours before therapeutic apheresis prevents these reactions.<sup>76</sup>

Anticoagulation must be carefully managed during any therapeutic apheresis procedure. Fortunately, clinically serious thromboembolic complications are rare, and the most common clotting issues relate to catheter function or machine flow rates, not patient morbidity. Bleeding complications are mitigated by thoughtful replacement fluid selection and routine use of anticoagulants in the circuit. Citrate is a popular anticoagulant because of its short

half-life and low cost. Complications related to citrate are more likely when a blood product is the replacement fluid (discussed above) since they provide an additional source of citrate and usually begin with perioral and distal paresthesias heralding citrate-induced hypocalcemia, but metabolic alkalosis can also occur. Patients with liver dysfunction, altered mental status, or pediatric patients are at particular risk, but all patients are at risk due to the prolonged exposure throughout the procedure. Patients may also experience gastrointestinal issues, such as nausea or vomiting, and muscle cramps after the early sensory disturbances. In extreme cases, tetany, prolongation of the QT interval, arrhythmias, or hypotension may occur if the deficiency is not treated (Figure 25.4). It may be prudent to evaluate pre-, intra-, and post-procedural ionized calcium levels and perform electrocardiogram monitoring in patients who are unable to reliably communicate symptoms of hypocalcemia (e.g., pediatric and altered mental status patients) in addition to providing empiric calcium repletion during the procedure. Treatment of citrate-related complications consists of either slowing the rate of the procedure or administration of supplemental calcium. If resolution of symptoms does not occur, the evaluation of a magnesium level may be appropriate.

Iatrogenic removal of protein-bound medications or therapeutic antibodies can also be an adverse effect of plasma exchange since it is a nonspecific removal of plasma proteins and their bound analytes. Careful review of the patient's medications beyond ACI inhibitors and therapeutic anticoagulants along with consideration of the volume of distribution, dosing, and pharmacokinetics is important prior to the first procedure.<sup>78,79</sup> Most pharmacologic agents should be administered after, rather than before, a plasma exchange if possible to reduce iatrogenic removal. Agents on a continuous infusion may require intraprocedural monitoring or titration.<sup>80</sup>

### **Therapeutic apheresis in children**

TPE or cytapheresis can be performed on even very small children.<sup>81,82</sup> The major consideration is that the instruments are designed for adults, and thus the extracorporeal volume may be too large for small patients. This can be overcome by priming the instrument with red cells, albumin, or other combinations of fluids. Vascular access can also present additional concerns since insertion and maintenance can be more complicated in children.<sup>83</sup> The blood flow rates through the instrument are not high for adults but may represent a large portion of a small child's blood volume. Therefore, problems can arise quickly if there are difficulties with the lines or blood flow. Also, the rate of return of blood and solutions can be much greater in relation to the total blood volume of a small child, and thus citrate or other complications can occur more frequently than in adults if adjustments in blood flow are not made to reflect the small patient's blood volume.<sup>84</sup> Critically ill pediatric patients are more frequently supported by additional extracorporeal therapies than adults, making the impact of circuit volume an even more important factor in already complex and fragile pathophysiologic states.<sup>85</sup> Nearly a quarter of >1000 apheresis procedures reported from a quaternary pediatric hospital were for indications considered to be controversial or of uncertain benefit, reflecting the additional challenges of consultations for apheresis in children.<sup>86</sup>

### **Diseases treated by plasma exchange**

Apheresis allows for the separation of the different blood elements and nonselective removal of pathogenic cells, antibodies, toxic metabolites, and other plasma molecules. The therapeutic effect is based on different mechanisms, including (1) removing antibodies

directly involved in the pathogenesis of the disease (e.g., autoantibodies against the acetylcholine receptor in myasthenia gravis or alloantibodies causing solid organ transplant rejection), (2) removing toxic metabolites (e.g., acute liver failure), and (3) removing other plasma molecules and proteins (e.g., removal of lipid molecules in familial hypercholesterolemia). Not all diseases in which antibodies play a role in the pathophysiologic mechanism demonstrate a positive clinical response to apheresis treatment. This is the case of dermatomyositis and rheumatoid arthritis among others.

One of the main challenges in apheresis medicine, as in medicine in general, is obtaining high-quality evidence to support therapeutic decisions. There is a limited number of randomized controlled trials evaluating the efficacy of therapeutic apheresis, resulting in decisions made based on low-quality evidence. Some of the factors contributing to the scarcity of clinical studies include the low frequency of the disease, which results in small sample size, the challenges of recruiting large institutions with large apheresis capacity to enroll patients, defining clinical equipoise (i.e., reluctant providers to randomize patients based on their own beliefs), designing a control group (i.e., considering what would be an appropriate placebo), and funding.

The American Society for Apheresis (ASFA) took the lead in appraising the literature and developing guidelines with an indication category system, and evaluating the strength of the evidence using the GRADE system.<sup>87</sup> The guidelines are typically revised every three years, being the eight and last edition published in 2019. Each disease has a fact sheet describing the most relevant aspects of the pathophysiology and the category indication for the use of apheresis. There are currently 84 fact sheets included in the last edition. The indications are classified based on categories: Category I: diseases for which apheresis therapy is a standard first-line therapy; Category II: diseases in which apheresis is a valuable second-line therapy when first-line measures fail or are poorly tolerated; Category III: diseases in which there is uncertainty due to inadequate data or controversy due to conflicting reports; and Category IV: diseases in which there are negative data from controlled trials or anecdotal reports.

In this section, we group diseases classified as categories I and II based on the system involved and provide a brief description of the disease and the evidence to support TPE.

### **Therapeutic plasma exchange for neurologic disorders**

Immune-mediated processes, especially the formation of circulating antibodies to structures in the nervous system, have been implicated in several neurologic diseases, and TPE has become an important therapy for some of them. See Table 25.3 with a list of neurologic conditions classified as categories I or II. Neurologic disease with categories III and IV are not included in this table and can be found in the original publication.

### **Guillain–Barré syndrome**

Guillain–Barré syndrome (GBS) affects the peripheral nervous system. A typical clinical course begins with symmetric distal paresthesias, followed by leg and arm weakness. Symptoms spread proximally and reach a peak of severity by 14–30 days after onset. About one-fourth of patients with GBS have mild illness and remain ambulatory throughout. A nerve conduction defect resulting from demyelination is found in most cases, but there are variants in which axonal damage is evident in motor fibers or both motor and sensory fibers.<sup>88,89</sup>

**Table 25.3** Therapeutic Plasma Exchange for Neurologic Disorders

Disease Name	Indication	Category	Grade
Acute inflammatory demyelinating polyneuropathy (Guillain–Barré syndrome)		I	1A
Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)		I	1B
Myasthenia gravis		I	1B
	Acute, short-term treatment	I	1B
	Long-term treatment	II	2B
<i>N</i> -Methyl-D-aspartate receptor antibody encephalitis		I	1C
Paraproteinemic demyelinating polyneuropathies	IgG/IgA/IgM	I	1B
Acute disseminated encephalomyelitis (ADEM)		II	2C
Lambert–Eaton myasthenic syndrome		II	2C
Multiple sclerosis	Acute attack/relapse	II	1A
Neuromyelitis optica spectrum disorder (NMOSD)	Acute	II	1B
PANDAS	PANDAS exacerbation	II	1B
Phytanic acid storage disease (Refsum's disease)		II	2C
Steroid-responsive encephalopathy associated with autoimmune thyroiditis (Hashimoto's encephalopathy)		II	2C
Voltage-gated potassium channel antibodies		II	1C

PANDAS: pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections.

Source: Based on Padmanabhan *et al.* (2019).<sup>87</sup>

GBS is often associated with a history of recent infection with *Campylobacter jejuni*, cytomegalovirus, Epstein–Barr virus, *Mycoplasma pneumoniae*, or other organisms. It has been postulated that antibodies are formed in response to a strain-specific lipopolysaccharide that is antigenically similar to one of the myelin gangliosides (e.g., GM1 after *C. jejuni* infection).<sup>88,90</sup> Spontaneous recovery is the usual outcome of GBS and may be associated with the decline in antibody levels. Neither oral nor pulse intravenous steroids are helpful in GBS; however, large randomized controlled trials have documented that TPE can shorten recovery time and reduce disability.<sup>91,92</sup>

Later studies have shown that intravenous immunoglobulin (IVIG) is also beneficial in GBS. A large multicenter trial compared IVIG, TPE, and TPE followed by IVIG, with 121–130 patients in each treatment group.<sup>93</sup> The trends favored TPE plus IVIG, although none of the differences was statistically significant. Some authorities now favor IVIG for initial treatment, citing its relative simplicity, wider availability, and lower incidence of adverse effects.<sup>88</sup> Meta-analyses have supported this approach.<sup>94,95</sup>

### Chronic inflammatory demyelinating polyneuropathy

Chronic inflammatory demyelinating polyneuropathy (CIDP) is an acquired neuropathy that may follow either a continuously progressive or an intermittent, relapsing course. Both weakness and sensory loss are usually present, and both distal and proximal sites may be affected. Nerve conduction studies suggest demyelination, which may be apparent in nerve biopsy tissue if this is obtained. Patchy inflammatory infiltrates may be seen in nerve root biopsies. The cerebrospinal fluid usually has a moderately elevated protein concentration and a cell count less than 10/ $\mu$ L.<sup>96</sup> Although it is usually idiopathic, CIDP may also occur in the context of an associated condition, such as inflammatory bowel disease, chronic active hepatitis, connective tissue disease, Hodgkin's disease, human immunodeficiency virus (HIV) infection, or monoclonal gammopathy.<sup>96</sup>

The precise cause of CIDP remains unknown; however, the disease associations, the clinical similarities to GBS, and histopathology suggest an immune process. The presence of a monoclonal protein in some cases points to an antibody mediated disorder, as does the finding that an animal model of CIDP (experimental allergic neuritis) can be passively transferred with serum.

Treatment options include corticosteroids, IVIG or TPE, or a combination of treatments. TPE has been shown to be effective

in improving symptoms in randomized clinical trials.<sup>97–99</sup> Trials comparing TPE vs. IVIG demonstrated similar positive outcomes.<sup>100,101</sup>

### Myasthenia gravis

About 85% of patients with myasthenia have circulating antibodies to a portion of the  $\alpha$ -subunit of the acetylcholine (ACh) receptor molecule (AChR) on the motor end plate of muscle cells. Approximately 10% of the patients will demonstrate antibodies against muscle-specific kinase (MuSK), usually associated with more severe disease; a minority of patients will demonstrate antibodies against lipoprotein receptor-related protein 4 (LRP4) usually associated with less severe presentation.

TPE is a widely accepted therapy for myasthenia; however, it is not recommended for all patients. It is instead reserved for those with severe disease and those who are intolerant or unresponsive to other therapies. Patients whose breathing, swallowing, or walking is inadequate are good candidates for the rapid improvement from TPE, even as an initial treatment.<sup>102</sup> Numerous trials have suggested that TPE can lead to rapid symptomatic improvement in concert with lower levels of circulating AChR antibody and in patients that are refractory to other therapies.<sup>103</sup> TPE has also been effective in patients who test negative for antibody, suggesting that some pathogenic antibodies may not be detected by current assays.<sup>104–106</sup> Myasthenia may respond to IVIG, and it is considered equally effective with TPE.<sup>107</sup> Immunomodulators are also indicated to decrease ongoing antibody production.<sup>108</sup>

### *N*-Methyl-D-aspartate receptor antibody encephalitis

*N*-Methyl-D-aspartate receptor (NMDAR) encephalitis is the most frequent form of autoimmune encephalitis characterized by psychiatric (hallucinations, catatonia, and altered behavior) and autonomic (changes in blood pressure and heart rate, and excess salivation) symptoms. It is most commonly seen in children and young adults with female predominance. Some patients present with an occult tumor, in particular females with ovarian teratoma. Pathophysiology of the disease involves the presence of IgG antibodies directed against NMDAR. First-line treatment options include the treatment of the tumor if present, steroids, TPE, and IVIG. There are small case series evaluating the efficacy of TPE with positive results.<sup>109,110</sup> Second-line therapy includes immunomodulators such as rituximab, mycophenolate mofetil, and cyclophosphamide.

### Paraproteinemic demyelinating polyneuropathies

Patients with monoclonal gammopathies often present with some sort of polyneuropathy. Polyneuropathy classification can be rather complex considering their presentation (acute, subacute, and chronic), nerves involvement (sensory and/or motor fibers), and type of immunoglobulin involved (IgG, IgA, and IgM).

Most clinical features of neuropathies associated with monoclonal gammopathy are similar to CIDP, and although progression may be slower overall, spontaneous improvement is uncommon. The prevalence of neuropathy is higher in patients with IgM paraproteins than in those with IgG or IgA except in osteosclerotic myeloma, where the prevalence of neuropathy with IgG or IgA proteins is quite high, sometimes as a part of the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes). Patients with POEMS do not benefit from TPE. Patients with multiple myeloma or Waldenström's macroglobulinemia should be treated with appropriate chemotherapy and may experience improvement in the neuropathy as a result. Patients with IgM-associated neuropathy can present antibodies against myelin-associated glycoprotein (MAG). These patients typically present with distal sensory involvement. Current available data using immunotherapies, including the use of TPE, demonstrated very limited benefit on these patients.<sup>111</sup>

TPE can be helpful in MGUS-associated neuropathy. In a sham-controlled trial in 39 patients, twice-weekly exchange led to improvement in disability scores, weakness scores, and electrodiagnostic parameters in the blinded portion of the trial. Scores also improved in sham-treated patients who received true TPE in an open follow-up study.<sup>112</sup> In this and other studies, a response was noted more frequently in patients with IgG and IgA paraproteins than in those with IgM.

### Acute disseminated encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) affects the central nervous system, in particular the white matter of the brain and the spinal cord. Pathophysiology of the disease involves demyelinating lesions associated with an autoimmune destruction of oligodendrocytes. The onset of neurologic symptoms usually follows a viral or bacterial infection and includes acute encephalopathy and multifocal neurologic deficits such as weakness, ataxia, seizures, and others. It is more frequent in children and has good prognosis. The diagnosis is made based on clinical symptoms and MRI findings demonstrating demyelinating lesions. Treatment involves immunosuppressive medication, including high-dose corticosteroids. Although there are no clinical trials to support its use, TPE has demonstrated positive outcomes and it is considered second-line therapy for patients who do not respond to steroids.<sup>113</sup>

### Lambert-Eaton myasthenic syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is characterized by muscular weakness and fatigue. The syndrome is most often seen in patients with autoimmune diseases or cancer, with almost half of cases being in patients with small cell lung cancer. The pathophysiology of LEMS involves the neuromuscular junction affecting the nerve cell ending. Autoantibodies directed at the P/Q type voltage-gated calcium channel (VGCC) are found in the majority of patients. These antibodies reduce the amount of ACh released during depolarization events, causing weakness in affected skeletal muscles as well as dysfunction in autonomic nerves.<sup>114,115</sup>

Curiously, cholinesterase inhibitors are not as effective in LEMS as they are in myasthenia gravis.<sup>116,117</sup> More useful are agents that

prolong nerve action potentials by blocking voltage-gated potassium channels (VGKCs), such as aminopyridines, which are the first choice for symptomatic control in LEMS. Immunosuppressive drugs such as prednisone and azathioprine may also be beneficial in LEMS, and paraneoplastic cases may respond to specific antitumor therapy.<sup>114,116</sup>

TPE has demonstrated positive results in LEMS in the context of case series and case reports. Responses are usually less dramatic than those seen in myasthenia gravis. IVIG has also been reported to be active in both the short and long terms.<sup>116,118</sup>

### Multiple sclerosis

Multiple sclerosis (MS) is a disease characterized by localized neurologic dysfunction that is caused by demyelinated "plaques" in the CNS. The clinical presentation can be in the form of acute attacks that resolve fully or partially (relapsing-remitting), seen in approximately 70% of patients, or the form of a slow, continual progression of disease (chronic progressive). The frequency of attacks in relapsing-remitting MS tends to decrease with disease duration, and over time some patients evolve to a chronic progressive pattern.<sup>119</sup>

The radiologic hallmark of MS is the presence of discrete areas or plaques of demyelination in white matter, which are easily visualized with magnetic resonance imaging (MRI). The mechanism of the disease remains unexplained; it is suspected a combination of humoral and cellular immune system dysregulation.<sup>105,120</sup> These demyelinated plaques have four distinct histopathologic features, with the type II characterized by the deposition of complement and antibodies.<sup>111</sup> Plasma exchange is most effective in patients with type II lesions.<sup>121</sup>

Autoantibodies to myelin basic protein (MBP) or myelin oligodendrocyte glycoprotein (MOG) can be found both in CNS lesions<sup>122</sup> and in serum<sup>123</sup> in some MS patients. Although they are predictive of progression to MS in patients with a clinically isolated demyelinating event,<sup>124</sup> such antibodies do not produce MS in experimental animals.<sup>125</sup> Also, anti-MOG does not correlate with histopathologic classification or apparent responsiveness to TPE.<sup>126</sup>

The study of treatments for MS is complicated by the natural history of the disease, particularly the tendencies for acute attacks to subside and for attack frequency to decline, but also by other spontaneous fluctuations in disease activity. Immunosuppressive and immunomodulatory agents have been the mainstays of drug therapy in MS. Resolution of acute attacks is thought to be hastened by brief courses of either glucocorticoids or adrenocorticotropic hormone. The relentless progression of disability is probably not halted by these measures, although aggressive treatment of optic neuritis with intravenous steroids may delay the onset of frank MS that often follows. Immunomodulatory monoclonal antibodies, such as alemtuzumab, daclizumab, natalizumab, and rituximab, were also investigated with mixed results.<sup>127-129</sup>

The rationale for TPE in MS is uncertain, given the paucity of evidence that any circulating factor has a role in the etiology of acute attacks or chronic progression. TPE has nevertheless been used, and encouraging results have been reported from uncontrolled studies.<sup>130,131</sup> TPE has better outcomes when used in acute attacks and little or no value in chronic/progressive MS.

### Neuromyelitis optica spectrum disorder (NMOSD)

Neuromyelitis optica, also known as Devic's disease, is a demyelinating autoimmune inflammatory process affecting, in particular, the optic nerve and spinal cord. The spinal cord is typically affected in the form of longitudinal extensive transverse myelitis. Other areas of the brain that can be affected and are used as diagnostic criteria.<sup>132</sup>

The disease can present as an isolated acute attack (monophasic, minority of patients) or as a relapsing disease. It affects all age groups, and affects disproportionately more females and individuals of African descent.<sup>133</sup> NMOSD is associated with the presence of serum aquaporin-4 immunoglobulin G antibodies (AQP4-IgG) in approximately 70% of the patients; autoantibodies to myelin oligodendrocyte glycoprotein or anti-MOG have also been found in these patients. Treatment of acute attacks includes high-dose steroids. TPE is reserved for patients with severe manifestations or not responsive to steroids.<sup>134,135</sup>

### Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS)

PANDAS is a pediatric syndrome characterized by the sudden onset of a neuropsychiatric symptoms after a group A streptococcus infection. These symptoms include obsessive compulsive disorder, attention disorders, tics, and abnormal movements such as choreoathetosis and catatonia. It typically affects males more than females between 7 and 9 years of age. A crossreactive antibody response to streptococcal antigens could mediate symptoms in some of these patients. The first line of therapy includes antibiotic treatment against *Staphylococcus*, combined with psychiatric medications such as diazepam, valproic acid, carbamazepine, and haloperidol. For more severe or refractory cases, IVIG and TPE are considered second-line therapy.<sup>136</sup> Sydenham chorea is a related movement disorder that may follow a group A streptococcal infection in children. Patients with Sydenham chorea may also exhibit obsessive-compulsive symptoms, and it is considered a neuropsychiatric manifestation of acute rheumatic fever. TPE is not considered second-line treatment, and its use is not routinely recommended.<sup>137</sup>

### Phytanic acid storage disease (Refsum's disease)

Refsum's disease results from deficiency of the peroxisomal enzyme phytanoyl-CoA hydroxylase, which participates in the degradation of phytanic acid by  $\alpha$ -oxidation. Accumulation of diet-derived phytanic acid in plasma lipoproteins and in tissue lipid stores leads to symptoms, which may include peripheral neuropathy, cerebellar ataxia, retinitis pigmentosa, anosmia, deafness, ichthyosis, renal failure, and arrhythmias. Slow progression is the usual course, but rapid deterioration and even sudden death may follow a marked increase in plasma phytanic acid.<sup>138,139</sup>

Primary treatment is based on the restriction of dietary intake of phytanic acid via dairy products, meats, and fats. It leads to gradual clearing of phytanate stores by slow  $\omega$ -oxidation and gradual symptomatic improvement in most patients. Appropriate caloric intake must be maintained; however, because extreme dietary restrictions may cause the mobilization of calories from endogenous fat, increasing plasma phytanic acid levels acutely and resulting in clinical exacerbations. TPE will remove large quantities of phytanic acid incorporated into plasma lipids.<sup>140</sup> Apheresis therapy is most appropriate for patients who have very high plasma phytanate levels and an associated exacerbation of symptoms. Skin disease, neuropathic symptoms, and ataxia usually improve as plasma levels drop. Cranial nerve defects usually do not.<sup>140</sup>

### Steroid responsive encephalopathy associated with autoimmune thyroiditis (Hashimoto's encephalopathy)

Hashimoto's encephalopathy is characterized by acute onset of encephalopathy, high serum concentration of antithyroid antibodies, and responsiveness to glucocorticoids. Most patients present with seizures, psychosis, stroke-like symptoms, and subclinical

hypothyroidism, but normal thyroid function or hyperthyroidism can be present.<sup>141</sup> Antithyroid peroxidase (anti-TPO) and antithyroglobulin can be present, but their role in the pathophysiology of the disease is controversial. Psychiatric medication and high-dose steroids are the first-line treatment with excellent response. TPE and IVIG are considered second-line therapy for patients who do not respond to steroids.<sup>142</sup>

### Voltage-gated potassium channel antibody (VGKC) related diseases

Voltage-gated potassium channels modulate neuronal excitability by returning the polarized cells to a resting state. Several antigens are targeted for autoantibody formation, including leucine-rich glioma inactivated 1 (LGI1), contactin-associated protein-2 (CASPR2), and contactin-2. LGI 1 has been associated with limbic encephalitis, characterized by amnesia, seizures, disorientation, psychiatric disturbances, and neuromyotonia.<sup>143</sup> CASPR2 has been associated with Morvan syndrome, characterized by limbic encephalitis, neuromyotonia, pain, and autonomic dysfunction.<sup>144</sup> First-line therapy includes treatment for underlying neuropsychiatric symptoms with antiepileptic medication and immunotherapy including steroids and IVIG. TPE is considered second-line therapy, and its efficacy has been described in small case series and case reports.<sup>143,145</sup>

### Therapeutic plasma exchange in hematologic disorders

There are several hematological conditions for which TPE is used as a first- or second-line therapy (Table 25.4). TPE has been attempted as a therapeutic tool in many other hematological conditions with varied therapeutic results. These conditions are classified as Category III, implying that TPE treatment has been attempted but its efficacy is not yet determined. These diseases include but are not limited to the removal of coagulation factor inhibitors; hemolysis, elevated liver enzymes, and low platelet count (HELLP); hemophagocytic lymphohistiocytosis (HLH); heparin-induced thrombocytopenia and thrombosis (HIT/HITT); and refractory immune thrombocytopenia purpura (ITP) and post-transfusion purpura (PTP). In this section, we describe conditions for which TPE is considered first- or second-line therapy.

### TPE for thrombotic microangiopathies (TMAs)

Frequent indications for TPE include diseases presenting with thrombotic microangiopathy (TMA), including TTP. TMA is characterized by occlusive microvascular disease and intraluminal

**Table 25.4** Hematological Conditions for Which TPE is Considered First- or Second-Line Therapy.

Disease Name	Indication	Category	Grade
Thrombotic thrombocytopenic purpura		I	1A
Complement-mediated thrombotic microangiopathy	Factor H autoantibody	I	2C
Drug-associated thrombotic microangiopathy	Ticlopidine	I	1B
Hyperviscosity in hyperimmunoglobulinemia	Symptomatic Prophylaxis for rituximab	I	1B 1C
Catastrophic antiphospholipid syndrome (CAPS)		I	2C
Autoimmune hemolytic anemia: severe	Severe cold agglutinin disease	II	2C
Cryoglobulinemia	Symptomatic/severe	II	2A

thrombus formation, and manifests clinically as microangiopathic hemolytic anemia and thrombocytopenia. Diseases presenting with TMA can present with overlapping symptoms that pose a challenge when making a diagnosis and deciding treatment. TMAs have different pathophysiologic mechanisms that will determine the type of treatment indicated. Some examples of TMA include congenital TTP (cTTP), immune TTP (iTTP), infection-associated hemolytic-uremic syndrome (IA-HUS), complement-mediated hemolytic-uremic syndrome (CM-HUS) solid organ and bone marrow transplant associated TMA, disseminated intravascular coagulation (DIC), *Streptococcus pneumoniae*, Cobalamin C deficiency, connective tissue diseases, pregnancy-associated TMAs (HELLP syndrome and pre-eclampsia), drugs (most relevant ticlopidine, gemcitabine, bleomycin, mitomycin, and others), pancreatitis, and malignancies.<sup>146</sup> In this section, we discuss diseases presenting with TMA for which TPE is indicated as a first- or second-line therapy.

### **Thrombotic thrombocytopenic purpura**

TTP is characterized by microangiopathic hemolytic anemia and thrombocytopenia. Central nervous system changes, fever, and renal abnormalities may be seen in advanced cases, although frank renal failure is unusual. Idiopathic TTP was formerly assigned a mortality rate of 90%, but empiric studies in the 1970s and 1980s and a clinical trial in the 1990s demonstrated much improved survival in patients receiving daily TPE with plasma replacement.<sup>147</sup> The pathogenesis of TTP involves the severe deficiency (<10%) of the metalloproteinase ADAMTS13 that cleaves ultralarge von Willebrand factor (vWF) multimers secreted by endothelial cells, yielding the smaller vWF polymers found in normal plasma.<sup>148,149</sup> Severe ADAMTS13 deficiency can be acquired (immune TTP [iTTP]) or genetic (Upshaw-Schulman syndrome). A genetic deficiency should be suspected in children and pregnant women presenting with TTP, which can be confirmed with genetic testing.<sup>150</sup> iTTP is most common in adults and it is confirmed by the presence of an autoantibody with ADAMTS13 inhibitor effect.<sup>148,149,151,152</sup>

Immune and congenital forms have similar clinical presentation; persistence of ultrahigh-weight vWF in the circulation promotes inappropriate adherence of platelets to endothelial cells and to each other, leading to consumptive thrombocytopenia and to microvascular obstructions that cause mechanical trauma to red cells and varying degrees of end-organ ischemia. The clinical presentation and severity are quite variable, with a range that goes from patients who present with asymptomatic thrombocytopenia to patients who present with minor symptoms and sudden death.<sup>153</sup> Relapses after the initial episode are common.

ADAMTS13 activity during remission is variable and unpredictable.<sup>153</sup> Response to treatment is also variable, with patients who recover clinically with increased ADAMTS13 activity after a series of daily TPE, and no relapse. There are other patients with refractory disease requiring prolonged TPE treatment and intensive immunosuppression presenting with both decreased or normal ADAMTS13 activity and no relapse, and other patients with refractory disease and relapses.<sup>153</sup>

First-line therapy includes a combination of TTP and steroids. Plasma infusion can be started if TPE is not readily available. Periodic plasma infusion may prevent attacks in congenitally deficient patients by supplying active enzyme.<sup>152</sup> Idiopathic cases respond better to TPE (78% response rate vs. 63% for plasma infusion),<sup>147</sup> presumably because exchanges remove inhibitory antibody

as well as replace the deficient enzyme.<sup>147</sup> TPE is performed daily until the platelet count has normalized.

Rituximab has been used in different situations: in combination with TPE as first-line therapy<sup>154,155</sup> or for patients who are refractory or fail TPE and steroids, and to prevent relapses without TPE.<sup>156</sup>

Caplacizumab, an anti-von Willebrand factor humanized, bivalent variable-domain-only immunoglobulin fragment, has recently been evaluated in two clinical trials for the treatment of TTP. Caplacizumab inhibits interaction between von Willebrand factor multimers and platelets. The TITAN trial included 75 patients who were randomized to Caplacizumab or placebo. Patients in the intervention group recovered faster but had an increased risk of bleeding.<sup>157</sup> The HERCULES trial included 145 patients with a diagnosis of TTP undergoing TPE. The addition of caplacizumab resulted in faster recovery of platelet counts and decreased number of exacerbations (defined as disease recurrence during therapy or within 30 days of stopping TPE) but increased number of relapses (defined as disease recurrence between 30 days and 12 months of stopping TPE). Mucocutaneous bleeding was more frequent in the Caplacizumab group.<sup>158</sup>

The clinical manifestation and response to the treatment of patients with TTP is quite heterogeneous. The best treatment approach should be evaluated in the context of clinical presentation, previous events, and level of evidence supporting the efficacy of the interventions being considered.<sup>159</sup>

### **Complement-mediated thrombotic microangiopathy**

Complement-mediated thrombotic microangiopathy (CM-TMA), formerly known as atypical hemolytic uremic syndrome (aHUS), is a rare, life-threatening disorder associated with dysregulation of the alternative pathway of the complement system.<sup>160</sup> It typically presents in children and young adults with TMA, diarrhea, and acute kidney failure. Multiple mutations affecting complement regulatory proteins have been identified. Mutations that result in loss of function of complement regulatory proteins include complement factor H (CFH), complement factor I (CFI), thrombomodulin (THBD), or CD46/membrane cofactor protein (MCP). Mutations in complement activating proteins including complement factor B (CFB) and C3 can result in gain of function with subsequent dysregulation.<sup>161</sup> The diagnosis is challenging and other causes of TMA need to be ruled out. It is common to start treatment with TPE until the diagnosis of CM-TMA is confirmed through genetic analysis. Eculizumab, a monoclonal antibody directed against C5 is considered first-line therapy. The benefit from TPE is controversial, but some patients do benefit from it, most likely due to the removal of mutated complement proteins and substitution with normal proteins present in donor plasma.<sup>162,163</sup>

**Thrombotic microangiopathy, drug associated, ticlopidine**  
TMA has been observed in some patients taking the antiplatelet drugs ticlopidine<sup>164</sup> and clopidogrel (although this is an ASFA Category III indication).<sup>165</sup> Antibody to ADAMTS13 has been detected in such case,<sup>166</sup> and TPE has been reported to improve outcome (76% survival vs. 50% for unexchanged patients in a retrospective study of ticlopidine recipients).<sup>164</sup>

### **Hyperviscosity in hypergammaglobulinemia**

Hyperviscosity was the first condition to be treated successfully with manual plasmapheresis, the precursor to TPE. The full-blown syndrome consists of neurologic symptoms, a bleeding diathesis, a peculiar retinopathy marked by alternating dilated and constricted

segments in retinal veins, and hypervolemia caused by expansion of plasma volume. Symptoms are uncommon if the relative serum viscosity is below four and become more likely when it exceeds six. The hyperviscosity syndrome is most often seen in patients with Waldenström's macroglobulinemia, who have IgM paraproteins, but it may also occur in multiple myeloma.<sup>167,168</sup>

At higher paraprotein levels, a relatively large change in viscosity may follow a relatively small change in concentration. It is this non-linear relationship that allowed the two-unit manual plasmapheresis technique available in the 1950s to lower viscosity enough to relieve symptoms. Because most IgM paraproteins are roughly 80% intravascular, the same relationship also predicts that a one plasma-volume automated exchange will provide a wide margin of safety and can therefore be repeated less frequently for hyperviscosity than is necessary for many other conditions. Viscosity measurements should guide therapy, but treatment every 1–2 weeks may be adequate.<sup>167</sup>

Paraproteins may interfere in platelet and clotting factor interactions in the absence of hyperviscosity. Such coagulopathies are found in 60% of patients with macroglobulinemia, 40% of patients with IgA myeloma, and 15% of patients with IgG myeloma.<sup>169</sup> In instances that are clinically significant, TPE therapy can help restore adequate hemostasis.

TPE is considered first-line therapy for patients with symptomatic hyperviscosity and as a prophylactic treatment for patients receiving treatment with rituximab. Note that TPE provides symptomatic relief but has no effect on underlying disease process. Treatment with rituximab can result in transient increase of circulating IgM and subsequent hyperviscosity in patients at risk, including those with a baseline elevated serum viscosity.<sup>170</sup>

### Catastrophic antiphospholipid syndrome (CAPS)

Catastrophic antiphospholipid syndrome (CAPS) is a life-threatening autoimmune disease characterized by microvascular venous or arterial thrombosis resulting in multiorgan failure. The disease is characterized by the persistent presence of autoantibodies against phospholipids present in a variety of cells. These antibodies have a prothrombotic effect inducing endothelial, platelet, and coagulation cascade activation, affecting the microvasculature and resulting in acute thrombotic microangiopathy. Virtually any organ can be affected, but life-threatening presentations usually involve the brain, kidneys, lungs, and heart. Patients can present with stroke, acute kidney failure, thrombocytopenia, and anemia. These signs and symptoms can overlap with TTP, which should be considered in the differential diagnosis.<sup>171</sup> CAPS can be precipitated by an acute event such as trauma, infection, or inflammatory process.<sup>172</sup> Laboratory diagnostic criteria include the presence of lupus anticoagulant, moderate-to-high titer anticardiolipin antibodies, and/or moderate-to-high titer anti-b2-glycoprotein I antibodies.<sup>173</sup> The first line of therapy for patients with CAPS is immediate anticoagulation to halt the progression of thrombosis. TPE and immunomodulatory agents, such as IVIG, prednisone, and cyclophosphamide, are also part of the first-line treatment to remove and decrease antibody levels, respectively.<sup>173</sup>

### Autoimmune hemolytic anemia (AIHA)

AIHA is caused by autoantibodies to red cells antigens. Such antibodies are classified as either "cold" or "warm" agglutinins, depending on the temperature of maximal activity. Cold agglutinins are usually IgM antibodies directed against the I/i antigens; they bind most strongly at low temperatures and may produce a syndrome of complement-mediated intravascular hemolysis (cold agglutinin

disease [CAD]). Warm agglutinins are usually IgG, bind stronger at body temperature, and produce a predominantly extravascular hemolytic syndrome (warm autoimmune hemolytic anemia [WAIHA]). Autoimmune hemolytic anemia can be idiopathic but can also be associated with infections, lymphoproliferative disorders, or other autoimmune diseases. The direct antiglobulin test (DAT) is positive for 3d complement in CAD, and for IgG and sometimes complement in WAIHA.

Most patients with warm autoantibodies do not develop hemolysis, but the patients who do develop hemolysis will need treatment. Standard therapy is aimed at lowering antibody production and inhibiting destruction of sensitized cells. Combined treatment of prednisone with rituximab is considered first-line treatment, and IVIG and splenectomy are often effective.<sup>174</sup> Other immunosuppressive drugs, such as cyclophosphamide, azathioprine, dapsone, and others, have been used for refractory or recurrent disease.<sup>175</sup> TPE is not routinely used as a therapeutic strategy.<sup>176,177</sup>

Pharmacological treatment CAD is typically more challenging and steroids have demonstrated marginal benefits.<sup>178</sup> First-line therapy include rituximab and bendamustine therapy.<sup>179</sup> Complement inhibitors, such as the monoclonal antibody against C1 sutimlimab, demonstrated to be safe and efficacious in stopping hemolysis.<sup>180</sup> Other complement inhibitors directed against more downstream complement proteins, such as eculizumab that inhibits C5, also demonstrated efficacy in stopping hemolysis.<sup>181</sup> Because the IgM antibodies in CAD are predominantly intravascular and only loosely bound to cells, their removal by TPE relatively more efficient when compared to IgG antibodies. TPE is considered second-line therapy, and it is typically used in more severe or refractory cases or before surgical procedures that require hypothermia.<sup>182</sup>

### Cryoglobulinemia

Cryoglobulins are abnormal serum proteins that precipitate reversibly at 4 °C; some will precipitate at higher temperatures. Such precipitates always contain immunoglobulin, and immunoelectrophoretic or immunofixation analysis allows distinction of three types. Type I cryoglobulins consist of a single species of monoclonal immunoglobulin. These are usually found in B-cell lymphoproliferative disorders such as myeloma or Waldenström's macroglobulinemia. Cryoglobulin levels are often quite high (>500 mg/dL) and may cause Raynaud phenomenon or acral necrosis due to microvascular obstruction, as well as other symptoms. Type II cryoglobulins contain both monoclonal and polyclonal immunoglobulins. The former is usually an IgM with anti-IgG specificity, and the latter is polyclonal IgG bound to the IgM in an immune complex. Most cases occur in the context of chronic hepatitis C infection. They typically manifest a cutaneous vasculitis on the lower extremities and may have visceral manifestations of immune complex disease as well.<sup>183</sup> Type III cryoglobulins are mixed polyclonal, often with IgM anti-IgG that binds IgG in immune complexes. These may arise in acute infections, such as hepatitis B, or in chronic inflammatory states, such as severe rheumatoid arthritis. Clinical manifestations resemble serum sickness.

If there is an underlying condition, cryoglobulin levels and related symptoms may decrease with the treatment of this primary disorder, for example chemotherapy for myeloma or interferon for hepatitis C virus infection.<sup>184</sup> For idiopathic and secondary cases of mixed cryoglobulinemia, prednisone alone or combined with rituximab, azathioprine, or cyclophosphamide have been proven to be effective.<sup>185</sup> Alkylating agents may be useful in patients with severe symptoms resistant to prednisone.

TPE will reduce cryoglobulin levels and control symptoms, even in the absence of other treatments,<sup>186,187</sup> but inconvenience and expense mitigate against such use. It should be started promptly for patients who seek treatment for severe acral ischemia or visceral manifestations of vasculitis, in whom it can help achieve control of symptoms until immunomodulatory therapy takes hold.<sup>188</sup> Patients with chronic vasculitic skin ulcers may also benefit.<sup>189</sup> In all cases, replacement fluids should be warmed to body temperature before infusion.

### TPE in other immunologic and metabolic disorders

TPE has been used as a therapeutic tool in a number of rheumatic diseases and other diseases that are considered to have an immune or autoimmune etiology (see Table 25.5). Not every disease that is antibody mediated benefits from TPE. In this section, we discuss diseases for which TPE is considered first- or second-line therapy.

#### Goodpasture syndrome

Goodpasture syndrome (GPS) is characterized clinically by pulmonary hemorrhage and rapidly progressive glomerulonephritis. Light microscopy of renal biopsies shows crescent formation in many glomeruli, and immunofluorescent and electron microscopy reveal linear subendothelial immune deposits that may also be evident in a lung biopsy. In 95% of cases, there is a circulating antibody that binds to glomerular basement membrane (anti-GBM). Such antibodies are specific for a noncollagenous sequence near the carboxy terminus of the  $\alpha 3$  chain of type IV collagen, which is found in appreciable quantities only in renal and pulmonary basement membranes. Untreated GPS progresses quickly and relentlessly, and most patients die of uremia or complications of lung hemorrhage.<sup>190</sup>

The preferred treatment for GPS is high-dose prednisone and cyclophosphamide, combined with intense TPE, to quickly reduce anti-GBM levels and minimize progression of tissue damage.<sup>191</sup> Exchanges are usually carried out daily and may be continued for up to two weeks. A single controlled trial failed to show an advantage for GPS patients who received TPE; however, this study has been largely discounted because the TPE schedule (every three days) was not sufficiently aggressive and because the extent of renal damage at entry was worse in the TPE group than in controls.<sup>192</sup> Early treatment is recommended because patients who are already dialysis-dependent at the onset of TPE are unlikely to recover renal function.<sup>193</sup> Patients whose renal biopsies show irreversible lesions

are not likely to benefit from TPE unless they also have pulmonary hemorrhage. Patients affected with diffuse alveolar hemorrhage have a very good response to TPE.

#### ANCA-associated vasculitis

ANCA-associated vasculitis (AAV) is an autoimmune disorder characterized by necrotizing inflammation of small- and medium-sized vessels and the presence of antineutrophil cytoplasmic antibodies (ANCA). There are clinical diseases associated with AAV, including granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic GPA (EGPA). The major antigens targeted by ANCA are proteinase 3 (PR3) and myeloperoxidase (MPO). Most patients present with renal disease in the form of rapidly progressive glomerulonephritis.<sup>194</sup>

First-line therapy of the disease to induce remission includes glucocorticoids in combination with either cyclophosphamide and rituximab, followed by maintenance therapy with low-dose steroids combined with azathioprine, mycophenolate mofetil, or rituximab. When compared to glucocorticoids alone, TPE was shown to be effective in increasing renal function in patients who did and did not require dialysis.<sup>195,196</sup> In contrast, a recent randomized clinical trial reported no benefit in mortality or end stage kidney disease when plasma exchange was used in patients receiving either low- or high-dose steroids.<sup>197</sup> A recent meta-analysis including five randomized clinical trial and 937 patients comparing TPE vs. no TPE and TPE vs. steroids concluded that there was no difference in clinical outcomes when TPE was used. Most importantly, TPE is not without risks and adds significant expense to the treatment. Careful consideration should be made when evaluating TPE indication.

#### Vasculitis with hepatitis B-associated polyarteritis nodosa

Polyarteritis nodosa (PAN) is characterized by necrotizing vasculitis affecting medium-sized arteries. It can affect any organ, most commonly the skin, peripheral nervous system, and visceral vessels, but typically does not affect the lungs. The underlying pathophysiology involved the immune-complex deposition with antigen excess. PAN can be idiopathic, or can present as two variants of clinical forms, including cutaneous PAN and hepatitis B infection-associated PAN (HB-PAN).<sup>198</sup> Idiopathic and cutaneous forms are typically treated with corticosteroids with or without cyclophosphamide. Treatment for HB-PAN involves antiviral therapy (vidarabine, interferon- $\alpha$ , and lamivudine) combined with TPE.<sup>199,200</sup>

#### Focal segmental glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) is one of the leading cases of end stage renal disease in the United States. It is characterized by podocyte injury of different underlying pathologic mechanisms including primary (idiopathic) and secondary forms. Secondary forms include genetic mutations (more than 40 genes affected), adaptive FSGS (excessive nephron workload or reduced nephron capacity), APOL1 FSGS (patients of sub-Saharan African descent), infection/inflammation associated FSGS (HIV, CMV, EBV, and others), and medication associated FSGS (interferon- $\alpha$ ,  $\beta$ , or  $\gamma$ ; bisphosphonates, sirolimus, and others). There are also distinct morphological patterns, including the tip lesion and the collapsing variant. The combination of clinical presentation, classification, and histological patterns needs to be considered to tailor treatment options and determine expected efficacy.<sup>201</sup> First-line therapy for primary FSGS includes prednisone with or without cyclophosphamide, and calcineurin inhibitors for patients who are

**Table 25.5** Immunologic and Metabolic Disorders

Disease Name	Indication	Category	Grade
Antiglomerular basement membrane disease (Goodpasture's syndrome)	Diffuse alveolar hemorrhage (DAH)	I	1C
Vasculitis, ANCA-associated	Dialysis independence	I	1B
	Rapid progressive glomerulonephritis	I	1A
	Diffuse alveolar hemorrhage (DAH)	I	1C
Vasculitis, hepatitis B polyarteritis nodosa		II	2C
Focal segmental glomerulosclerosis (FSGS)	Recurrent in transplanted kidney	I	1B
Wilson's disease	Fulminant	I	1C
Myeloma cast nephropathy		II	2B
Overdose, envenomation, and poisoning	Mushroom poisoning	II	2C
Systemic lupus erythematosus	Severe	II	2C
Thyroid storm		II	2B

resistant to steroids.<sup>202</sup> Other immunosuppressive medications such as azathioprine and levamisole have also been used.<sup>203</sup> Rituximab has been evaluated in observational studies with positive therapeutic effect.<sup>204</sup> The rationale to use TPE is based on the presumed existence of a circulating factor that contributes to the pathogenesis of the disease. A promising candidate is the soluble urokinase plasminogen activator receptor (suPAR),<sup>205</sup> but its role as a disease marker or in disease pathogenesis is controversial.<sup>206</sup> Plasmapheresis is typically reserved for patients with recurrence of the disease after transplant.<sup>207,208</sup>

### Wilson disease

Wilson disease is a recessive genetic disorder caused by a mutation in the Wilson disease protein (*ATP7B*) gene, which results in abnormal copper secretion with subsequent pathologic deposition in several organs including the brain, liver, and cornea. The main treatment involves chelation therapy with penicillamine and trientine. Patients with liver cirrhosis are candidates for liver transplant. Patients TPE has been helpful in acute hepatic failure in Wilson's disease in preparation for liver transplant.<sup>209,210</sup>

### Myeloma cast nephropathy

Multiple myeloma (MM) is a plasma cell proliferative disorder that commonly affects the kidneys. The most common pathophysiology of renal failure is light chain cast nephropathy. Other mechanisms include immunoglobulin light chain amyloidosis and monoclonal immunoglobulin deposition disease. Several randomized controlled trials evaluated the efficacy of TPE in patients with MM and renal disease and demonstrated benefits on the use of TPE.<sup>211,212</sup> Another randomized trial failed to demonstrate any benefit with the use of TPE, but an important limitation was the lack of biopsy as an including criterion.<sup>213</sup> The combination of bortezomib and TPE also had positive renal function recovery.<sup>214</sup>

### Overdose/mushroom poisoning

Toxic effects may occur after exposure to excessive doses of pharmacologic agents or to harmful agents in the environment. Management techniques for both types of events are similar and may include removal of toxin still in the gastrointestinal tract, enhancement of renal elimination, and direct removal from blood by hemodialysis, hemoperfusion (e.g., over charcoal columns), or TPE.<sup>215</sup> Specific antidotes may also be given if available. Serious events are usually treated with multiple measures.

TPE has been reported to be beneficial, when combined with other therapies, in cases involving substances such as methyl parathion, vincristine, and cisplatin that bind tightly to plasma proteins. TPE has been reported in poisonings due to ingestion of the *Amanita phalloides* mushroom; however, diuresis clears more *Amanita* toxin.<sup>191</sup>

Unfortunately, the literature on this topic is older and entirely anecdotal. Furthermore, TPE has always been used in combination with other therapies that are presumably effective. This complicates the formulation of firm, rational guidelines.<sup>216</sup> Nevertheless, it seems reasonable to offer TPE to a severely affected patient with an overdose or poisoning who has a high blood level of a toxic agent that binds to plasma proteins. It should also be noted that TPE has shown minimal or no beneficial effect in overdosage of drugs known to bind to tissue proteins and lipids, including barbiturates, chlordcone, aluminum, tricyclic antidepressants, benzodiazepines, quinine, phenytoin, digoxin, digitoxin, prednisone, prednisolone, tobramycin, and propranolol.<sup>191</sup>

### Systemic lupus erythematosus (SLE)

SLE has long been regarded as the prototypic autoimmune disease. The most important diagnostic criterion, circulating antibodies to DNA, especially double-stranded DNA (anti-dsDNA), identifies patients who may have a variety of other autoantibodies and a disparate array of clinical syndromes in which skin disease, joint disease, cytopenias, or nephritis may be the sole or dominant problem.

Immunosuppressive measures are the cornerstone of therapy for SLE. Most patients are given prednisone in varying doses, and those with severe disease may also receive azathioprine or cyclophosphamide. The plethora of autoantibodies that seem relevant to clinical signs made SLE an obvious target for TPE. It was one of the first illnesses to be treated with automated TPE in the early 1970s, and early case reports and uncontrolled series suggested a favorable effect.<sup>217</sup>

Lupus nephritis is a particularly devastating manifestation in which glomerular deposition of immune complexes and anti-DNA is believed to have a prominent role in pathogenesis. Thus, it seemed an attractive setting for randomized trials of TPE. A controlled trial with only eight patients suggested benefit.<sup>218</sup> However, in a multicenter randomized controlled trial comparing oral cyclophosphamide plus TPE to oral cyclophosphamide alone, there was no advantage for the patients receiving TPE.<sup>219</sup> A later international trial, which enrolled patients with a variety of severe manifestations, was structured to exploit enhanced sensitivity to a properly timed pulse dose of intravenous cyclophosphamide that was believed to follow pathogenic antibody removal by TPE.<sup>220</sup> This trial also failed to show any advantage for all patients treated with TPE<sup>221</sup> or for a subgroup with nephritis.<sup>222</sup> Thus, large controlled studies have failed to confirm any worthwhile effect of TPE in SLE.

There are some severe LES manifestations for which TPE could be considered, including CAPS, TTP, cryoglobulinemia, and DAH.<sup>223</sup>

### Thyroid storm

Thyroid storm, also known as thyrotoxic crisis, is an acute, life-threatening disorder characterized by excess of thyroid hormone. It is most frequently associated with patients presenting with hyperthyroidism, in particular Grave's disease. Other forms of thyrotoxicosis not associated with hyperthyroidism include thyroiditis (postpartum and subacute thyroiditis) and extrathyroidal source of hormone.<sup>224</sup> Patients typically present with signs and symptoms of excess thyroid hormone and increase sympathetic activity, including irritability, psychosis, tachycardia, arrhythmias, heart failure, and fever. If untreated, it can progress to stupor, coma, and death. These episodes are usually triggered by a stressor, such as infection, radiation thyroiditis, stopping antithyroid medication, or thyroidectomy. First-line therapy includes medications to stop the synthesis and release of thyroid hormones, such as propylthiouracil and iodine, respectively, and beta blockers to decrease the adrenergic effects. TPE can be added for patients not responding to first-line therapy. TPE has been shown to be effective in decreasing thyroid hormones in the acute phase but levels bounce back the following day.<sup>225,226</sup>

### TPE in transplantation

TPE has been used before transplant to remove pre-existing ABO or HLA antibodies (desensitization), or after transplant in the setting of antibody-mediated rejection (AMR). A summary is provided in Table 25.6. For solid organ transplantation, ABO compatibility between the donor and recipient is critical to ensure organ

**Table 25.6** TPE in Transplantation

Disease Name	Indication	Category	Grade
Liver transplantation, ABO-incompatible	Desensitization, living donor	I	1C
Renal transplantation, ABO compatible	Desensitization, living donor	I	1B

viability and successful engraftment. The importance of HLA compatibility is critical for stem cell transplant but varies between solid organs. In this section, we describe solid organ and stem cell transplantation for which TPE has been shown to be effective in removing antibodies. The role of photopheresis in the transplant setting is described in Chapter 26.

### Desensitization

Desensitization involves the removal of circulating antibodies in the recipient to prevent hyper acute rejection of the transplanted organ. This becomes critical when a patient is in acute need of an organ, but compatible donors are not available. Liver transplant can be a life-saving procedure for patients presenting with fulminant liver failure or other forms of severe liver dysfunction. The mortality rate of patients with kidney disease increases as the kidney disease progresses.<sup>227</sup> ABO compatibility is a major determinant of organ availability, and many patients die while waiting for a compatible transplant. Strategies to increase the donor pool include the use of living donors (for liver and kidney transplants) and the use of incompatible organs. Incompatible transplants can be performed in the setting of desensitization protocols to decrease antibody synthesis and remove circulating antibodies.

For liver transplants, the use of desensitization protocols in recipients of incompatible organs from living donors demonstrated good survival rates. Different protocols can include a combination of rituximab, TPE, IVIG, steroids, splenectomy, and prostaglandin E1 infusions.<sup>228</sup> A series of TPE before transplant effectively removes ABO antibodies preventing hyperacute rejection. ABO isoagglutinins typically bounce back after transplant requiring a series of TPE posttransplant. Rituximab has been shown to be effective as the main desensitization strategy. Biliary complications and antibody-mediated rejection are more frequent complications in incompatible transplants when compared to compatible transplants.<sup>229</sup>

In the case of kidney transplantation, TPE can be used to remove HLA and ABO antibodies for desensitization in the setting of living donors and antibody-mediated rejection (AMR). HLA-sensitized patients presenting with donor-specific antibodies (DSAs) have longer waiting time to receive an organ, which has a negative impact on their overall health and survival. These patients might be able to find a suitable living donor through kidney-paired donation or desensitization.<sup>230,231</sup> Desensitization protocols for HLA-sensitized patients include a combination of TPE and immunosuppressive drugs, including IVIG, rituximab, and bortezomib.<sup>232,233</sup> ABO-incompatible kidney transplants demonstrate positive outcomes.<sup>234</sup>

Desensitization protocols include a combination of intensive TPE to decrease isoagglutinin titers, IVIG, and immunosuppressive medication including tacrolimus and mycophenolate mofetil, daclizumab, and steroids.<sup>235</sup>

Desensitization protocols can also be used in patients waiting for a cardiac transplant. Not all patients are eligible for this treatment and the outcomes are not equivalent to compatible transplant due to higher risk of AMR. A combination of TPE, IVIG, and rituximab with or without bortezomib is typically used.<sup>236</sup>

### Rejection

Standard post-transplant management for kidney and heart transplantation consists of prophylactic immunosuppression with glucocorticoids, a calcineurin inhibitor (cyclosporine or tacrolimus), and an antimetabolite such as azathioprine or mycophenolate mofetil. High-risk recipients and those who have rejection episodes in spite of these standard measures are treated with pulse steroids, T-cell antibody preparations, or both.<sup>237,238</sup>

Case reports and uncontrolled series published in the late 1970s and early 1980s suggested TPE was beneficial in renal transplant rejection. Then, five controlled trials<sup>191</sup> were reported in the mid- and late-1980s. Four showed no significant benefit for patients receiving TPE in addition to standard drug therapy, even in the sub-groups whose transplant biopsies showed “vascular” histologic changes. In the one study suggesting benefit, the mean treatment time was 10–11 months after transplant, when antibody-mediated rejection is less likely. The last and largest study concluded that TPE therapy for renal transplant rejection could no longer be recommended.<sup>239</sup> Nevertheless, the use of TPE for this purpose continued to be reported.<sup>191</sup>

In the more recent past, a new wave of enthusiasm for TPE has focused on patients with clinical and histologic evidence of acute rejection who also have circulating donor-specific antibody and/or deposition of complement component C4d in transplant biopsy tissue, suggesting a humoral mechanism.<sup>240</sup> The antibody can be shown by a positive crossmatch with donor cells or by flow cytometric reactions with donor antigens. C4d deposition is demonstrated by immunofluorescence microscopy.<sup>241</sup>

In summary, evidence from controlled trials has not shown global efficacy for TPE in reversing established rejection episodes in renal allografts. Anecdotal experience focusing on patients with circulating antibody and immunopathologic evidence of humoral rejection seems more promising, but controlled trials in such patients have not been published. Clarification of the role of TPE in cardiac transplantation awaits controlled studies targeting patients with documented humoral rejection and circulating DSA.

### Controversial applications of therapeutic plasma exchange

Every new patient consultation is an assessment of pros and cons. There are patient- or institution-specific factors that impact the feasibility or appropriateness of embarking on a course of apheresis therapy, just as there is for performing any medical procedure. Many apheresis services utilize the ASFA guidelines to establish a framework of diagnostic settings when there is some evidence, of often variable quality, particularly for Category I or II indications, where apheresis “is accepted as a first- or second-line therapy.”<sup>287</sup> Category III diagnoses are defined as entities where the “optimum role of apheresis therapy is not established”<sup>87</sup> and have not been reviewed here based on the lack of strong evidence in favor of an important role for apheresis in disease management. Clinical consultations should always be individualized.<sup>242</sup> It is essential to

analyze whether the potential benefits of a procedure, whether short term or long term, outweigh the risks for a particular patient in a particular clinical setting. The core of an apheresis consultation is achieving a balance between guiding medical management toward the root causes of disease pathogenesis and judicious deployment of a “brute force” extraction of a blood constituent. Conflicting data, less convincing putative mechanisms, or symptom-based, rather than pathophysiologically based, justifications for plasmapheresis abound in the medical literature. To attempt to review all reports of a “successful” plasmapheresis case reports is beyond the scope of this chapter, but future rigorous clinical trials can hopefully test the value of TPE in diseases published in case reports or series but not discussed here.

### Specialized therapeutic plasma processing

There are 30 Category I, II, or III indications for therapeutic immunoabsorption (IA), LDL apheresis, or rheopheresis (a form of double-membrane filtration plasmapheresis or DFPP) in the current ASFA guidelines. 87 IA is essentially an alternative to TPE in these guidelines in that it shares the same designation with TPE for seven Category I, six Category II, and seven Category III indications, occasionally with a lesser grade of evidence. For one indication, dilated cardiomyopathy, it has a higher category designation than TPE (II vs. III). Lipid apheresis has six Category I, II, or III indications. In contrast to standard plasmapheresis, which nonspecifically removes plasma, the following discussion focuses on therapeutic procedures that are designed to remove a specified fraction of the plasma. The first step is the separation of plasma using a membrane followed by passing the plasma across a selective filter, which may be either single use or regenerating. A pathogenic plasma substance (e.g., a specific autoantibody) is usually present at relatively low levels in the circulation. Thus, selective extraction of pathologic plasma constituents in a way that minimizes the sacrifice of healthy plasma proteins could be a more efficient treatment of disorders with lesser theoretical iatrogenic coagulopathy than TPE.

### Immunoabsorption apheresis

Immunoabsorption systems employ the principle of affinity chromatography and make use of immobilized sorbents or ligands that have enhanced or specific binding affinity for a specific antigen, antibody, immune complex, or other substance in the patient's circulation.<sup>81</sup> Examples include (1) staphylococcal protein A or sheep antihuman immunoglobulin (IgG) for the extraction of IgG and immune complexes from the circulation, (2) sheep antihuman low-density lipoprotein (LDL) or apolipoprotein B antibody for the extraction of LDL, (3) synthetic blood group substances for the removal of ABO isoagglutinins, and (4) DNA for the removal of DNA antibody. Although no longer commercially distributed in the United States, two immunoabsorption systems that have received approval from the FDA are the staphylococcal protein A sepharose column (Immunosorba, Fresenius HemoCare, Redmond, WA) and the staphylococcal protein A silica column (Prosorba, Fresenius HemoCare).<sup>243</sup> Protein A is a cell-wall constituent of the Cowan I strain of *Staphylococcus aureus*. Mammalian IgG binds to five homologous regions at its amino terminus, but interaction of protein A with other plasma proteins is insignificant. Processing of 2.5 plasma volumes using a protein A agarose column resulted in a 97% reduction in IgG1, a 98% reduction in IgG2, a 40% reduction in IgG3, a 77% reduction in IgG4, a 56% reduction in IgM, and a 55% reduction in IgA, whereas plasma levels of albumin, fibrinogen, and

antithrombin were reduced by less than 20%.<sup>244</sup> Thus, in principle, plasma adsorption with protein A affinity columns permits the processing of more plasma than does TPE without unacceptable loss of other essential plasma constituents.<sup>245</sup> In practice, some clinical coagulation tests, particularly fibrinogen, can be statistically significantly affected by IA.<sup>246,247</sup> The use of these devices in a variety of clinical conditions in Europe and Japan has been extensively reviewed.<sup>81,248</sup>

### Dilated cardiomyopathy

Dilated cardiomyopathy (DCM) describes a cardiac disorder in which the left ventricle is dilated and exhibits impaired contraction. It may be idiopathic, familial, postviral, alcohol- or drug-induced, or related to other cardiac disease. A genetic mutation can be found in about 35% of patients.<sup>249</sup> Both ventricles may be affected. It presents with heart failure, is often progressive, and may be complicated by arrhythmias, thromboembolic events, and sudden death. It is the most frequent antecedent cause of heart transplantation throughout the world.<sup>250</sup> Approximately 60–80% of patients with DCM harbor autoantibodies directed against cardiac myosin heavy chain, myocardial  $\beta_1$ -adrenergic receptors, or other cardiac tissue with a predominance of antibodies of the IgG 3 subclass.<sup>251–253</sup>

### Immunoabsorption in the treatment of autoantibody-associated dilated cardiomyopathy

Autoantibodies targeting guanine nucleotide-binding protein-coupled receptor (GPCR) that blocks myocyte signaling cascades were first described in the late 1980s, but their potential relevance to clinical DCM was initially explored using IA in the mid-1990s using an antihuman polyclonal immunoglobulin (AHPI) system known as Therasorb.<sup>254</sup> In a pilot study of eight patients with DCM and advanced congestive heart failure who were subjected to a series of four or five IA procedures per week over two weeks,  $\beta_1$ -adrenoreceptor autoantibody levels decreased by an order of magnitude and heart failure symptoms improved in seven of the subjects. The effect was transient, however, and autoantibodies and symptoms returned to baseline 75 days after completion of IA.<sup>254</sup> A more durable reduction in  $\beta_1$ -adrenergic receptor antibodies was found in a 34-patient randomized controlled trial that correlated with improvement in both left ventricular ejection fraction (LVEF) at 12 months and 5-year survival (82% in IA-only treated group vs. 41% in controls;  $p < 0.0001$ ).<sup>255</sup> No concomitant IVIG that might confound results was given in that study. A second randomized trial using the same IA platform studied 18 patients with DCM and advanced heart failure who were assigned to either best medical therapy (control group) or best medical therapy with the addition of IA.<sup>256</sup> During the first course of IA, procedures were performed on three consecutive days, and patients received 0.5 g/kg of IVIG by intravenous infusion. Three subsequent courses of IA, performed on two consecutive days at four-week intervals, were also followed by infusions of IVIG at the same dose. After the first course of IA/IVIG, a sustained improvement in many clinically relevant parameters, including the LVEF, cardiac index, stroke volume index, and systemic vascular resistance, was reported. Improvement in symptoms and functional status paralleled the hemodynamic changes. The control group demonstrated no hemodynamic improvement at the end of the three-month study.  $\beta_1$ -Adrenergic receptor antibodies decreased by >80% after the first course of IA but tended to rise between monthly courses of treatment. There have now been multiple trials, case reports, and case series generally supporting improvement.<sup>148,257</sup>

The vast majority of studies infused intravenous IgG (IVIG), which might solely, or in concert with IA, account for clinical improvement. Unfortunately, trials of treatment with IVIG alone have been equivocal. One trial, in which patients initially received a total of 2 g/kg followed by 0.4 g/kg monthly for five months, demonstrated significant improvement in left ventricular ejection fraction in the treatment group but not the placebo group.<sup>258</sup> A second trial, in which patients received a single course totaling 2 g/kg, demonstrated no effect of IVIG on left ventricular ejection fraction after 6 or 12 months (although both the treatment and placebo groups showed improvement).<sup>259</sup> The in vitro inotropic activity of antibodies removed from patients who responded to IA was stronger than antibodies from patients who did not respond to antibody-removal therapy, supporting a pathophysiological relevance to these antibodies *in vivo*.<sup>260,261</sup> Overall, since most studies have been conducted using IA, ASFA designates DCM a Category II indication for IA and a Category III indication for TPE.<sup>87</sup>

### Familial hypercholesterolemia

Familial hypercholesterolemia (FH), an autosomal dominant disorder, is a major cause of death or early disability resulting from premature atherosclerotic heart and peripheral vascular disease.<sup>262</sup> It is caused by mutations in the LDL receptor (LDL-R), with frequencies of 1:500 for heterozygotes and 1:1,000,000 for homozygotes.<sup>263</sup> Clinical features including xanthomas, xanthelasmas, corneal arcus, and the occurrence of coronary heart disease, stroke, and death are common in the fourth or fifth decade of life.<sup>262</sup> A serum LDL cholesterol (LDL-C) level below 100 mg/dL (achieved through diet, lifestyle modification, and 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibiting drugs or statins) can lower cardiovascular morbidity and mortality in high-risk patients, but a sizable minority of high-risk patients fail to achieve LDL-C-lowering goals by this approach.<sup>264</sup> New medical therapies target the recycling of LDL-R in hepatocytes. A serine protease in plasma called proprotein convertase subtilisin-kexin type 9 (PCSK9) binds to the LDL-R, flagging the LDL-R for degradation. Lower surface receptor levels lead to increased plasma LDL-C levels.<sup>265</sup> A PCSK9 inhibitor, evolocumab, effectively decreased LDL-C by 20% in homozygous FH and by 55% in severe heterozygous FH over a four-year period, giving new hope for an effective medical therapy beyond statins.<sup>266</sup>

### LDL apheresis

Manual, then automated, plasma exchange was successfully employed as an adjunct to lipid-lowering therapy beginning over 40 years ago. However, the kinetics of restoration of plasma lipid levels and the unwanted lowering of essential plasma proteins (e.g., fibrinogen and albumin) rendered this approach challenging for long-term therapy. The development of apheresis devices that permit a more selective removal of plasma LDL cholesterol and related substances has provided a practical approach to managing statin-resistant patients in conjunction with statins and other medical therapies.<sup>267</sup>

Two apheresis systems for selective removal of LDL cholesterol are FDA approved for use in the United States. The Liposorber LA15 system (Kaneka Pharma America, New York, NY) uses dextran sulfate bound to cellulose to selectively extract LDL cholesterol from plasma. In this popular system, plasma is initially separated from the cellular components of blood by filtration through a disposable semipermeable polysulfone hollow fiber column, and the

separated plasma is then perfused over a disposable adsorption column that contains 150 mL of dextran sulfate. Dextran sulfate has strong affinity for lipoproteins and adsorbs these from the plasma. The H.E.L.P. system (B. Braun Medical, Bethlehem, PA) employs a 0.55-μm hollow fiber column to separate the plasma from the cellular elements of the blood. The plasma is acidified with 0.3 M sodium acetate buffer, and heparin is added to precipitate LDL-C. The LDL-C-heparin precipitate is filtered from the plasma using a 0.45-μm polycarbonate filter, excess heparin is adsorbed from the filtered plasma with a DEAE cellulose membrane filter, and the filtered plasma is then restored to physiologic pH by bicarbonate hemodialysis.

ASFA has designated FH a Category I indication for LDL apheresis in homozygotes and a Category II indication for LDL apheresis in heterozygotes.<sup>87</sup> The FDA-approved indications include homozygotes with plasma LDL cholesterol >500 mg/dL and heterozygotes with LDL cholesterol >300 mg/dL (or >200 with known coronary artery disease). A regimen that combines medical therapy with LDL apheresis on a biweekly schedule can effectively lower LDL cholesterol by 60–80% in otherwise treatment-resistant patients, improve the physical stigmata of hypercholesterolemia such as xanthomas and xanthelasmas, improve myocardial perfusion and coronary artery patency, and favorably affect other markers of cardiovascular risk (e.g., triglycerides, fibrinogen, homocysteine, C-reactive protein, and adhesion molecules).<sup>268</sup> Vascular access is either peripheral or by arteriovenous fistula or graft, due to the chronic treatment requirements of this genetic disease.<sup>269</sup> More recently, LDL apheresis has been found effective in ameliorating drug-refractory coronary artery disease in patients with Lp(a)hyperlipoproteinemia.<sup>270</sup>

### Conclusions

Therapeutic plasma exchange and specialized plasma therapies occupy a distinct clinical niche, thanks largely to advances in the last 50 years in biomedical engineering and transfusion medicine. On the horizon is the expanding armamentarium and applications of immunotherapies, particularly in the treatments of autoimmune diseases and immunomodulation. We hope these elegant approaches will better focus future therapy on treating the causes of disease rather than using the nonspecific apheresis-based methods described here to remove their accumulated consequences.

### Acknowledgments

The authors acknowledge the contribution of this chapter in the prior edition by Shanna Morgan and Jeffrey McCullough in providing a foundation for the current chapter.

## CHAPTER 26

# Therapeutic phlebotomy and cellular hemapheresis

Patricia A. R. Brunker<sup>1</sup> & Jeffrey A. Bailey<sup>2</sup>

<sup>1</sup>Blood Transfusion Service, Department of Pathology, Massachusetts General Hospital, Harvard University, Boston, MA, USA

<sup>2</sup>Department of Pathology and Laboratory Medicine, Warren Alpert Medical School, Brown University, Providence, RI, USA

The eighth comprehensive, evidence-based analysis of apheresis therapies by the American Society for Apheresis (ASFA) recorded 72 disease conditions as category I (apheresis as first-line therapy) or category II (apheresis as second-line or adjuvant therapy) indications for therapeutic apheresis.<sup>1</sup> Among these, 43 (60%) were indications for plasma exchange, consistent with prior surveys that found plasma exchange to be the predominant form of apheresis therapy in North America.<sup>2,3</sup> Whereas apheresis procedures have been in wide use for decades,<sup>4</sup> many on the basis of accumulated experience, the approval of new therapeutic indications, devices, and drugs is increasingly dependent on the presentation of carefully acquired supportive evidence in randomized controlled trials.<sup>5,6</sup> This applies to phlebotomy and apheresis therapies as well<sup>7,8</sup> and ASFA presents its recommendations, and the strength of the evidence that underlies them, according to the G.R.A.D.E. system.<sup>1</sup> Accordingly, this chapter, which reviews therapeutic phlebotomy and specialized apheresis procedures that target specific cellular compartments of the blood for processing, emphasizes those procedures that are supported by evidence.

### Therapeutic red cell apheresis

*Therapeutic erythrocytapheresis* is the removal of red cells, typically using automated blood-processing instruments that are capable of selectively removing erythrocytes while returning the plasma, buffy coat cells, and additional isotonic saline to the patient.<sup>9</sup> The therapeutic replacement of patient red cells for donor red cells is more specifically referred to as *red cell exchange* (RCE) or a *red cell exchange transfusion* to contrast it with a *simple transfusion*,<sup>10</sup> although the term erythrocytapheresis is frequently used synonymously.<sup>1</sup>

### Red cell exchange (RCE)

Therapeutic RCE can be performed manually or with programmable automated blood-processing (apheresis) instruments. Manual exchange is mainly limited to neonates or resource-limited settings. Partial manual exchange (PME) transfusion is performed in some settings when access to an automated procedure is limited, uneconomical, an apheresis catheter is undesirable, or for some pediatric settings.<sup>11–13</sup> Although PME may be required due to

logistical constraints, automated RCEs are generally more efficient and patients meet therapeutic goals more consistently than with PME.<sup>14,15</sup> Thus, this discussion focuses on automated RCE.

Basic features of automated blood processors that perform therapeutic apheresis using centrifugation technology are detailed in Chapter 24. The machine operator enters the patient's gender, height, and weight into the instrument's computer to calculate total blood volume. The operator also inputs the known starting and desired ending hematocrit of the patient, the average hematocrit of red cell replacement units to be used, and the desired fluid balance (a default of 100% may be offered by the instrument). Finally, the operator can choose to enter the desired fraction of the preprocedure red cells remaining (FCR) within the patient's circulation at the end of the procedure or the volume of replacement fluid (e.g., red cells of average hematocrit as programmed into the instrument's computer) needed for the procedure.

Calculation of the desired FCR depends on the starting points and targeted endpoints of both the patient's hematocrit and the relevant therapeutic parameter (e.g., percent Hgb S or parasitemia). Most RCEs also achieve a net positive transfusion to treat symptomatic anemia, but if no increase in hematocrit is desirable (e.g., if concerns for increased whole blood viscosity in a sickle cell anemia patient were clinically relevant), then the first factor below cancels out to 1:

$$FCR = 100 \times \left( \frac{\text{starting hematocrit}}{\text{ending hematocrit}} \right) \times \left( \frac{\text{endpoint parameter}}{\text{starting parameter}} \right) \quad (1)$$

For example, a sickle cell patient with a hematocrit of 25% and 100% Hgb S, targeted to an endpoint of Hgb S 30% and ending hematocrit of 30%, would yield

$$FCR = 100 \times \left( \frac{25\%}{30\%} \right) \times \left( \frac{30\%}{100\%} \right) = 25\%$$

The replacement volume needed to reach the desired FCR is dependent on the patient's blood volume, the starting hematocrit, the target hematocrit, fluid balance, and the average hematocrit of the replacement RBC units. It is important to remember that modern automated apheresis instruments incorporate the starting and

endpoint hematocrit, and thus the machine FCR simply approximates the desired fraction of original parameter of interest. In clinical circumstances when the volume of available or appropriate donor blood may be limited, such as a highly alloimmunized hemoglobinopathy patient who requires rare, multiply antigen-negative units and an urgent procedure, the replacement volume available for the exchange can determine the maximum achievable FCR given the patient's starting Hct and the targeted end Hct.

According to ASFA, RCE is indicated as first- or second-line therapy for the management of sickle cell disease (SCD) and for the treatment of severe manifestations of the protozoal infections (e.g., malaria and babesiosis).<sup>1</sup>

### Sickle cell disease

Symptoms of SCD and traditional treatments have long existed in Africa.<sup>16</sup> Genetic analysis suggests that the origin of the genetic mutation responsible for SCD has an age of 259 generations.<sup>17</sup> The indigenous names of this malady reveal not only its enduring presence for many African peoples, but also capture the agonizing and unremitting nature of its relentless pain. The Banyagi diagnosis *adep* means “beaten up,” and both the Adagme and Ewe have captured SCD’s iterative and gnawing misery in their terms *hemkom* (“body biting”) and *nuidudui* (“body chewing”).<sup>18</sup> Specific iatrogenic limb girdle tribal markings have been applied to people with *hemkom* in the Adagme group in Ghana as described by local physicians, and the disease has been traced in one Ghanaian family to 1670.<sup>19,20</sup> The first association of recurrent bone pain with cold weather, fever, and joint pain was documented in the English literature in 1874 by Sierra Leonean physician Dr. Africanus Horton.<sup>21</sup> Sickled erythrocytes were first described in Western medicine in 1910 by Dr. J.B. Herrick, who noted the abnormally shaped red cells in the peripheral blood film of a dental student from the Caribbean island of Grenada.<sup>22</sup> An underlying mutation results in substitution of valine for glutamic acid as the sixth amino acid residue in the hemoglobin β chain and likely arose approximately 7300 years ago either in the Sahara or in west/central Africa.<sup>17</sup> Forces of balancing selection have been at play to maintain the variant in human populations due to its protective effects from severe falciparum malaria in the heterozygous state (sickle trait).<sup>23</sup> However, once at appreciable frequency in a population, the homozygous sickle state leads to SCD. The description of these countervailing forces on survival provided one of the initial and strongest examples of heterozygous advantage.<sup>24,25</sup>

At a molecular level, sickling is due to increased hydrophobic interactions between nearby Hgb S molecules whereby deoxygenated Hgb S aggregates into large inflexible polymers and inflexible sickled red cells. Increased sickled cell adhesion, inflammation, and vasculopathy lead to vaso-occlusive crises.<sup>26,27</sup> The exquisite dependence of polymerization on the proportion of HgbS<sup>28</sup> has provided a scientific basis, in concert with the strong clinical basis,<sup>29</sup> for the transfusion therapy of normal red cells in sickle cell anemia.

SCD is the most common inherited blood disorder in the United States, affecting an estimated 100,000 Americans, with an estimated 3000 neonates born with SCD each year.<sup>30,31</sup> FDA-approved medical therapies for SCD include hydroxyurea, voxelator, crizanlizumab, and L-glutamine to reduce severity or frequency of acute complications, but transfusion therapy remains a mainstay of both acute and chronic disease management.<sup>32,33</sup> For the most part, clinical studies related to transfusion management of SCD have focused on simple transfusion or manual partial exchange transfusion.<sup>29,34–37</sup> The efficacy of manual versus automated RCE in

**Table 26.1** Red Cell Exchange in Sickle Cell Disease (2019 ASFA “Strong Recommendation” Grade 1 Evidence)<sup>1,33</sup>

Clinical Setting	Diagnosis or Purpose	2019 ASFA category
Acute or emergent	Acute vaso-occlusive stroke	I
	Severe acute chest syndrome	II
Chronic/nonacute	Prevention of stroke in high-risk children	I
	Secondary stroke prevention	I

the treatment of SCD has not been directly compared.<sup>33</sup> For most SCD complications, simple transfusions may likely be as effective, but automated RCE can more rapidly decrease the proportion of Hgb S red cells during severe acute episodes.<sup>1</sup> In SCD patients who receive chronic transfusion, automated RCE can mitigate iron overload<sup>38,39</sup> while maintaining a low Hgb S level. Thus, it has entered into routine use in centers where therapeutic apheresis is available. Its indicated roles in the aspects of SCD (Table 26.1)<sup>1,33,40</sup> are discussed here. Exchanges performed using isotonic saline, rather than red cells, as the replacement fluid in the early phases of the procedure are called *depletion exchanges* or *isovolemic hemodilution* and can reduce the number of donor red blood cell (RBC) units required by reducing the removal of the initial replacement red cells.<sup>38,39</sup>

### Life- or organ-threatening complications

RCE is standard therapy (ASFA category I) for patients with acute vaso-occlusive stroke,<sup>1</sup> and although the efficacy of transfusion (either simple or exchange) has not been studied by randomized trials, emergency RCE should be performed shortly following documentation of thrombotic (rather than hemorrhagic) stroke by noncontrast computed tomography.<sup>29,33,40</sup> The treatment goal should be a hemoglobin concentration between 9 and 10 g/dL and less than 30% Hgb S. Acute intervention, followed by chronic maintenance transfusion therapy, may limit early morbidity and mortality and prevent recurrence (discussed further in this chapter).<sup>29,40</sup>

The National Acute Chest Syndrome Study Group’s (NACSSG) definition of the acute chest syndrome (ACS) remains the standard since its report in 2000,<sup>36</sup> and is based on the presentation with a new alveolar infiltrate involving one or more complete lung segments (atelectasis excluded) and accompanied by chest pain, a fever >38.5 °C, tachypnea, wheezing, or cough in a patient with SCD. ACS is the second most common cause for hospitalization and the leading cause of death in SCD.<sup>40,41</sup> Although the NACSSG report was not powered to detect a particular advantage of RCE over simple transfusion,<sup>36</sup> and there is only one small RCT addressing the use of even simple transfusion in ACS,<sup>42</sup> the consensus opinion of experts in the field is to recommend RCE for severe ACS (oxygen saturation <90% despite supplemental oxygen).<sup>43</sup> Both RCE and simple transfusion are characterized by this same expert consensus panel as “acceptable treatment modalities” for “moderate” ACS.<sup>1,27</sup>

Acute multiorgan failure syndrome is a common cause of death in SCD,<sup>33,41,44</sup> may present as an unusually severe pain episode in patients with Hgb SS or Hgb SC disease, and is characterized by fever, accelerated hemolysis with a rapid decrease in hemoglobin and platelet count, nonfocal encephalopathy, and rhabdomyolysis.<sup>44</sup> Besides the central nervous system, other organs, including liver and kidney, may be involved.<sup>28,44</sup> Standard red cell transfusion therapy is likely effective if severe anemia is present. Although evidence is limited to case

reports and series, RCE should be considered with higher hemoglobin levels.<sup>33</sup> RCE can also be considered for hepatic sequestration and intrahepatic cholestasis.<sup>40,45</sup> Splenic sequestration occurs most commonly in young children, and for patients with significant anemia on presentation, simple transfusion restores the circulating blood volume sufficiently to support remobilization from the spleen. The transfusion strategy should maintain a hematocrit low enough to avoid possible hyperviscosity syndrome when sequestered RBCs are eventually returned to the circulation. For the rare adults with this presentation or for patients without significant anemia, an exchange transfusion may be considered.<sup>46–49</sup> The role of transfusion and exchange transfusion in priapism, which occurs in approximately 30–90% of males with SCD,<sup>40,44</sup> has been debated.<sup>50</sup> However, there is increasing consensus that early transfusion is not warranted, supported by an NIH expert panel that states that transfusion should not be used,<sup>27,40</sup> although British guidelines include consideration of RCE if patients do not respond to initial shunt procedures.<sup>51</sup> Studies have shown no benefit over conventional therapies, the time to resolution is often longer for those transfused, and further interventions such as surgical decompression are often required.<sup>29</sup> In addition, severe neurologic abnormalities have been associated with RCE, as first reported in six boys with sickle cell anemia 1–11 days following partial exchange transfusion for priapism unresponsive to conservative therapy.<sup>52</sup> The syndrome was called ASPEN (Association of Sickle cell Priapism, Exchange transfusion and Neurological events) and was characterized by severe headache at the onset, often associated with increased intracranial pressure and further neurologic events ranging from seizure activity to obtundation requiring ventilatory support.<sup>52–54</sup> It is likely that ASPEN was caused by hyperviscosity since the postexchange Hct was greater than the pre-exchange values in the initial publications, and a subsequent report that did not raise the hematocrit postexchange was not associated with ASPEN.<sup>55</sup> However, the mean time to detumescence did not differ significantly between patients treated with transfusion (mean of 10.8 days) versus those treated with conventional therapies (8.0 days) in a review of 42 case reports of SCD-associated priapism.<sup>56</sup> Neurologic complications with transfusion therapy were described in nine cases, some with persistent long-term deficits. Taken together, there are many alternative treatments favored as first-line therapies for SCD-associated priapism, with a limited role of RCE.<sup>57,58</sup>

### **Primary and secondary prevention of stroke**

Approximately 5–10% of untransfused children with SCD will have a clinically evident cerebral infarction by the age of 20 years.<sup>59,60</sup> An additional 40% are estimated to experience silent cerebral infarcts (SCIs), which are radiologically indistinguishable<sup>61</sup> and lack overt signs of stroke, but which are highly morbid events associated with decreased intellectual abilities, poor academic achievement, additional SCIs, and progression to overt stroke.<sup>62,63</sup> A recent meta-analysis did not find an increased risk of stroke for patients with sickle trait,<sup>64,65</sup> although a potential interaction with chronic kidney disease may affect 30-year ischemic stroke risk in patients with sickle trait in one recent study.<sup>66</sup> There are likely many distinct but clinically coincident pathophysiological mechanisms by which stroke occurs in both children and adults with SCD, including thromboembolic mechanisms, endotheliopathy, or decreased cerebral vascular reserve or autoregulation.<sup>67</sup> Chronic transfusion therapy (CTT), given every 3–4 weeks, to maintain the level of Hgb S below 30% can improve the arteriographic appearance of affected cerebral vessels and reduce the risk of recurrent stroke from 66% to 90% to approximately 10%.<sup>33,40</sup> Chronic automated RCE can be

substituted for simple transfusion, with the added potential benefit of preventing or mitigating iron overload.<sup>38,39</sup> Reports of recurrent stroke rates of 50% or greater after discontinuation of transfusion therapy, coupled with increased mortality in the first three years when patients stop transfusion during a pediatric-to-adult care transition, have led most to recommend indefinite prophylactic transfusion regimens.<sup>33,40,68,69</sup>

The demonstration that transcranial Doppler ultrasound (TCD) was highly predictive of stroke risk in children with SCD<sup>68</sup> led to the Stroke Prevention Trial in Sickle Cell Anemia (STOP trial),<sup>35</sup> which examined the ability of CTT to prevent a *first* stroke in high-risk children with SCD. Increased cerebral blood flow (CBF) likely occurs in SCD as a compensation for reduced oxygen content due primarily to anemia from chronic hemolysis. Chronic anemia also pathologically increases the oxygen extraction fraction (OEF) of cerebral blood in SCD. Both the CBF and OEF can be markedly reduced, although not entirely to normal levels, with chronic RCE.<sup>70</sup> Importantly, there is no validated radiologic or laboratory test that predicts stroke risks in adults with SCD.<sup>71</sup> Time-averaged mean blood flow velocity of at least 200 cm/s in the internal carotid or middle cerebral artery and a stroke-free history were required for STOP study entry.<sup>35</sup> Over a period of approximately 2–3 years, transfusion therapy to maintain Hgb S below 30% without exceeding a hemoglobin concentration of 12 g/dL reduced the occurrence of stroke in the treatment group by 90% compared to the control group.<sup>35</sup> A follow-up study (STOP2)<sup>72</sup> examined the effect of discontinuation of transfusion therapy after 30 months in children from the first STOP trial whose TCD readings had reverted to normal. The study was halted when an interim analysis revealed that, of 41 children randomly assigned to discontinue transfusions, 14 had reverted to elevated TCD findings within nine months after stopping transfusions and two had suffered ischemic strokes. Neither elevated TCDs nor strokes were observed in the controls continuing transfusion. The TCD With Transfusions Changing to Hydroxyurea (TWiTCH) trial showed that children with abnormal TCDs but no history of prior stroke could transition to hydroxyurea for primary stroke prophylaxis after an initial period of transfusions (12% of which were RCEs).<sup>73</sup> Despite years of awareness of the importance of identifying children who require CTT using TCD for primary stroke prevention, failure to comprehensively screen children with SCD is a significant contributor to preventable stroke in children with SCD in the “post-STOP” trial era.<sup>74</sup> Further, the indication for transfusion in primary stroke prevention may broaden, given the lower rates of both silent and overt strokes among children with magnetic resonance imaging (MRI)-demonstrated silent infarcts, but lacking elevated intracranial arterial flow rates, who were randomized to receive chronic transfusions (the Silent Infarct Transfusion [SIT] trial).<sup>75,76</sup>

Chronic transfusion remains the mainstay of secondary stroke prevention.<sup>77,78</sup> The early closure of the Stroke With Transfusions Changing to Hydroxyurea (SWiTCH) trial, which was halted when interim analysis revealed reversion to elevated TCD and increased incidence of overt secondary stroke when transfusions stopped, reaffirmed that current medical therapy alone cannot substitute for transfusion (with chelation).<sup>79</sup> As a result of these studies demonstrating no equivalent therapy or safe endpoint for CTT, the current recommendation is that individuals with a history of elevated transcranial arterial flow or a history of stroke continue transfusion therapy indefinitely.<sup>33</sup>

Whether chronic transfusion therapy takes the form of simple or exchange transfusions is a multifactorial decision but may be

informed by distinguishing the effect of anemia (manifest by low total Hgb) from the Hgb S levels on pathogenesis. Interestingly, hemoglobin level was an independent predictor of both CBF<sup>80</sup> and OEF,<sup>70</sup> but percent Hgb S was not, suggesting that simple transfusion to treat anemia may help prevent strokes by improving cerebral metabolic reserve and RCE's rapid decrease in percent Hgb S may protect patients through different mechanisms.

### **Prevention of transfusional iron overload**

There are no randomized, prospective comparisons of simple transfusion versus automated RCE in the prevention of iron overload in children with SCD who require chronic transfusion therapy. Nonetheless, RCE results in 85% less iron loading compared to simple transfusion and may prevent iron overload if used as the initial form of CTT and particularly if combined with chelation therapy.<sup>14,81</sup> Iron accumulation will be slower but will still occur if the postprocedure hematocrit is greater than the preprocedure value, resulting in a net gain of iron; therefore, chelation therapy may still be required. In four case series of 8–14 children<sup>38,39</sup> who either converted from a simple transfusion program to monthly RCE, began on RCE early on with variable chelation therapy with deferoxamine,<sup>40</sup> serum ferritin tended to stabilize in those who were not on chelation therapy and significantly decreased in those who continued on chelation therapy. However, RCE resulted in a 25–100% increase in red cell usage and a concomitant increase in donor exposures.

### **Controversial clinical presentations in SCD patients**

In 2016, there were over 130,000 SCD-related inpatient hospitalizations in the United States.<sup>82</sup> The average length of stay was five days with 70% of these admissions in children and young adults aged less than 34 years. Adults aged 18–34 years had higher than average 30-day readmission rates, demonstrating the chronic, pernicious nature of this disease. There is variation in exchange transfusion practices<sup>83</sup> and in consensus guidelines about automated or manual exchanges,<sup>1,43,51</sup> demonstrating both the lack of conclusive data on which to make evidence-based recommendations and the requirement to take an individualized approach for consideration of RCE in these situations. Transfusion medicine practitioners, particularly those in metro areas, are likely to receive consultation requests about management (with either simple or exchange transfusion) for patients with SCD suffering from many of its complications other than those described above, such as acute or chronic vaso-occlusive pain, associated with bone marrow transplant to treat their SCD<sup>84–86</sup> or those requiring medical attention for unrelated conditions, such as pregnancy or preoperative evaluation, which we briefly explore here.<sup>33</sup>

### **Pregnancy**

Determining the potential role of chronic transfusion therapy in pregnancy is the first step to determining if that transfusion therapy should be performed via simple or exchange transfusions. A meta-analysis comparing prophylactic or chronic transfusions during pregnancy to ad hoc transfusions showed reduced maternal mortality, pain episodes, pulmonary complications, pyelonephritis, perinatal mortality, neonatal death, and preterm birth with the prophylactic transfusion strategy. However, other important outcomes, such as intrauterine fetal demise, small-for-gestational-age infants, or low-birth-weight infants, or preeclampsia did not differ between the groups.<sup>87</sup> One RCT did demonstrate fewer pain events in the chronic transfusion group, but fetal or maternal

outcomes could not be detected due to the size of the study.<sup>88</sup> The 2020 ASH guidelines support prophylactic transfusion at regular intervals at the onset of pregnancy for women with a history of severe complications of sickle cell disease or pregnancy comorbidities,<sup>89</sup> but routine implementation of red cell exchange transfusion is not indicated.

### **Preoperative**

The Transfusion Alternatives Preoperatively in Sickle cell disease (TAPS) trial randomized 67 individuals in Canada and Europe with SCD who were undergoing low- or intermediate-risk procedures to preoperative transfusion with a goal of 10 g/dL Hgb or no transfusion.<sup>90</sup> Twice as many patients in the untransfused arm experienced postoperative complications, including acute chest syndrome than the transfused arm, providing good evidence to support a hemoglobin threshold of 10 g/dL prior to low- or intermediate-risk procedures. Neither hospital stay nor readmission rates differed between the groups. Simple transfusions are an acceptable method to receive this transfusion therapy, a practice supported by a 1995 RCT that demonstrated no advantage to RCE over simple transfusion in terms of perioperative complications.<sup>34</sup> There are no data specifically favoring a particular Hgb S% prior to general anesthesia that reduces perioperative complications so simple transfusions are the preferred transfusion method for most patients.<sup>40</sup>

### **Protozoan disease**

Severe manifestations of malaria and babesiosis are ranked as category III and II indications, respectively, by ASFA, largely on the basis of anecdotal evidence.<sup>1,91–94</sup>

### **Malaria**

Globally, severe malaria is most commonly caused by *Plasmodium falciparum*.<sup>95</sup> Plasmodium infection results from injection of sporozoites into the bloodstream by the bite of a female *Anopheles* mosquito. The sporozoites migrate to and infect liver cells, where they asexually reproduce to form numerous merozoites that burst forth and invade RBCs. This initiates the erythrocytic life cycle with repeated rounds of RBC infections and increasing parasitemia, and symptoms such as recurrent fever, which can culminate in life-threatening end-organ dysfunction that defines severe malaria.<sup>96</sup>

The relative severity of *P. falciparum* malaria is due to adherence of falciparum-infected erythrocytes to glycosylated molecules on microvascular endothelium and to platelet CD36 via *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1), an adhesive protein expressed on the surface of infected erythrocytes.<sup>97–99</sup> The sequestration and vaso-occlusion combined with the elaboration of proinflammatory cytokines such as tumor necrosis factor- $\alpha$  (TNF $\alpha$ ) and interferon- $\gamma$  result in the severe manifestations of the disease.<sup>99</sup> The use of exchange transfusion and automated RCE in the treatment of severe malaria is based on an ability to rapidly reduce the burden of parasitemia and the potential to thereby improve the rheologic properties of the blood and reduce the level of toxic mediators such as cytokines.<sup>1</sup> On the other hand, it is unclear what effect peripheral parasite removal has on sequestered parasites. Sporadic case reports and case series continue to be associated with rapid reduction in parasitemia and clinical improvement.<sup>100</sup> However, the evidence for improved survival is mixed, with retrospective case control series variably favoring antibiotic therapy

alone or adjunct exchange transfusion, but all studies have suffered from poor control for malaria severity.<sup>192</sup>

The US Centers for Disease Control and Prevention (CDC) no longer recommends consideration of RBC exchange in cases of severe malaria with parasitemia >10%.<sup>1</sup> This was based on the lack of high-quality evidence in the literature and analysis of their malaria reporting data from 1985 to 2010 comparing 101 exchange transfusion cases with 314 propensity-matched nonexchange cases of severe malaria.<sup>101</sup> They found no survival advantage with 17.8% mortality in the exchange-transfused group compared to the 15.9% for the controls. However, their retrospective analysis only had power to assuredly detect a very strong effect (<4.6% mortality in exchange transfused at 90% power, presuming 15.9% in controls) and lacked key data for the vast majority of cases (e.g., <10% of cases reported parasitemia levels, a key trigger for exchange per ASFA guidelines). These study limitations were cited in ASFA's response to this publication saying that the ASFA category III recommendation for RCE would stand.<sup>102</sup> What is not in dispute is that current artemisinin combination therapies lead to rapid parasite clearance, in line with the rapidity of clearance by apheresis or manual exchange.<sup>103</sup> Given that these drugs also clear sequestered parasites definitively, artemisinin-based therapy limits the rationale for adjunct RCE.<sup>101,103</sup> However, in the face of the emergence and spread of artemisinin resistance in Southeast Asia and<sup>104</sup> and the lack of another effective antimalarial,<sup>104</sup> a properly controlled prospective trial to determine the benefit of exchange (e.g., 50% improved survival) may be of value if parasite clearance by drug becomes ineffective.

### Babesiosis

Babesiosis is a zoonotic disease and is spread to humans primarily through ticks of the genus *Ixodes*.<sup>105</sup> The first reported case of human babesiosis was in an asplenic individual from Europe.<sup>106</sup> The first case in a patient with an intact spleen was reported in Nantucket.<sup>107</sup> Within the United States, the predominant organism is *Babesia microti*, the reservoir hosts are wild rodents, and the vector is the deer tick *Ixodes scapularis*, which is the same tick that transmits *Borrelia burgdorferi*, the causative agent of Lyme disease.<sup>105</sup> Over the past several decades, the endemic range has expanded, and now encompasses seven states in the Northeast and the Midwest United States, which accounted for >86% of 2161 reported babesiosis cases in 2018.<sup>108</sup>

When injected into the human bloodstream, the sporozoites of babesia, akin to plasmodium, directly invade RBCs. After asexual budding into four merozoites, the parasites perforate the erythrocyte membrane, resulting in hemolysis.<sup>109</sup> They are then free to infect other erythrocytes and transform into dividing trophozoites (ring forms and tetrads visible on peripheral blood films).<sup>105,109</sup> One to six weeks following inoculation, infected patients develop a flu-like syndrome characterized by fever, fatigue, and malaise.<sup>110</sup> Headache, chills, sweats, myalgia, and arthralgia are frequent complaints. Physical findings may include fever and splenomegaly, and jaundice and pallor may accompany marked extravascular hemolysis. Although most cases are subclinical or mild,<sup>111</sup> severe manifestations, including disseminated intravascular coagulation, respiratory failure, and renal failure, may occur. Immunocompromised or asplenic individuals are typically more severely affected.<sup>105,112</sup>

Transfusion transmission occurs in endemic areas, leading to infections of those most vulnerable: neonates, the immunocompromised, and the elderly.<sup>113</sup> Both community-acquired and transfusion-transmitted cases have increased in recent years,<sup>114,115</sup> prompting the

FDA to issue a final industry guidance in 2019 recommending blood donor testing in 14 endemic states and Washington, DC, as well as the addition of a specific babesiosis history question to donor eligibility screening across all US blood collection areas.<sup>116</sup> Although clinical trials are lacking, several case reports and case series suggest that, given the absence of a microvascular sequestration of infection, RCE, whole blood exchange, or RCE followed by plasma exchange, combined with antibiotic therapy, can rapidly reduce parasitemia and be potentially beneficial in severe cases of babesiosis with >5–10% parasitemia.<sup>1,117–120</sup> Exchange also appears effective in neonates with severe transfusion-associated babesiosis.<sup>121</sup> Current recommendations from ASFA<sup>1</sup> and ISDA<sup>122</sup> support RCE in severely ill individuals. A single one- to two-volume RCE can reduce the circulating population of parasitized erythrocytes by 85–90%.<sup>1</sup> Unfortunately, the true effectiveness of RBC exchange on morbidity and mortality has been difficult to glean and ultimately still awaits better controlled data and potentially randomized controlled trials.<sup>94,123</sup>

### Erythrocytapheresis and therapeutic phlebotomy

Therapeutic phlebotomy or venesection is a procedure that has been performed throughout recorded history. In current clinical practice, therapeutic phlebotomy is an evidence-based intervention for disorders such as polycythemia vera and hemochromatosis.<sup>124</sup> Although erythrocytapheresis has been investigated as a means of more rapid removal of red cell mass and limiting plasma loss, phlebotomy remains the therapeutic mainstay in most settings given its simplicity.<sup>125</sup>

### Polycythemia vera

Classified as a bcr/abl-negative classic myeloproliferative neoplasm showing absolute erythrocytosis,<sup>126</sup> it is further characterized by panmyelosis in the marrow and peripheral blood, splenomegaly, hyperviscosity of the blood, thrombosis, and a tendency to evolve into either acute myeloid leukemia or myelofibrosis.<sup>127,128</sup> Over 95% of cases are now known to be associated with an acquired point mutation, V617F, in exon 14 of the Janus kinase 2 (JAK2) gene on chromosome 9p24.<sup>129</sup> The remaining 5% of patients appear to have mutations in exon 12 of JAK2, some of whom may have a more benign phenotype (idiopathic erythrocytosis).<sup>129</sup> World Health Organization (WHO) diagnostic system (Table 26.2) recognizes the predominance of JAK2 mutations in polycythemia and key finding of erythrocytosis and hypercellular bone marrow.<sup>130</sup> Setting precise cutoffs for erythrocytosis is challenging, and the most recent findings lean toward sensitivity given the utility of mutational detection for specificity. Although more rarely used, The International Council for Standardization in Haematology recognizes absolute erythrocytosis in an individual whose measured total red cell volume, or *red cell mass*, is more than 25% above

**Table 26.2** Diagnostic Criteria for Polycythemia Vera. Source: Adapted from Barbui et al.<sup>130</sup>

<b>Major</b>	<b>1. Male: Hgb &gt; 16.5 g/dL (Hct 60%); female: 16.0 g/dL (Hct &gt; 48%) or other evidence of increased RBC mass</b>
	2. Bone marrow with hypercellularity for age and trilineage myeloproliferation
<b>Minor</b>	3. Presence of JAK2 V617F or JAK2 exon 12 functional mutation
	1. Serum erythropoietin level below laboratory reference range

Diagnosis: All three major criteria or first two major criteria and the minor criterion.

the mean predicted value for a person of the same body surface area.<sup>128</sup> This formed the basis for previous Hgb/Hct cutoff of  $\geq 60\%$  (Hgb  $\geq 18.5$  g/dL) and women with a hematocrit  $\geq 56\%$  (Hgb  $\geq 16.5$  g/dL). But such specific cutoffs for Hgb in the WHO criteria were not sensitive enough and missed mildly elevated RBC mass in early polycythemia vera.<sup>131</sup>

### Therapeutic phlebotomy in polycythemia vera

The increased whole blood viscosity that results from the expansion of total red cell volume in patients with polycythemia vera is the underlying basis of the life-threatening prothrombotic state and the headache, fatigue, dyspnea, cyanosis, and other signs and symptoms that characterize the disorder.<sup>130</sup> Aggressive phlebotomy to a hematocrit below 45% in males and females is indicated for the prevention of life-threatening thrombotic complications of polycythemia vera.<sup>132</sup> High-risk patients (age  $>60$  years or history of thrombosis) should also be treated with cytoreductive hydroxyurea or, if erythrocytosis is recalcitrant, a second-line agent (e.g., busulfan or interferon- $\alpha$ ).<sup>132</sup> Low-risk patients (age  $<60$  years, no cardiovascular risk, platelet count  $<1,000,000/\mu\text{L}$ ) may initially be managed with phlebotomy alone.<sup>132</sup> Low-dose aspirin (100 mg/day) is recommended for all patients without specific contraindications to its use.<sup>132</sup> In general, approved Janus kinase inhibitors are reserved as second-line therapy when standard cytoreductive therapy fails or is not tolerated.<sup>132,133</sup> The development of agents with greater JAK2 and mutant specific inhibition still holds great promise and should influence future management of polycythemia vera.<sup>133,134</sup>

### Erythrocytapheresis in polycythemia vera

According to ASFA, polycythemia vera is a category I indication for red cell volume reduction by erythrocytapheresis.<sup>1</sup> A retrospective case series of 69 patients with polycythemia vera who underwent 206 isovolemic erythrocytapheresis procedures using 4% albumin as replacement fluid reported the reduction of hematocrit from  $56.8 \pm 5.6\%$  to  $41.9 \pm 6.6\%$  after the removal of  $1410 \pm 418$  mL of red cells.<sup>135</sup> A subset of 21 patients for whom close follow-up data were available maintained a hematocrit of  $<50\%$  for a median of six months.<sup>135</sup> The volume of red cells to be removed (VR) during an erythrocytapheresis in order to achieve a desired hematocrit can be calculated as (Formula (2)):<sup>135,136</sup>

$$\text{VR} = \left( \frac{\text{starting HCT} - \text{desired Hct}}{79} \right) \times \left( \frac{\text{blood volume}}{\text{(ml/kg)}} \right) \times \left( \frac{\text{blood weight}}{\text{(kg)}} \right) \quad (2)$$

Thus, for a 70-kg person with a blood volume of 70 mL/kg whose hematocrit is to be lowered from 68% to 55%, the volume of red cells to be removed is calculated as

$$\text{VR} = \left( \frac{68-55}{79} \right) \times (70 \text{mL/kg}) \times (70 \text{kg}) = 910 \text{mL of red cells}$$

Additional studies have confirmed that erythrocytapheresis can rapidly decrease hematocrit for extended intervals relative to simple phlebotomy.<sup>136-138</sup> Costs may be more equivalent when patient time lost to increased visits with traditional phlebotomy is considered.<sup>138</sup> Automated erythrocytapheresis may have a role for patients with acute thrombotic or microvascular complications, or to avoid perioperative thrombohemorrhagic complications in a patient with an uncontrolled hematocrit who requires urgent surgery.<sup>1,136</sup>

### Secondary erythrocytosis

Secondary erythrocytosis includes conditions that result in an elevated total red cell volume but are not clonal disorders of the marrow.<sup>126,128,139</sup> Congenital and acquired causes have been described, and they are relatively rare and predominantly involve the regulation or aberrant expression of erythropoietin or abnormalities of the erythropoietin receptor (see Table 26.3).<sup>140,141</sup> The vast majority of cases are hypoxia-stimulated, usually due to chronic lung disease, smoking, or apnea. A diagnostic investigation of a patient with suspected erythrocytosis is performed in order to (1) establish that a true state of erythrocytosis exists (i.e., an elevated total red cell volume), (2) rule out polycythemia vera, and (3) determine the cause of secondary erythrocytosis, thereby leading to clinical management to alleviate the underlying cause.<sup>126,128,139-141</sup>

### Therapeutic phlebotomy in secondary erythrocytosis

The role of phlebotomy is less certain in secondary erythrocytosis than in polycythemia vera.<sup>1,141</sup> As suggested by Table 26.3, secondary erythrocytosis is generally an adaptation to the disordered regulation of erythropoietin or to hypoxemia. In some cases, the underlying cause can be treated medically or surgically, and in others the erythrocytosis represents a physiologic adaptation to a chronic condition such as hypoxia but without thrombotic risk.<sup>142</sup> For example, adults with cyanotic congenital heart disease are not considered to be at heightened risk for thrombotic stroke despite mean hematocrits of  $57.5\% \pm 7.2\%$ <sup>143</sup> and do not exhibit symptoms of hyperviscosity until hematocrits reach 65% (in the absence of dehydration or iron deficiency).<sup>144</sup> A program of therapeutic phlebotomy should not be undertaken purely for the sake of achieving a target hematocrit in an asymptomatic individual. Isovolemic phlebotomy, with saline replacement, should be reserved for patients who are neither dehydrated nor iron deficient, and who have moderate symptoms of hyperviscosity (i.e., headache, slow mentation, visual disturbance, tinnitus, dizziness, etc.).<sup>144</sup> Withdrawal of up to a unit of whole blood, replaced by 750–1000 mL of isotonic saline, has been recommended for the relief of symptoms. Similar recommendations may refer to patients with high oxygen-affinity hemoglobin levels who have symptoms such as dizziness, dyspnea, or angina, which are believed to result, in part, from an expanded total red cell volume.<sup>141</sup> There is again no formal evidence that phlebotomy is beneficial, and a modest target (i.e., a hematocrit  $<60\%$  achieved with fluid replacement) has been recommended.<sup>141</sup> Likewise, patients with chronic hypoxic lung disease and erythrocytosis or with smoker's erythrocytosis are best managed using medical therapy to deal with their underlying pulmonary disorder. Uncontrolled studies suggest that phlebotomy to a hematocrit of 50%–52% may improve exercise tolerance, alleviate headache and confusion, and otherwise ameliorate symptoms of hyperviscosity.<sup>141</sup>

Postrenal transplant erythrocytosis, defined as a persistently elevated hematocrit above 51%, occurs spontaneously in 15–20% of kidney transplant recipients in the first 8–24 months after engraftment.<sup>145-147</sup> One-fourth of cases remit spontaneously within two years of onset, with the balance persisting for up to several years until chronic graft rejection supervenes.<sup>141</sup> The major risk factors are retention of the native kidneys, male gender, smoking, a rejection-free course with a well-functioning graft, and adequate red cell production (without the need for erythropoietin or transfusion) prior to transplant.<sup>145,147</sup> Hyperviscosity symptoms such as malaise, headache, plethora, lethargy, and dizziness are described as common among patients with this condition, and 10–30%

**Table 26.3** Secondary Erythrocytosis<sup>140,141</sup>

Type	Underlying Cause
Congenital	Genetic mutations <ul style="list-style-type: none"> <li>• High oxygen-affinity hemoglobin</li> <li>• Bisphosphoglycerate mutase deficiency</li> <li>• Erythropoietin receptor mutation</li> <li>• Oxygen-sensing pathway mutations (<i>VHL</i>, <i>PHD2</i>, and <i>HIF-2a</i> gene mutations)</li> </ul>
Acquired	Hypoxia-stimulated <ul style="list-style-type: none"> <li>• Cyanotic congenital heart disease</li> <li>• Chronic lung disease</li> <li>• High-altitude habitat</li> <li>• Smoker's erythrocytosis</li> <li>• Carbon monoxide poisoning</li> <li>• Chronic hyp ventilation (sleep apnea)</li> <li>• Renal artery stenosis</li> </ul> Inappropriate erythropoietin production <ul style="list-style-type: none"> <li>• Renal cancer</li> <li>• Hepatic cancer</li> <li>• Cerebellar hemangioblastoma</li> <li>• Endocrine tumors</li> <li>• Uterine leiomyoma</li> <li>• Polycystic kidney</li> <li>• Meningioma</li> </ul> Drug-mediated <ul style="list-style-type: none"> <li>• Androgen therapy</li> <li>• "Blood doping" (surreptitious erythropoietin use)</li> </ul> Multifactorial etiology <ul style="list-style-type: none"> <li>• Postrenal transplant erythrocytosis</li> </ul>

develop significant thromboembolic complications.<sup>145,147</sup> The pathogenesis appears to be multifactorial and likely involves an interplay between endogenous erythropoietin production by the retained native kidney, the renin-angiotensin system, androgen secretion, insulin-like growth factors, and cytokines.<sup>145,146</sup> One retrospective series reported 11 thromboembolic events, including transient ischemic attacks and strokes, and venous thromboembolism in 10 of 53 (19%) patients with postrenal transplant erythrocytosis but in none of 49 control cases ( $p < 0.001$ ). This sort of experience has led to an appreciation of the need to control the red cell volume in these patients.<sup>145–147</sup> The mainstay of treatment is angiotensin-converting enzyme inhibition or angiotensin-converting enzyme receptor blockade, sometimes in combination with theophylline, which lowers hemoglobin and hematocrit within eight weeks, with peak effect seen after up to 12 months.<sup>148</sup> Phlebotomy is reserved for cases where erythrocytosis inadequately responds to drug treatment.

#### Erythrocytapheresis in secondary erythrocytosis

Automated erythrocytapheresis is seldom recommended for the management of secondary erythrocytosis,<sup>149</sup> and its optimum role has not been established, thus requiring individualized decisions.<sup>1</sup> It may be useful in circumstances where isovolemic procedures are called for, such as in cyanotic heart disease.<sup>144</sup> Erythrocytapheresis has not been reported in the management of posttransplant erythrocytosis.

#### Hereditary hemochromatosis (HH)

Hereditary hemochromatosis is an inherited disorder that, untreated, results in iron deposition in, and damage to, the liver, heart, pancreas, and other organs, including bronze pigmentation of the skin.<sup>150,151</sup> Its prevalence is approximately 1:200 among those of European ancestry.<sup>150,152</sup> The most common genetic mutation, accounting for >90% of cases (and almost all cases in persons of Northern European ancestry), is homozygosity for a missense mutation (G845A) in the *HFE*

gene resulting in tyrosine substituted for cysteine (C282Y).<sup>153</sup> HFE C282Y (as well as H63D) decreases hepcidin transcription by stabilizing the ALK3 protein that inhibits transcription.<sup>154</sup> In the absence of a physiological means of body iron excretion, the increased iron uptake resulting from these mutations leads to the slow accumulation of iron in the liver and other organs, and eventual liver failure (via cirrhosis, hepatocellular carcinoma, etc.), diabetes, hypogonadism, hypopituitarism, arthropathy, cardiomyopathy and heart failure, and skin pigmentation.<sup>152</sup> A presenting syndrome of asthenia, arthralgia, and abnormal liver function (the three As) has been described as classic for the clinical disease.<sup>151</sup> Because of the central importance of iron loading in the pathogenesis of HH, iron removal by phlebotomy is the mainstay of treatment.<sup>152,155</sup> Diagnostic elements of HH are provided in Table 26.4.

#### Therapeutic phlebotomy in HH

Therapeutic phlebotomy has been the primary mode of iron reduction in HH for over a half century.<sup>150,156</sup> Phlebotomy therapy should be started in all patients whose serum ferritin level is elevated (Table 26.4) and should not be withheld from the elderly on the basis of age or from iron-loaded patients who have not developed clinical symptoms.<sup>151,156</sup> A common treatment approach is to perform one phlebotomy per week (1 unit or 7 mL/kg of whole blood not to exceed 550 mL per phlebotomy) until the serum ferritin is below 50 ng/mL (although this endpoint is not based on clear-cut evidence).<sup>155–157</sup> Thereafter, it is usually necessary to annually remove 3–4 units of blood to maintain the ferritin between 50 and 100 ng/mL. Strict maintenance below 50 ng/mL and <50% transferrin saturation has been recommended by others as optimal.<sup>155,158</sup> While transferrin saturation control has been associated with decreased disease progression in terms of arthropathy based on retrospective data, well-controlled data for ferritin and other markers to inform best maintenance targets are lacking.

Malaise, weakness, fatigability, skin pigmentation, cardiac function, and liver transaminase elevations often improve with treatment, whereas diabetes, cirrhosis, arthropathy, pituitary dysfunction, and hypogonadism almost never improve. Importantly, the risk of hepatocellular carcinoma will persist if cirrhosis was present before the onset of phlebotomy therapy.<sup>151,156</sup>

**Table 26.4** Some Diagnostic Considerations in HH (Absent a Cause of Secondary Iron Overload)<sup>156,157</sup>

Diagnostic tests	

### Erythrocytapheresis in HH

This was first described in Europe, where a German group from Munich reported successful lowering of iron in 14 patients with hemochromatosis, with intervals of 2–11 months between procedures.<sup>9</sup> Their follow-up study<sup>159</sup> described prospective observations on eight patients who were treated with isovolemic erythrocytapheresis (1000 mL removed) every four weeks until serum ferritin fell below 300 ng/mL. Iron depletion, thus defined, was achieved after a mean of 8.5 months, during which a mean of 9.4 liters of red cells was removed in a mean of 8.9 procedures. Subsequent studies have supported these findings, and, based on this rapidity of response and the potential removal of 2–3 times more RBCs per procedure compared to a simple phlebotomy, it has been designated a first-line therapy (category I) in the ASFA guidelines.<sup>1</sup> Recently, there have been controlled trials comparing the relative efficacy and cost-effectiveness of erythrocytapheresis versus simple phlebotomy.<sup>160,161</sup> The first study compared 500 mL weekly phlebotomies to erythrocytapheresis every two weeks. The authors found that erythrocytapheresis patients demonstrated a more rapid decline and normalization of ferritin; however, this group started with a lower average ferritin. This higher iron load in the phlebotomy group was supported by the fact that threefold more phlebotomies were needed to normalize the serum ferritin level, even though erythrocytapheresis removed only twofold more iron-containing RBCs.<sup>160</sup> Overall, these data suggest that an erythrocytapheresis procedure every two weeks and weekly whole blood phlebotomy are equivalent, a strategy that is supported by another randomized control trial that found no significant difference in mean time to iron depletion (ferritin <50 ng/mL).<sup>161</sup> In this study, the mean technician time was increased for the apheresis group,<sup>161</sup> consistent with the added procedural complexity, and thus decisions between the two modalities should probably be determined by patient and institutional preferences related to costs and effort. Intriguingly, although on average two simple phlebotomies remove equivalent iron to one erythrocytapheresis, individuals with larger blood volumes see a greater gain from erythrocytapheresis.<sup>125</sup> This is a consequence of the lack of volume adjustment for simple phlebotomy and suggests that blood-volume-based simple phlebotomies could be an optimal solution in terms of costs and effort. Recent work examining maintenance phlebotomy suggests that there is minimal difference in procedure numbers (3.3 vs 1.9 annually for phlebotomy and cytapheresis, respectively) and thus cost of apheresis was not significantly defrayed.<sup>162</sup> A recent Cochrane review reported insufficient evidence to recommend erythrocytapheresis over therapeutic phlebotomy for HH.<sup>163</sup> Without consensus, leveraging predictive models can help determine individuals who may be most appropriate for cytapheresis.<sup>164</sup>

### Therapeutic platelet apheresis

*Thrombocytosis* (or *thrombocythemia*) is defined as a platelet count  $>450 \times 10^3$  cells/ $\mu$ L for adults, with typically higher thresholds for infants and children.<sup>165,166</sup> Elevated platelet counts can arise from primary myeloproliferative diseases or secondary to a range of conditions. Mutations in erythropoietin (*EPO*), its receptor (*MPL*), associated signaling pathways (via *JAK2*), and calreticulin (*CALR*) underlie many primary thrombocythemic states.<sup>165,167</sup> In children and younger adults, most thrombocytosis is reactive (Table 26.5).<sup>168–170</sup> Extreme thrombocytosis (EXT) is defined as a platelet count  $>1000 \times 10^3$  cells/ $\mu$ L and occurs in approximately 1% of hospitalized

**Table 26.5** Some Causes of Primary (Clonal) and Secondary (Reactive) Thrombocytosis

Type	Possible Causes
Primary thrombocytosis	Essential thrombocytosis Polycythemia vera Chronic myelogenous leukemia Myelofibrosis Myelodysplastic syndrome (5q-) Acute hemorrhage
Secondary thrombocytosis	Chronic blood loss with iron deficiency Tissue damage or trauma Malignancy Inflammatory bowel disease Acute or chronic inflammation Acute or chronic infection Physical exercise Rebound (after chemotherapy, splenectomy, or immune thrombocytopenic purpura) Medication

patients.<sup>171</sup> There is great variability and tolerance of such high counts in individuals, which is likely related to the underlying cause as well as the duration of the high count. In children, extreme thrombocytosis is almost always reactive, transient, and does not require specific medical treatment.<sup>165,172</sup> The most common setting of EXT in a recent adult series was reactive thrombocytosis in post-surgical patients (50.8%). Hematologic malignancy was a cause in 30% of all patients, but it was 3.4 times more likely to be the cause of EXT in outpatients compared to inpatients. Most cases were multifactorial and resolved by treating the underlying causes.<sup>171</sup>

*Thrombocytapheresis* is a term that describes the selective removal of platelets from a patient, for therapeutic purposes, using a blood-processing (apheresis) device.<sup>170</sup> The 2019 ASFA review of indications for apheresis therapy lists “symptomatic thrombocytosis” as a category II indication for thrombocytapheresis.<sup>1</sup> This designation refers to primary thrombocytosis as results from a clonal (myeloproliferative) disorder of the marrow.<sup>168</sup> Thrombocytapheresis for prophylaxis in asymptomatic patients or to lower the platelet count in cases of secondary or reactive thrombocytosis is listed as a category III (i.e., specific role of the procedure not determined in this condition) indication because published evidence is insufficient to establish when the procedure is of benefit in these circumstances.<sup>1</sup> Secondary thrombocytosis per se does not convey a risk of thromboembolic morbidity absent confounding factors such as malignancy or major surgery.<sup>169,173</sup> Even then, antiplatelet agents should be the first option for treatment.<sup>170</sup> In any case, the treatment of the underlying cause is the prime factor in the resolution of secondary thrombocytosis. In fact, given the absence of risk posed by the platelet count in secondary thrombocytosis, the platelet count may be considered a laboratory sign of an underlying condition that should be investigated.<sup>168</sup>

### Primary thrombocytosis (essential thrombocythemia, ET)

Thrombocytosis with thromboembolic complications is a feature common to chronic myeloproliferative disorders,<sup>66,126</sup> of which half are essential thrombocythemia.<sup>95,169</sup> Thus, the remainder of this discussion will focus on essential thrombocythemia. Both thrombotic and hemorrhagic complications result in patients with essential thrombocythemia.<sup>168,174</sup> The molecular basis of myeloproliferative neoplasms has provided new insights into the pathophysiology of this disease. Somatic mutations in *JAK2*, *CALR*, or *MPL* have been

reported in approximately 90% of patients, aid in diagnosis, and influence the clinical presentation.<sup>167,174</sup> Factors that increase risk of arterial thrombosis include age greater than 60 years; thrombosis history; cardiovascular risk factors such as hypertension, hypercholesterolemia, and diabetes; and *JAK2* V617F positivity;<sup>98,175</sup> 50–60% of patients with ET have a *JAK2* mutation, which leads to thrombopoietin-independent cell proliferation. *CALR*-mutated ET is associated with extreme platelet counts ( $>10^6/\mu\text{L}$ ), reduced risk of thrombosis, and bleeding due to an acquired von Willebrand syndrome (AvWS). AvWS results from the accelerated clearance of hemostatically competent large multimers of von Willebrand factor from the circulation, which improves with therapeutic reduction of the platelet count.<sup>175–177</sup> The *MPL* gene encodes the thrombopoietin receptor, and several mutations cause a small proportion of ET (about 5% of cases). A recent systematic review found that platelet activation is increased in ET, particularly in patients with a history of thrombosis, but other platelet attributes or function were inconsistent.<sup>178</sup> There is no evidence in favor of prophylactic apheresis treatment of low-risk, asymptomatic patients, regardless of platelet count, but high-risk and symptomatic patients may be treated to lower their platelet count to below  $400,000/\mu\text{L}$ . Low-dose aspirin is a proven treatment in all patients, although AvWS should be screened for in those with extreme thrombocytosis ( $>10^6/\mu\text{L}$ ).<sup>179</sup> The United Kingdom Medical Research Council Primary Thrombocythemia 1 Study has established hydroxyurea plus low-dose aspirin as the treatment of choice in high-risk patients.<sup>180</sup> Whereas the rate of first thrombosis in an untreated high-risk population is approximately 26% at two years, the rate decreases to about 4% at two years with hydroxyurea and aspirin.<sup>180</sup>

### **Therapeutic thrombocytapheresis in primary thrombocytosis**

Rapid lowering of an elevated platelet count, using apheresis and/or chemotherapy, is indicated for patients with myeloproliferative neoplasms who present with clinical syndromes of microvascular thrombosis such as digital or cerebral ischemia.<sup>1</sup> Case series and case reports have reported successful, rapid lowering of the platelet count in symptomatic patients in whom chemotherapy either was not an immediate option or was judged to have an insufficiently rapid effect.<sup>181</sup> Procedures in which 1.5–2.0 blood volumes are processed, and crystalloid replacement fluids are used to manage fluid balance, can lower the platelet count by approximately 40–60%,<sup>1,182</sup> but reductions as great as 65–70% have been reported with the latest apheresis instruments.<sup>183,184</sup> Like all cytapheresis, thrombocytapheresis without concomitant pharmacotherapy is not a practical means for controlling the platelet count beyond the acute setting. Although thrombocytapheresis has been used in the past for the management of a high-risk pregnant patient with essential thrombocythemia for whom hydroxyurea is contraindicated, interferon-alpha is the treatment of choice in pregnancy.<sup>1,185</sup>

### **Therapeutic white cell apheresis**

Hyperleukocytosis (white cell count  $>100,000/\mu\text{L}$ ) with symptomatic leukostasis is a category II indication for therapeutic leukocytapheresis.<sup>11</sup> Leukocytapheresis by selective adsorption techniques has shown a disappointing lack of efficacy in trials for idiopathic inflammatory bowel disease.<sup>186,187</sup> For ulcerative colitis, the remission rate was 17% for leukocytapheresis and 11% for the sham control ( $p = 0.36$ );<sup>186</sup> and for Crohn's disease, the remission rate was 18% for the leukocytapheresis and 19% for the sham control ( $p = 0.86$ ).<sup>187</sup>

Currently, ASFA rates immunoabsorption for IBD as a category III indication, except for ulcerative colitis in Japan, which is category II and may be due to the fact that TNF $\alpha$  blockade is not standard therapy in Japan.<sup>1</sup>

### **Leukocytapheresis for hyperleukocytosis**

Hyperleukocytosis is a major risk factor for early mortality, often from pulmonary and/or central nervous system hemorrhage, in adults and children with acute myeloblastic leukemia or other hyperleukocytic leukemias.<sup>188</sup> It occurs in 5–13% and 12–25% of adult and pediatric AML cases, respectively.<sup>189</sup> The reported incidence in acute lymphoblastic leukemia ranges from 10% to 30%.<sup>189</sup> Mortality rates of 20–40% have been reported.<sup>189</sup> Leukostasis represents end-organ damage due to leukocyte-mediated microvascular occlusion and damage resulting in infarct and hemorrhage. It usually does not occur until white blood cell counts surpass  $100,000/\mu\text{L}$  in acute myelogenous leukemia (AML) and  $400,000/\mu\text{L}$  in acute lymphoblastic leukemia (ALL).<sup>1</sup> Clinical features of leukostasis include respiratory distress, hypoxemia, diffuse interstitial or alveolar infiltrates on chest X-ray, confusion, somnolence, stupor or coma, headache, dizziness, tinnitus, gait instability, or visual disturbances.<sup>190</sup> Physical examination may demonstrate papilledema, dilated retinal veins and/or retinal hemorrhages, cranial nerve defects, or meningeal signs.<sup>189</sup> Metabolic derangements caused by tumor lysis may include hyperkalemia, hyperuricemia, hypocalcemia, and hyperphosphatemia and may result in renal failure and early death. Coagulopathy results from release of lysosomal enzymes from myeloid blasts, disseminated intravascular coagulation, and thrombocytopenia resulting from marrow failure.<sup>190</sup>

A standard treatment approach to hyperleukocytosis includes intravenous hydration and lowering of plasma uric acid using allopurinol or urate oxidase. Hydroxyurea may be prescribed to rapidly lower the total circulating nucleated cell count without precipitating a tumor lysis syndrome.<sup>189</sup> Induction chemotherapy may be used for this purpose but may precipitate tumor lysis syndrome and hemorrhage.<sup>191</sup> The impact of leukocytapheresis (or *leukapheresis*) on important clinical outcomes, including overall survival, is controversial. There is no doubt that processing 1.5–2.0 blood volumes by apheresis can reduce the circulating white cell count by up to 60%.<sup>1,190–193</sup> However, a recent meta-analysis across 13 retrospective studies involving 1743 patients showed that leukapheresis did not improve early mortality compared to medical therapies (RR, 0.88; 95% confidence interval, 0.69–1.13;  $p = 0.321$ ), consistent with a prior meta-analysis from 2014.<sup>194,195</sup> This lack of improved survival is seen in diverse global populations, such as a group of 40 Indonesian patients for whom there was no difference in either 7-day or 28-day survival for patients receiving leukapheresis in addition to chemotherapy compared to patients receiving chemotherapy alone, although poor survival did correlate with age  $>60$  years, creatinine  $>1.4$ , blasts  $\geq 90\%$ , and DIC.<sup>192,193,196,197</sup> Hyperleukocytosis is distinct from leukostasis since the metabolic anomalies, coagulopathy, tumor lysis, and multiorgan failure that characterize the leukostasis syndrome may occur at variable WBC counts.<sup>198–200</sup> Hyperleukocytosis without symptoms is an ASFA category III (individualize decision-making) for leukocytapheresis. Hyperleukocytosis with leukostasis is classified as category II mainly based on anecdotal reports of rapid reversal of signs and symptoms. Cytoreduction by medical therapies remains the emergent, first-line treatment for symptomatic leukostasis.<sup>1</sup>

## Extracorporeal photopheresis

Extracorporeal photopheresis (ECP or *photochemotherapy*) describes a procedure in which circulating mononuclear cells are collected by centrifugal apheresis, treated with 8-methoxypsoralen (8-MOP, a photoactivating agent that intercalates with DNA), and then exposed to ultraviolet A (UVA) light. The treated cells are then reinfused into the patient. A full procedure is completed in approximately 1.5–3 hours.<sup>201,202</sup> The mechanism of action of ECP is poorly understood. In a broad sense, DNA crosslinking in photo-treated leukocytes is thought to induce apoptosis in treated cells, which are then phagocytosed by immature dendritic cells upon reinfusion, resulting in both direct and indirect immunomodulation.<sup>202,203</sup> Although the main effects vary somewhat among diseases, they likely include the generation of tolerogenic dendritic cells, skewing toward anti-inflammatory cytokine production, and increased tolerogenic and regulatory T-cell populations.<sup>202,203</sup> Currently, erythrodermic cutaneous T-cell lymphoma (CTCL) is the only category I indication for ECP. ASFA has listed the prophylaxis and treatment of heart transplant cellular rejection, acute or chronic graft-versus-host disease (GVHD), and chronic lung allograft rejection from bronchiolitis obliterans syndrome as category II indications for ECP, with variable qualities of evidence. There is a growing body of potential applications in transplant rejection as well as in autoimmune diseases for which the ASFA recommendations are generally category III.<sup>1,204</sup> Some ECP regimens used in the treatment of the category I and II indications are described in Table 26.6.

**Table 26.6** Regimens of Extracorporeal Photochemotherapy (ECP)

Indication	Treatment
Cutaneous T-cell lymphoma	ECP cycle (two consecutive days) once or twice a month; continue for six months before declaring treatment failure
Cardiac allograft rejection	<p>Prophylaxis</p> <ul style="list-style-type: none"> <li>• Month 1 after transplant: ECP days 1 and 2, 5 and 6, 10 and 11, 17 and 18, and 27 and 28</li> <li>• Months 2 and 3 after transplant: ECP on two successive days every two weeks</li> <li>• Months 4–6 after transplant: ECP on two successive days every four weeks</li> </ul> <p>Acute (moderate) rejection</p> <ul style="list-style-type: none"> <li>• ECP procedures on two consecutive days at weekly episode intervals as needed to resolve rejection as indicated by endomyocardial biopsy</li> </ul> <p>Recurrent/refractory cellular rejection</p> <ul style="list-style-type: none"> <li>• ECP on two consecutive days weekly for one month, then every two weeks for two months, and then monthly for three months (total of 22 procedures)</li> </ul> <p>Chronic rejection</p> <ul style="list-style-type: none"> <li>• Beginning within one month of transplantation: ECP on two successive days every four weeks for twelve months, every six weeks for next six months, and every eight weeks during next six months</li> <li>• ECP two consecutive days: weekly for two months, then every two weeks for the next two months, then monthly for a total of six months</li> <li>• ECP on two consecutive days every 1–2 weeks, and then consider monthly interval; treat at least six months before declaring treatment failure</li> <li>• ECP two consecutive days weekly for two months (approximately 20 procedures), then weekly for three months, tapering to one procedure every other week, and then monthly till tapered completely</li> </ul>
Lung allograft rejection: bronchiolitis obliterans syndrome (BOS)	
Chronic graft-versus-host disease	

## Cutaneous T-cell lymphoma (CTCL)

The CTCLs are a heterogeneous group of extranodal non-Hodgkin lymphomas of T-cell origin that target the skin.<sup>205</sup> Mycosis fungoides, the most common form of CTCL, accounts for almost half of all primary cutaneous lymphomas.<sup>202</sup> It is largely a disease of adults (median age 55–60 years at diagnosis) and typically presents as an indolent disorder that progresses slowly over years from patchy skin involvement to infiltrated plaques, tumors, and widespread disease.<sup>202</sup> Whereas localized (e.g., nonerythrodermic) mycosis fungoides is adequately managed with topical therapies, the application of ECP in erythrodermic mycosis fungoides is recommended by ASFA.<sup>1</sup> Whereas limited-stage mycosis fungoides does not shorten life expectancy, advanced-stage disease may be associated with a 10-year disease-specific survival of 20%.<sup>206</sup> Sézary syndrome is defined as a triad of erythroderma, generalized lymphadenopathy, and the presence of neoplastic T cells (Sézary cells) in the skin, lymph nodes, and peripheral blood.<sup>202,207</sup> A retrospective cohort study from Stanford University of 106 patients with erythrodermic mycosis fungoides and Sézary syndrome identified age  $\geq 65$  years, clinical Stage IV, and circulating Sézary cells  $\geq 5\%$  of total lymphocytes as independent negative prognostic factors for survival.<sup>207</sup> Median survivals of patients with none, one, or more than one of these adverse prognostic factors were 122 months ( $n = 36$ ), 44 months ( $n = 39$ ), and 18 months ( $n = 31$ ), respectively ( $p < 0.005$ ).<sup>208</sup>

The 1987 report by Edelson *et al.*<sup>209</sup> of a successful pilot trial of ECP, in which 27 of 37 treatment-resistant patients with CTCL experienced an average 64% decrease in cutaneous involvement after  $22 \pm 10$  weeks, led to US Food and Drug Administration (FDA) approval of ECP for the treatment of CTCL later that year. Long-term follow-up of the original 29 patients with erythrodermic CTCL from that pilot study<sup>209</sup> reported that median survival of the treated patients was 60.33 months from diagnosis and 47.9 months from the start of ECP. Four of the six patients who achieved complete responses in the original study remained in complete remission.<sup>210</sup> Between 1987 and 2001, 21 studies reported a total of 485 patients treated using ECP.<sup>202,211</sup> Although most patients in these studies had erythrodermic CTCL, most studies did not report the response rates separately for the erythrodermic subjects.<sup>212</sup> In addition, responses were defined as  $>25\%$  skin clearing in some studies and  $>50\%$  skin clearing in others, and complete responses were defined as either 75–100% skin clearing,  $>90\%$  skin clearing, or 100% skin clearing.<sup>202</sup> Nonetheless, overall response rates reported in these studies ranged from 31% to 87.5%, and complete response rates ranged from 0% to 54% (20–30% in most studies).<sup>202,211–213</sup> The variability in response rates has been attributed to differences in entry criteria, prior or concurrent therapy, duration between diagnosis and application of ECP, the ECP protocol followed, and the definition of response.<sup>211</sup> Based on the above, ECP has been recommended by several international clinical guideline groups,<sup>213</sup> including the category I recommendation for erythrodermic CTCL from ASFA.<sup>1</sup>

## Cardiac and lung allograft rejection

In the United States, the rate of heart transplantation remained steady in the 2200–2500 range from the early 1990s to the 2010s, with an increase to 3500–3600 by 2020, but lung transplants have increased from less than 100 in 1989 to 2500 in 2020.<sup>214–216</sup> Rejection is still a serious problem for both heart and lung allografts, accounting for approximately 11% of deaths in the first three years after heart transplant, and underlies the majority of

graft failures that account for 35% of overall deaths.<sup>214</sup> Similarly for lung allografts, rejection underlies approximately 25% of mortality at five years, when bronchiolitis obliterans syndrome (BOS), the end result of chronic rejection, is included.<sup>215</sup> Immunosuppressive therapy to prevent allograft rejection has included perioperative antilymphocyte antibody (polyclonal antilymphocyte or antithymocyte globulin, OKT3, or IL-2 receptor antibodies), chronic postoperative calcineurin inhibitors (e.g., tacrolimus and cyclosporine), mycophenolate mofetil, sirolimus, and others.<sup>214,215</sup> Because of the association between rejection, graft failure, and death, evidence of rejection should result in adjustment in the immunosuppressive regimen to initially resolve the episode of rejection. For unresponsive cardiac rejection or lung transplant BOS, ECP is an appropriate adjuvant; and these are listed by ASFA as category II indications for ECP based on the evidence described below.<sup>1</sup>

### **Extracorporeal photochemotherapy in the treatment of cardiac allograft rejection**

Studies in support of ECP for treatment of cardiac allograft rejection focus on the effects of ECP on endomyocardial biopsy findings rather than on survival or graft function.<sup>211</sup> Two pilot studies have shown evidence that the risk of acute cellular rejection episodes can be decreased by incorporating ECP into the prophylactic immunosuppressive regimen of cardiac allograft recipients without increasing the risk of infection caused by immunosuppression.<sup>217,218</sup> A prospective randomized pilot trial comparing 10 cases receiving ECP and 13 controls treated with only immunosuppression reported that the development of panel-reactive antibodies (responsible for chronic antibody-mediated rejection) and coronary artery intimal hyperplasia (a pathogenetic mechanism of graft failure in chronic rejection) are mitigated by the addition of ECP to the posttransplant immunosuppressive regimen for the first two years after transplant surgery.<sup>219</sup> Dall'Amico and colleagues in Padua, Italy, reported a prospective pilot trial in eight patients, with recurrent acute rejection episodes despite immunosuppression, who were treated with two consecutive days of ECP every four weeks for six months.<sup>220</sup> Seven benefited with a reduction in the number and severity of rejection episodes; reduction in daily prednisone, cyclosporine, or azathioprine doses; and improvement on endomyocardial biopsy specimens. The proinflammatory cytokine IL-6 was decreased in 13 recipients who were treated with ECP for recurrent AMR, and ejection fraction increased from  $35 \pm 20\%$  to  $45 \pm 23\%$  ( $p = 0.004$ ) after ECP, although antibody levels were unchanged.<sup>221</sup> Other small case series and case reports have presented corroborating data supporting ECP efficacy.<sup>222</sup>

### **Extracorporeal photochemotherapy in the treatment of lung allograft rejection**

The use of ECP in lung transplant is a promising new avenue,<sup>223</sup> although mostly retrospective studies have been reported thus far. A major RCT on the topic, designed to assess the efficacy and tolerability of ECP for either refractory or newly diagnosed BOS, is due to be completed in 2025.<sup>223</sup> The first reports of treatment were in 1995 and represented a handful of cases pointing to effective improvement in clinical lung function (FEV<sub>1</sub>) and histological improvement. A number of small studies followed that generally supported these findings.<sup>222</sup> Only recently have larger studies examining ECP been reported,<sup>87,224,225</sup> encompassing a total 135 patients and supporting a role for ECP in stabiliz-

ing lung function (FEV<sub>1</sub>) with minimal procedural side effects. This trend has persisted, with nearly 200 additional patients reported in retrospective studies<sup>226</sup> and a single report of 51 patients in a prospective study also showed significantly longer survival in the 61% of patients who responded to ECP compared to both ECP-nonresponders and patients without ECP treatment.<sup>87</sup> Although the lack of adequate controls leaves a larger question as to the benefit of ECP compared to regimens that do not include ECP, there is a decrease in donor-specific antibodies in patients treated with ECP compared to controls, akin to ECP for cardiac rejection.<sup>227</sup>

### **Graft-versus-host disease**

GVHD occurs in hematopoietic progenitor cell transplant recipients when T cells of donor origin (either transplanted with, or that developed from, the graft) interact with tissue in the HLA-matched but genetically nonidentical host.<sup>228</sup> Classical acute GVHD develops within 100 days of transplantation, with skin manifestations that vary from an erythematous morbilliform rash to epidermal necrolysis, mucosal inflammation causing diarrhea and abdominal cramping, and abnormalities of liver function tests.<sup>228</sup> GVHD that develops beyond 100 days of transplantation, or persists more than three months, is traditionally referred to as chronic GVHD and is characterized by an oral, ocular, and mucous membrane sicca syndrome; skin involvement; scleroderma; bronchiolitis obliterans; joint contractures; myofascitis; esophageal stricture; or other fibrotic complications in various organ systems.<sup>228</sup> The cumulative incidence of acute GVHD is approximately 12–75%, and the cumulative incidence of chronic GVHD is approximately 15–70% after hematopoietic progenitor cell transplantation, depending on whether the donor-recipient pair are related or unrelated and whether a myeloablative or nonmyeloablative conditioning regimen was used.<sup>229,230</sup> Accurate diagnosis and staging are important in that recurrent or late-onset acute GVHD may not require prolonged therapy as is required with chronic GVHD, whereas overlap syndromes may require shorter courses of typical treatments for chronic GVHD.<sup>231</sup>

### **Extracorporeal photochemotherapy in the treatment of GVHD**

The application of ECP to the treatment of GVHD has been extensively reviewed.<sup>211,232</sup> Among the larger prospective reports is one from a London group that treated 28 patients who had developed steroid-refractory chronic GVHD following HLA-matched allogeneic marrow or peripheral blood progenitor cell transplant.<sup>233</sup> Among the patients, 27 were classified as having extensive chronic GVHD and 20 had involvement of more than 50% of their skin surface. Patients were given ECP on two consecutive days every two weeks for the first four months and monthly thereafter. ECP was initiated within a median of 34 months (range 10–167) after transplantation and 23 months (range 2–164) from the onset of chronic GVHD. Of the 21 patients with cutaneous involvement who were evaluable, a 25% reduction in skin involvement was noted in eight (38%) after three months and in 10 (48%) after six months, and a statistically nonsignificant improvement in liver function tests was noted.<sup>233</sup> There is only one randomized control study that failed to show significant improvement in the primary outcome, which was a decrease in skin involvement (14.5% for ECP arm vs 8.5% in control); however, there was significant decrease in steroid usage compared to the control arm.<sup>234</sup> Given the lack of large randomized prospective studies, a

meta-analysis was performed combining 18 prospective and retrospective studies of steroid-refractory GVHD with sufficient comparable cases.<sup>232</sup> This meta-analysis found significant efficacy with a complete response rate of 29% (CI 19–42%) along with particularly strong response rates of 74% (CI 60–85%) and 68% (CI 55–77%) for skin and liver, respectively.<sup>232</sup> Only modest activity was seen for lung or gastrointestinal manifestations. Based on the overall evidence, ASFA considers skin manifestations to be a category II indication for ECP, with a slightly better quality of evidence for chronic over acute presentations.<sup>1</sup>

### **Therapeutic apheresis of nonhematopoietic cells**

#### **Loiasis**

Loiasis is a parasitic infection by the nematode *Loa loa* that is transmitted by *Chrysops* flies via blood meals.<sup>235</sup> Adults reside in the subcutaneous tissues but produce microfilaria that are found in the blood and most body fluids. While most people are asymptomatic, the most common findings are Calabar swellings that are localized nontender sites usually on arms and legs near joints and eye worm that represents adult worm movement across the cornea. Fatigue, itching, malaise, and eosinophilia are often associated. Diethylcarbamazine (DEC) is the treatment of choice killing all life stages. However, there is a risk of neurologic complications with DEC treatment in those with high peripheral blood microfilarial levels (>8000/ $\mu$ L). Currently, while not specifically covered in the ASFA guidelines<sup>1</sup>, CDC treatment recommendations include the reduction of parasites to below 8000/ $\mu$ L with cytapheresis or initial albendazole prior to initiating DEC.<sup>235</sup> Apheresis has been used successfully in the past to significantly reduce parasite burden based on individual and series of cases, paying particular attention to the diurnal variation in parasitemia. Differences in methodology and the number of procedures make it difficult to determine the cellular constituent to target in the buffy coat region to maximize microfilarial removal. Buffy coat removal and platelet apheresis have shown good microfilarial reductions but often promote thrombocytopenia.<sup>236,237</sup> More recent mononuclear cell targeting using standard apheresis methods may work just as well as previous methods and spare platelets.<sup>238</sup>

### **Conclusion**

Refining the role of therapeutic cellular apheresis as a treatment option in diverse clinical conditions depends not only on a better understanding of the pathophysiology of the disorders in question

but also on the rapid, recent development of potent and effective medical therapies, particularly in the areas of antimicrobials, chemotherapy and chemical cytoreduction, and disease modifiers in sickle cell anemia. Evidence of the clinical impact and efficacy of apheresis therapies from properly conducted clinical studies should guide and direct the appropriate and deliberate application of apheresis technologies.

## Introduction

Patient blood management (PBM) is a multidisciplinary approach to improve patient outcomes using evidence-based strategies in patients who may need transfusion. PBM encompasses all aspects of patient evaluation and the transfusion decision-making process. Despite continued declines in demand for blood products, blood transfusion remains one of the most commonly performed medical procedures in the United States and other developed countries.<sup>1</sup> The goal of PBM is not only to improve outcomes by transfusing blood appropriately, but also to introduce strategies to prevent patients from needing a transfusion in the first place. Avoiding and/or minimizing transfusion certainly leads to fewer transfusion reactions, fewer donor exposures, and in some cases lower cost. It has been stated that transfusions are also associated with worse patient outcomes, including bacterial infections, increased length of stay, prolonged ventilation, and mortality.<sup>2</sup> Such statements are based primarily on observational data or meta-analyses<sup>3</sup> and are controversial because of potential confounding and/or methodologic issues.<sup>4</sup> Even in the absence of serious morbid events causally related to transfusion, if a transfusion does not confer a benefit, it should be avoided. In a 2011 survey of 1342 US hospitals, 30% of respondents stated they offered some components of a PBM program and PBM programs were reported by 37.8% of the 1068 US hospitals surveyed by the AABB in 2013.<sup>5,6</sup> The uptake of PBM has undoubtedly risen since then, but compliance with PBM standards remains suboptimal in some regions.<sup>7</sup> Several professional organizations have focused on PBM: AABB, the Society for the Advancement of Blood Management (SABM) and the Network for Advancement of Transfusion Alternatives (NATA) in Europe. Each of these organizations has annual meetings with PBM content and abundant written resources, including published PBM program guidelines or standards.<sup>8,9</sup> An effective PBM program combines multiple approaches that span patient care from prehospitalization to the inpatient setting and even after discharge. Furthermore, the techniques of PBM are not limited to surgical patients. The features of a comprehensive PBM program are shown in Figure 27.1 and are discussed in this chapter.

## Definitions of PBM

*"Patient blood management (PBM) is a patient-focused, evidence-based and systematic approach to optimize the management of patients and transfusion of blood products for quality and effective patient care. It is designed to improve patient outcomes through the safe and rational use of blood and blood products and by minimizing unnecessary exposure to blood products."*

- World Health Organization (WHO) Global Forum for Blood Safety:  
Patient blood management<sup>10</sup>

*Patient blood management (PBM) is "the timely application of evidence-based medical and surgical concepts designed to maintain hemoglobin concentration, optimize hemostasis, and minimize blood loss to improve patient outcome."*

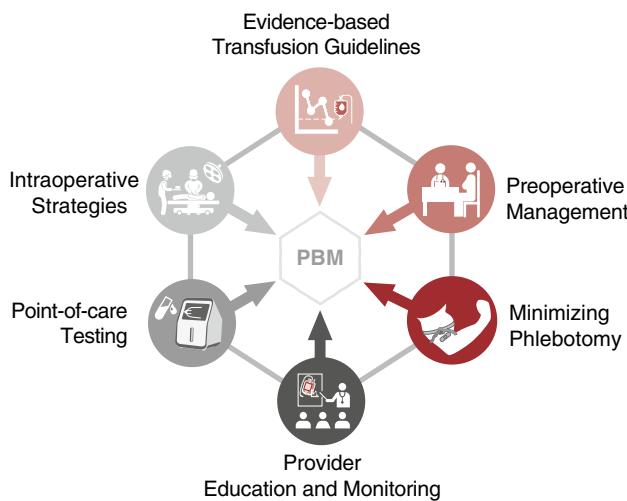

- Society for the Advancement of Blood Management (SABM)<sup>11</sup>

*"Patient Blood Management (PBM) is a multidisciplinary, evidence-based approach to optimising the care of patients who might need a blood transfusion. It represents an international initiative in best practice for transfusion medicine. It is a long-term approach to improve patient care and save money. It requires co-ordinated planning at national and local level and resources and investment."*

- National Health Service (NHS) Blood and Transplant, United Kingdom<sup>12</sup>

## Implementing a PBM program

There exists no single approach to implementing a PBM program that is appropriate for all hospitals. The approach will vary depending on the size of the hospital, patient populations, and hospital resources. Strategies common to a successful program have been described.<sup>13–15</sup> By its nature, a PBM program is multidisciplinary, and thus a program should start by identifying and recruiting the relevant physician, nursing, and administration stakeholders or "champions" from a variety of specialties. Once identified, these champions can form the basis for a PBM oversight committee with representatives from transfusion medicine, surgery, anesthesia, critical care medicine, hematology/oncology, nursing, information

**Figure 27.1** Features of a patient blood management (PBM) program: evidence-based guidelines for transfusion thresholds, indications and dose; preoperative anemia evaluation and management; physician education and monitoring; point-of-care hemostasis testing; intraoperative strategies (autologous salvage, acute normovolemic hemodilution, and use of hemostatic agents); and limiting phlebotomy blood loss for laboratory testing.

technology (IT), and data analytics. Some PBM committees also include representatives from perfusion, pharmacy, laboratory medicine, internal medicine, risk management, or hospital administration. Many institutions have created a coordinator position called a Transfusion Safety Office (TSO) or PBM coordinator. This position is analogous to an Infection Control Officer but focuses on transfusion and PBM. The TSO is typically a nurse but could be a person with a laboratory or a quality systems background. Such individuals act as a liaison between the PBM committee and clinical services focusing on education, auditing, monitoring, data collection, and reporting. The PBM committee should have a medical director or codirectors responsible for direction, organization, and oversight of committee activities and representing the committee within the hospital. Ideally, the chair should be a clinician with credibility among the physicians who order blood products. A transfusion medicine physician may also serve well in this role. The most important point is that it is a physician who is committed and passionate about creating a successful PBM program.

Essential to the success of the PBM committee is visible and vocal support of the hospital leadership. This includes the hospital chief executive officer (CEO) and senior management or administration as well as the departmental chairs of the key clinical services that utilize blood products. Effective leadership drives physicians and staff to participate in PBM initiatives. Some PBM initiatives may require financial investment, such as hiring a TSO or building IT infrastructure. Such vital investment will require institutional leaders to “buy in” to the notion of investing now in order to improve patient care and ultimately reduce future costs. A lack of hospital leadership support is the most common reason why PBM programs fail to achieve their goals.

Many hospitals have an existing transfusion committee or similarly tasked committee that reports to the hospital medical executive committee or in some cases through the hospital quality assurance structure. Traditional transfusion committee activities will include some, but not all, PBM activities. For example, transfusion

committees typically monitor blood usage and adverse event reports, but not the management of preoperative anemia or the use of point-of-care testing. It is prudent for the PBM committee to work closely with the transfusion committee to complement but not duplicate their activities. When the transfusion committee is a standing committee, it can be a useful conduit for the approval of PBM policy proposals and education, and an additional source of resources for PBM activities. It is also feasible to roll the oversight of PBM activities into the responsibilities of the existing transfusion committee.

Once the PBM committee has been constituted, it should define the scope of activities it will address. Figure 27.1 presents a comprehensive set of PBM activities, but rarely can all be addressed and almost certainly not simultaneously. The goal is to achieve measurable, impactful, and lasting success. Thus, initially it would be wise to address those aspects that are the most feasible and that will have the greatest impact on patient care. In this way, the program can attract positive attention to itself, and perhaps garner additional PBM champions, and continued administrative support. Later, as the program matures and circumstances change, other aspects of the program can be addressed. Monitoring, measurement, and metrics are vital components of a PBM program.<sup>16</sup> The metrics or key performance indicators should be meaningful, quantitative, and feasible to measure. This is where IT/ data analytics support and having a TSO/PBM coordinator to collect and analyze the data are so important. As part of defining its scope of activities, the PBM committee should define the metrics for each activity and acceptable targets for success (goals), as well as the IT resources and data analytics support (e.g., for reports) and/or other staff needed for chart review.

Several professional organizations have developed best practice guidelines for PBM, including AABB, the Society for the Advancement of Blood Management (SABM), NATA in Europe, NHS Blood and Transplant in the United Kingdom, and the National Blood Authority in Australia.<sup>8,9,12,17</sup> The Joint Commission, in partnership with the AABB, in the United States also offers a two-year voluntary certification process that provides a third party evaluation of a hospital’s PBM program; the accreditation process is based on the AABB Standards for a Patient Blood Management Program, which were originally published in 2014 and updated in 2018.<sup>18</sup>

The 2018 Frankfurt Consensus Conference catalogued the current state of the PBM evidence base for RBC transfusion by analyzing 145 studies, including 63 randomized clinical trials (RCTs) with 23,143 patients and 82 observational studies with more than four million patients. The scientific committee established 10 clinical recommendations and 12 research recommendations for management of preoperative anemia, transfusion thresholds for adults, and implementation of PBM programs.<sup>19</sup> The clinical recommendations are summarized in Table 27.1. While these recommendations focus on red cell transfusions only, they are a useful resource for institutions embarking on implementation of a PBM program.

### Evidence-based transfusion guidelines

There is no doubt that evidence-based transfusion guidelines derived from review of the current literature are a key component of a PBM program. They do not, however, solely constitute a PBM program. If the transfusion committee does not already have such guidelines in place, the PBM committee should develop a set of transfusion guidelines for the hospital. A number of organizations have conducted careful literature reviews based on Grading of

**Table 27.1** Clinical Recommendations from the 2018 Frankfurt Consensus Conference on PBM

Category	Clinical Recommendation	Level of Evidence
Preoperative Anemia	CR1—Detection and management of preoperative anemia early enough before major elective surgery	Strong recommendation, low certainty in the evidence of effects
	CR2—Use of iron supplementation to reduce red blood cell transfusion rate in adult preoperative patients with iron-deficient anemia undergoing elective surgery	Conditional recommendation, moderate certainty in the evidence of effects
	CR3—Do not use erythropoiesis-stimulating agents routinely in general for adult preoperative patients with anemia undergoing elective surgery	Conditional recommendation, low certainty in the evidence of effects
	CR4—Consider short-acting erythropoietins in addition to iron supplementation to reduce transfusion rates in adult preoperative patients with hemoglobin concentrations <13 g/dL undergoing elective major orthopedic surgery	Conditional recommendation, low certainty in the evidence of effects
Red Blood Cell Transfusion Thresholds	CR5—Restrictive RBC transfusion threshold (hemoglobin concentration <7 g/dL) in critically ill but clinically stable intensive care patients	Strong recommendation, moderate certainty in the evidence of effects
	CR6—Restrictive RBC transfusion threshold (hemoglobin concentration <7.5 g/dL) in patients undergoing cardiac surgery	Strong recommendation, moderate certainty in the evidence of effects
	CR7—Restrictive transfusion threshold (hemoglobin concentration <8 g/dL) in patients with hip fracture and cardiovascular disease or other risk factors	Conditional recommendation, moderate certainty in the evidence of effects
	CR8—Restrictive transfusion threshold (hemoglobin concentration 7–8 g/dL) in hemodynamically stable patients with acute gastrointestinal bleeding	Conditional recommendation, low certainty in the evidence of effects
Implementation of Patient Blood Management Programs	CR9—Implementation of PBM programs to improve appropriate RBC utilization	Conditional recommendation, low certainty in the evidence of effects
	CR10—Computerized or electronic decision support systems to improve appropriate RBC utilization	Conditional recommendation, low certainty in the evidence of effects

Abbreviations: CR: clinical recommendation; PBM: patient blood management; RBC: red blood cell.

Modified from Mueller *et al.* (2019).<sup>19</sup>

Recommendations Assessment, Development and Evaluation (GRADE) methodology, and published suggested guidelines.<sup>8,20–22</sup> The multidisciplinary membership of the committee lends itself to the adoption of the guidelines across the clinical services. The guidelines should address the indications for each blood component *and* the recommended dosing. Transfusing one unit of red cells at a time for an appropriate indication and reevaluating a stable patient are mainstays of optimal red cell transfusion practice.<sup>15</sup> Other chapters in this textbook provide transfusion guidelines and dosage recommendations for each component and a detailed review of the evidence for these guidelines. Once guidelines have been established, physician education, implementation, and auditing of transfusion practice are the next steps. These steps, particularly implementation and auditing, are far more difficult than developing the guidelines.

### Physician education and monitoring

To implement the various aspects of PBM, detailed information on baseline practices is required.<sup>14,23</sup> Although some of this information might be obtainable through a manual review of patient charts, large-scale data mining is really only possible by implementing electronic monitoring programs and by facilitating the storage of relevant data in a structured format. These programs can not only serve to harvest data to elucidate the state of practice, but can also be used to advise clinicians about potentially unnecessary transfusions before the order to transfuse is placed. Broadly known as clinical decision support systems (CDSS), these automated

programs can be designed to accomplish several tasks that would otherwise be impossible to achieve using a manual system once they are integrated into the computerized physician order entry (CPOE) system. Once deployed, the CDSS can operate continuously, and dispassionately provide suggestions every time that it detects a blood product order on a patient whose laboratory values do not indicate that a transfusion is necessary—a task that, although potentially successful,<sup>24</sup> would otherwise require a significant time commitment from the blood bank staff. Several large meta-analyses have shown practice improvements following the implementation of CDSS in various clinical areas.<sup>25,26</sup>

As it pertains to transfusion, a CDSS can be very basic or highly complex. A basic system would, for example, consider only one parameter (e.g., a hemoglobin or platelet value) in its analysis of whether a transfusion order was in accordance with the institutional guidelines. Several studies have reported on using a single pretransfusion hemoglobin value to evaluate the suitability of the transfusion order.<sup>27–29</sup> However, this “one-size-fits-all” or static approach to laboratory-based transfusion threshold values is not amenable to the needs of physicians who are caring for patients with specialized disorders or for patients in specific clinical situations. Different patients can benefit from transfusion at different hemoglobin concentrations.<sup>30–32</sup> Thus, the evolution of the CDSS can be toward an “adaptive alert” system. This type of CDSS often requires the prescriber to first select an indication for the transfusion; associated with each indication is an evidence-based threshold for the product (Table 27.2). If the patient’s most recent laboratory values are higher than the recommended guideline

**Table 27.2** List of Transfusion Indications in the Computerized Physician Order Entry Screen at the Authors' Institutions

**(A) Red blood cells**

- Acute bleeding with blood pressure instability\*
- Hemoglobin**  $\leq 7.0 \text{ g/dL}$  and/or **hematocrit**  $\leq 21\%$  in a hemodynamically stable patient in the ICU
- Hemoglobin**  $\leq 8.0 \text{ g/dL}$  and/or **hematocrit**  $\leq 24\%$  in a non-ICU patient with signs and symptoms of anemia
- Hemoglobin**  $\leq 10.0 \text{ g/dL}$  and/or **hematocrit**  $\leq 30\%$  associated with acute ischemic cardiovascular disease (angina pectoris and myocardial infarction)
- Hemoglobin**  $\leq 7.5 \text{ g/dL}$  and/or **hematocrit**  $<22.5\%$  in the intraoperative setting for a cardiac patient
- Hemoglobin**  $\leq 8.5 \text{ g/dL}$  and/or **hematocrit**  $\leq 25.5\%$  in an outpatient setting
- Surgical blood loss anticipated\*
- Other (alert generated if **hemoglobin**  $>8.5 \text{ g/dL}$  and/or **hematocrit**  $>25.5\%$ )

**(B) Plasma**

- Coagulation disorders associated with active bleeding and **INR**  $\geq 1.6$  and/or **abnormal viscoelastic test parameters (R time/CT, K time/CFT)**
- Coagulation disorders, with **INR**  $\geq 1.6$  and/or **abnormal viscoelastic test parameters (R time/CT, K time/CFT)**, in patients undergoing surgery or invasive procedures, where the INR elevation is not due to vitamin K deficiency/ antagonist
- To correct warfarin effect in cases of active bleeding or emergent surgery (**INR**  $\geq 1.6$ )
- Therapeutic plasma exchange\*
- Massive bleeding\*
- Other (alert generated if **INR**  $< 1.6$ )

**(C) Platelets**

- Platelet count  $<10,000/\mu\text{L}$  ( $10 \times 10^9/\text{L}$ ) in a stable patient
- Platelet count  $<20,000/\mu\text{L}$  ( $20 \times 10^9/\text{L}$ ) with evidence of platelet consumption (e.g., fever and sepsis)
- Platelet count  $<50,000/\mu\text{L}$  ( $50 \times 10^9/\text{L}$ ) with active bleeding or prior to an invasive procedure
- Active bleeding or need for emergent procedure on antiplatelet medications\*
- Platelet dysfunction documented by abnormal platelet function tests (e.g., PFA-100/200 Closure Time, VerifyNow, and viscoelastic tests)
- Massive bleeding\*
- Other

**(D) Cryoprecipitate**

- Active bleeding associated with or prior to an invasive procedure with hypo- and/or dys-fibrinogenemia: **Fibrinogen level**  $<100 \text{ mg/dL}^{**}$  and/or **abnormal viscoelastic test parameters (K time/CFT, } \alpha\text{-angle}**
- Massive bleeding\*
- Other

\* Indicates that an antecedent laboratory value is not required to order the product, and an alert will not be triggered if a blood product is ordered using this indication.

\*\* Fibrinogen level thresholds may be higher in certain settings, e.g., obstetric hemorrhage.

Abbreviations: CT: clotting time (rotational thromboelastometry or ROTEM); CFT: clot formation time (ROTEM); INR: international normalized ratio.

values (or lower, in the case of plasma transfusion and an INR threshold), an alert will appear on screen to inform the prescriber that, based on their patient's laboratory values, the transfusion does not appear to be indicated. The prescriber can again override the alert or warning and proceed to order the product or can cancel the transfusion altogether, a so-called "soft stop." "Hard stops," where the prescriber is unable to override the alert or warning, are generally not considered appropriate for PBM programs since transfusion indications are not all-encompassing and there are inherent risks associated with not providing a blood product when a clinician deems it necessary, even if the patient does not meet the transfusion indications. Baer *et al.*<sup>33</sup> reported on the implementation of a CDSS that displayed their neonatal intensive care units' (ICU) transfusion thresholds when the prescriber was ordering a blood product in the CPOE.

Compared to a period before the implementation of a CDSS, most studies have demonstrated a statistically significant improve-

ment in institutional transfusion threshold compliance after one was implemented.<sup>34–43</sup> Although the exact reason for the improved compliance is unclear, it is reasonable to assume that being repeatedly presented with the institution's transfusion guidelines at the time of blood product ordering is sufficient to change some practices. Having adaptive alerts also helps to improve compliance by facilitating a patient-centric approach to transfusion decision-making. At the authors' institutions, there were statistically significant decreases in the number of RBC orders that were placed and the number of orders that generated an alert after the "static" alert was changed to an adaptive alert. There was a clinically relevant, although not statistically significant ( $p = 0.089$ ), reduction in the median number of RBCs ordered per month after the adaptive alerts were implemented compared to the four months preceding the implementation of the adaptive alerts.<sup>44</sup> Similarly, several other studies have reported reduced RBC transfusions after a CDSS was implemented, although for many of these studies, the differences observed also did not reach statistical significance.<sup>27,29,33–35,37–40,42,43,45</sup>

There are fewer studies that have analyzed the effect of a CDSS on plasma orders, although the evidence has been accumulating recently. One single-center study in 2017 demonstrated a 17.4% reduction in plasma utilization after implementation of a CDSS, but found a relatively low alert acceptance rate of only 33% and marked variations in alert acceptance across different specialties.<sup>46</sup> Other groups have also described reductions in plasma utilization but have highlighted the importance of optimal CDSS design in order to improve compliance rates.<sup>47</sup> At the authors' institutions, when the static alert for plasma transfusion (i.e., an alert was generated for any plasma order on a patient whose most recent international normalized ratio [INR] value was  $<1.6$ ) was replaced with an adaptive alert (Table 27.2), there was a 15% decrease in the number of orders that generated an alert ( $p < 0.0001$  compared to the period when a static alert was in place), and the percentage of alerts that were heeded increased significantly.<sup>48</sup> The implementation of the adaptive alerts for plasma in a neonatal ICU led to a significant reduction in the number of patients that received a plasma transfusion.<sup>24</sup> Similarly, when the CPOE displayed one institution's plasma transfusion guidelines, there was a decrease in the total number of plasma orders, inappropriate plasma orders, and plasma units transfused,<sup>49</sup> although the CDSS was not as successful in reducing "invalid" plasma orders at a different hospital.<sup>50</sup> As mentioned above, a CDSS that made recommendations for the number of plasma units to be transfused based on the recipient's characteristics and the intended goal of the transfusion led to the transfusion of 68 additional plasma units.<sup>34</sup>

Reports on the application of CDSS to platelet and cryoprecipitate orders are limited. Two earlier studies demonstrated nonstatistically significant reductions in the number of patients who received platelet transfusion after a CDSS was implemented,<sup>33,51</sup> whereas a more recent study showed a reduction in platelet transfusion order errors in the inpatient setting from 3.10% to 0.33% after a careful redesign of the CDSS.<sup>52</sup> Another study on restrictive transfusion policies in hematology patients also demonstrated a nonstatistically significant reduction in the proportion of noncompliant platelet orders from 41.9% to 31.2% ( $p = 0.16$ ) after implementation of a CDSS.<sup>53</sup> Two studies conducted in large health systems have analyzed the effect of a CDSS on cryoprecipitate orders.<sup>33,54</sup> At the authors' health system, CDSS implementation resulted in 49% of cryoprecipitate orders generating an alert, of which 14.9% were canceled.<sup>54</sup>

In addition to potentially realizing cost savings by transfusing fewer blood products and having patients experience fewer transfusion reactions, the CDSS can also inform the selection of electronic medical records for the audits that are performed by transfusion committees. It is important to note that laboratory values alone are sometimes insufficient to indicate why a patient might require a blood product. Thus, permitting the physician to add a free-text explanation to an order that might not appear warranted based on laboratory parameters is a useful feature in a CPOE system. Explanatory comments can also suggest other legitimate blood product order indications for the CDSS. Thus, although high-quality evidence should form the basis when establishing transfusion thresholds, the input of the blood product prescribers should also be sought in order to achieve consensus threshold values for the alerts.

In the absence of a CDSS, other metrics can be followed to ensure compliance with institutional guidelines. Once a restrictive RBC transfusion threshold is in place, evaluating the proportion of single unit RBCs transfusions and the recipients' mean pretransfusion hemoglobin values over time by service or by individual provider can identify nonevidence-based practices and focus interventional efforts to achieve higher compliance rates. Benchmarking between providers of similar procedures or between hospitals or national databases can also be employed to identify nonevidence-based practices.<sup>55–59</sup> All of these methods require significant support from the institution's IT department.

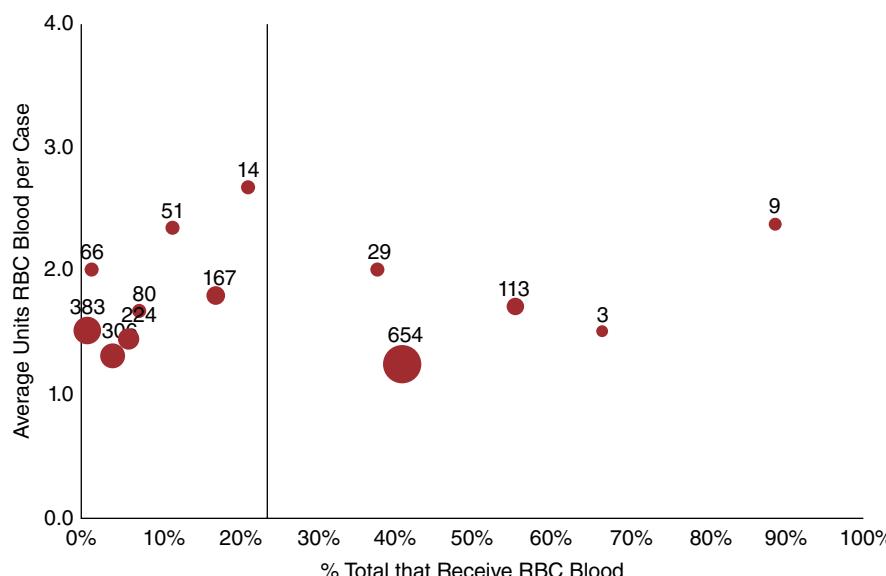

Targeted prescriber education can occur after the decision to transfuse a patient has been made, and the use of the electronic medical record can facilitate this sort of audit. Benchmarking of blood use between surgeons who perform the same procedures can be a useful way of establishing the current state of practice and permit the identification of any practitioners whose transfusion habits appear to be aberrant. For example, the RBC transfusion practice among orthopedic surgeons performing total hip arthroplasties (THAs) can be highly variable. This variability can range between surgeons who rarely transfuse their patients with RBCs (and, when they do, it is typically a small quantity) to those who routinely transfuse most of their patients with large quantities of RBCs.<sup>60</sup> The publication of the FOCUS study served as the benchmark against which

these surgeons' transfusion practice could be evaluated.<sup>32</sup> To this end, a "bubble graph" can be utilized (Figure 27.2). This graph plots all surgeons who perform THA surgeries by the frequency with which they transfuse RBCs to their patients and the mean number of RBCs that are transfused per patient. The size of the bubble reflects the number of cases. By identifying those who repeatedly transfuse greater than average quantities of RBCs, the transfusion committee or hospital transfusion service can provide focused feedback and education where and when it is required.

It is evident that automated prescriber education alone is insufficient to eliminate nonevidence-based transfusions. Surely, the best way to reduce aberrant transfusion practice is through a multimodal approach involving automated alerts, targeted education (e.g., at grand rounds), and informal discussions with the house staff and faculty when apparently nonevidence-based transfusion practices are detected, and by providing easy access to the most up-to-date and well-executed research studies. By providing a consistent message about transfusion thresholds, waste reduction strategies, and techniques to avoid transfusion, the optimal effects of PBM can be realized.

## Preoperative anemia management

The World Health Organization (WHO) defines anemia as a hemoglobin <13 g/dL in men and <12 g/dL in nonpregnant women or <11 g/dL in pregnant women.<sup>61</sup> Preoperative anemia is common in surgical patients with a prevalence ranging from 5% to 76% depending on the type of surgery, comorbidities, patient age, and gender.<sup>62</sup> A systematic review of patients undergoing hip and knee surgery reported a prevalence of 24–44%,<sup>63</sup> which is very similar to the 28–36% prevalence observed in patients undergoing coronary artery bypass grafting.<sup>64</sup> Multiple studies have shown that preoperative anemia in the orthopedic patient population is associated with a 5–12-fold higher risk of transfusion, prolonged length of stay, and higher readmission rates.<sup>63,65,66</sup> Preoperative anemia has also been associated with increased morbidity and mortality in surgical patients.<sup>63,67,68</sup> Carson *et al.*<sup>67</sup> reported a retrospective study of 1958 patients who refused blood transfusion and underwent noncardiac surgery, and found that perioperative mortality was significantly

**Figure 27.2** An example of a bubble plot. Each bubble represents a surgeon who performs total hip arthroplasties, and the size of the bubble represents the relative number of cases performed over a set time. The x-axis represents the percentage of patients who received at least one RBC unit during the case, and on the y-axis the average number of RBCs transfused is plotted.

increased when the preoperative hemoglobin was  $\leq 10$  g/dL. Wu *et al.*<sup>68</sup> reported a retrospective study of over 310,000 men  $> 65$  years old who underwent noncardiac surgery in the American Veterans' Affairs system showing that postoperative mortality and cardiac events progressively increased as the preoperative hematocrit fell below 39%. In a systematic review of the literature, Spahn *et al.*<sup>69</sup> found that preoperative anemia in orthopedic surgery patients was associated with more infections and higher mortality. Another study in orthopedic surgery patients, however, calls into question whether anemia is causally related to these outcomes.<sup>69</sup> Nonetheless, it is clear that anemia increases the risk of requiring a transfusion in the perioperative period. That reason alone would justify implementing measures to manage preoperative anemia.

PBM programs have been developed to manage preoperative anemia primarily in orthopedic surgery patients,<sup>65,70,71</sup> although these programs have also been applied to other patients who are undergoing elective surgery with expected significant blood loss. These programs consist of identifying patients undergoing elective

procedures ideally four weeks, but not less than two weeks, prior to surgery and performing a screening hemoglobin. This practice was suggested by the Joint Commission as a performance measurement initiative.<sup>72</sup> Using the WHO definition of anemia, patients would be referred to a hematologist, preoperative clinic, or other physician for the evaluation and management of the anemia. Several algorithms for the evaluation and management of preoperative anemia have been published, including one by the NATA group using the GRADE methodology (Figure 27.3).<sup>71</sup> This algorithm uses serum ferritin and transferrin saturation to triage patients to appropriate management strategies that may include oral iron, intravenous (IV) iron, folic acid, vitamin B<sub>12</sub>, and/or erythropoietin (EPO). Other algorithms use the red cell mean corpuscular volume (MCV)<sup>70</sup> or ferritin alone<sup>65</sup> as screening tests. There is no evidence that one particular strategy is superior to another.

The pharmacologic therapies for the management of preoperative anemia have been recently reviewed.<sup>71</sup> Oral iron may be sufficient to correct the anemia in patients who have iron-restricted

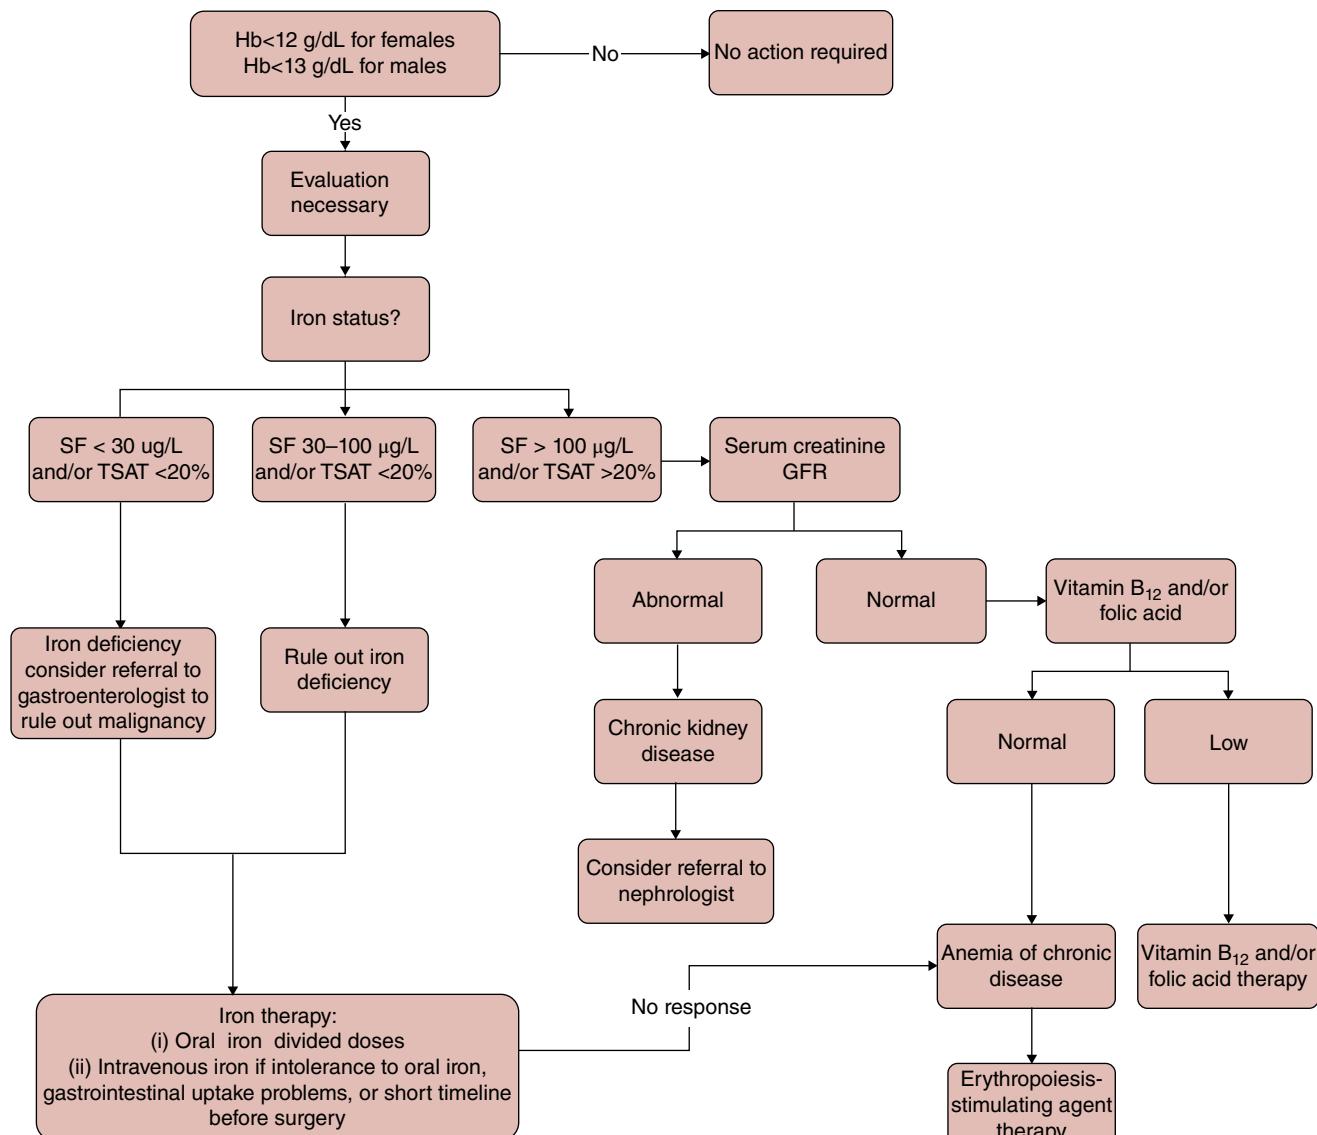

Figure 27.3 Proposed algorithm for the detection, evaluation, and management of preoperative anemia. GFR: glomerular filtration rate; SF: serum ferritin; TSAT: transferrin saturation. Source: Goodnough *et al.* (2011).<sup>71</sup> Reproduced with permission of Oxford University Press.

erythropoiesis due to absolute iron deficiency. Oral preparations include ferrous gluconate, ferrous fumarate, ferrous sulfate, and iron polysaccharide. The advantage of oral iron replacement is that it is inexpensive and easy to administer. There are several limitations, however, including gastrointestinal side effects and compliance issues. It also takes 2–4 weeks to increase hemoglobin levels. Oral iron is not very effective in patients with anemia of inflammation (chronic disease).

Intravenous (IV) iron therapy is becoming a more common strategy for the management of preoperative anemia as safer preparations are now available in the United States. IV iron bypasses absorption, tolerance, and compliance issues. It is also effective in patients with anemia of chronic disease in whom inflammation and subsequent elevated hepcidin levels prevent iron absorption.<sup>71</sup> The total dose of IV iron is typically 1 g, independent of the patient's weight. The number of doses required to deliver 1 g and achieve a therapeutic effect depends on the preparation used. An increase in hemoglobin is apparent at one week after starting IV iron therapy and reaches its apogee after two weeks.<sup>70</sup> Serious acute adverse events (i.e., anaphylaxis) have been associated with high-molecular-weight (HMW) dextran IV iron preparations but appear to be lower with low molecular-weight (LMW) dextran preparations. These iron dextran preparations have a US Food and Drug Administration (FDA) "black box" warning and require a test dose before infusion. LMW dextran preparations can be given as a single 1 g infusion and are less costly than other preparations. Other IV iron preparations that are approved in the United States include iron gluconate, iron sucrose, iron isomaltose, iron carboxymaltose, and iron carboxymethyl dextran; none of these preparations have a "black box" warning, and they do not require a test dose as they do not contain HMW dextrans. The iron gluconate and sucrose preparations are not approved for an infusion dose of more than 500 mg and thus would require the patient to return for one or more infusions. The other preparations can be given as a single total dose infusion.

Erythropoietic-stimulating agents (ESA) are FDA approved for use in patients with anemia due to chronic kidney disease (CKD), in oncology patients with chemotherapy-induced anemia, for HIV-therapy-related anemia, and in patients with anemia undergoing elective surgery.<sup>71</sup> There are three approved preparations: epoetin alfa (EPO- $\alpha$ ), epoetin beta-methoxy polyethylene glycol, and darbepoetin alfa. Epoetin beta-methoxy polyethylene glycol is only indicated for the treatment of anemia due to CKD.<sup>73</sup> Darbepoetin alfa is indicated for the treatment of anemia due to CKD and some patients with concomitant myelosuppressive chemotherapy excluding those where the anticipated outcome is cure or those in whom the anemia can be managed by transfusion.<sup>74</sup> Pregnesatide, a fourth drug approved by the FDA in 2012 for the treatment of adult patients on dialysis with anemia due to CKD, had its FDA approval withdrawn in February of 2019 following postmarketing reports of serious hypersensitivity reactions, including anaphylaxis.<sup>75</sup> EPO- $\alpha$  is the only ESA approved for use in elective surgery, and it is intended for patients with a preoperative hemoglobin >10 to ≤13 g/dL who are at high risk for perioperative blood loss from elective, noncardiac, and nonvascular surgery.<sup>76,77</sup> In this setting, EPO- $\alpha$  has been shown to be effective in reducing the need for transfusion.<sup>78</sup> Subsequent RCTs in patients undergoing hip or knee arthroplasty reported similar results<sup>79,80</sup> and did not find a difference in the rates of deep venous thrombosis between the EPO- $\alpha$  and control groups.

The preoperative dosing schedule for EPO- $\alpha$  is typically 600 U/kg weekly for three weeks and a fourth dose on the day of surgery. A daily regimen is also available but requires dosing for

10 consecutive days before surgery, on the day of surgery, and for four days after surgery. It is mainly of use in patients who have <2 weeks before scheduled surgery. The onset of action of EPO, indicated by a rise in hemoglobin, is 4–6 days. Concomitant iron therapy is necessary during EPO- $\alpha$  therapy due to increased demand for iron as it is incorporated into hemoglobin. EPO should not be used in patients with a hemoglobin >13 g/dL. Safety concerns about EPO in elective surgery patients have recently been raised. In 2007, the results of an RCT of EPO versus no EPO in 681 adult patients who underwent spine surgery without prophylactic anticoagulation were reported to the FDA.<sup>76</sup> Patients in the EPO arm received four weekly EPO doses of 600 U/kg EPO- $\alpha$  (21, 14, and 7 days before surgery, and the day of surgery). An increased incidence of deep vein thrombosis (DVT) in patients receiving EPO was observed (16 patients [4.7%]) compared to the control group (seven patients [2.1%]). Based on this study and a higher incidence of DVT in other patient populations treated with EPO, the FDA recommended that prophylactic anticoagulation be "strongly considered" when EPO- $\alpha$  is used in surgical patients. While ESA are not approved for use in patients undergoing cardiac or vascular surgery due to FDA concerns about increased mortality,<sup>76,77</sup> there is accumulating evidence that a single dose of ESA preoperatively may reduce peri-operative blood transfusion requirements in this high-risk surgical population without an increase in adverse events.<sup>81–83</sup> ESA use is also relatively contraindicated in patients with uncontrolled hypertension, recent coronary or cerebral ischemic events, and in patients who are unable to receive perioperative prophylactic anticoagulant therapy.<sup>84</sup>

## Cell salvage

The process of collecting shed autologous blood, its processing, and its readministration has been termed *cell salvage*, *autotransfusion*, *intraoperative blood recovery*, as well as *cell saving*. For the purpose of this chapter, the term *cell salvage* is used. Cell salvage can take place either in the intraoperative period or in the postoperative period. Salvage can also involve washing of the collected blood, or it can be simply readministered with microaggregate filtration.

## Unwashed cell salvage

To this day, both washed and unwashed salvage devices are used. Postoperative unwashed blood salvage has been utilized in a wide variety of surgical procedures,<sup>85</sup> but it is predominantly used after cardiac<sup>86</sup> and orthopedic procedures (Figure 27.4).<sup>87</sup> Estimates of postoperative blood loss after cardiac surgery range from 371 to 553 mL,<sup>88–90</sup> whereas volumes following total joint replacement range from 166 to 750 mL.<sup>91–93</sup> The average hemoglobin of this shed blood is reported to range from 20% to 30%.<sup>94,95</sup> At best, the volume returned to a patient would equal the red cell mass present in one unit of allogeneic red cells so the efficacy of this unwashed product in avoiding allogeneic transfusion is limited. Controversy arises as to whether the risks of retransfusion of this blood warrant the minimal amount of blood that is returned to the patient.

When one considers that this salvaged blood is laden with various inflammatory mediators,<sup>96,97</sup> fibrin split products,<sup>94,98,99</sup> complement fractions,<sup>100–102</sup> interleukins,<sup>103–105</sup> tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ),<sup>97</sup> and fat particles,<sup>106</sup> which are multiple degrees higher than circulating levels, it is easy to believe that there is risk from readministration of this shed, unwashed blood. This being said, the reported risks appear to be minimal. The most frequently reported complication following unwashed postoperative shed blood

**Figure 27.4** A salvage device for unwashed cells used for a knee replacement.

**Figure 27.5** A device for salvaging and washing blood is shown.

reinfusion relates to febrile reactions, which is a complication frequently seen following allogeneic transfusion. Dependent upon the study, the rates of febrile reactions after postoperative salvage readministration vary from 4% to 12%.<sup>92,93,107,108</sup> This complication is generally the only reported complication following readministration of unwashed, shed blood; however, all of these reports are small case series.

In a Cochrane systematic review, Carless *et al.* reviewed complications of all available studies on perioperative salvage.<sup>109</sup> They evaluated total complications, wound infections, and thromboembolic events that included nonfatal myocardial infarction. They found no difference in any of these events, but they mixed washed with unwashed salvage and the vast preponderance of studies was

from cardiac surgery. A simple solution to the perceived hazards of the contaminants of unwashed, postoperative cell salvage would be to wash the blood (Figure 27.5).

### Washed cell salvage

In a washed salvaged product, the blood is collected via suction into a reservoir where it is stored until processing. When adequate amounts of blood are collected, the blood is pumped into a centrifuge bowl where it is concentrated. During the concentration of the erythrocytes, plasma and anticoagulant are spilled into a waste bag. Following the concentration of the erythrocytes, normal saline or Ringers' Lactate solution is percolated through the red cell pack with the goal to wash out tissue factor and the inflammatory mediators mentioned previously. Following washing, the blood is leukoreduced by filtration and readministered to the patient. Washing comes with its own set of problems, which include air embolism<sup>110</sup> and exposure of red cells to nonisotonic solutions.<sup>111</sup> When the processing is completed, the blood is pumped into a reinfusion bag, and preceding the blood is a column of air. When multiple units of blood are processed, the air can accumulate in the reinfusion bag, which then presents a hazard to the patient if the patient's intravenous line is connected directly to this bag. In order to prevent this problem, the reinfusion bag should never be directly connected to the patient. Washing can also be problematic if a nonisotonic wash solution is chosen. For instance, if blood is washed with sterile water, the cells will all be lysed. If the free hemoglobin is administered to the patient, it could potentially result in renal failure or be fatal.

### Maximizing washed salvage efficiency

Washed cell salvage can provide multiple units of autologous erythrocytes for a bleeding patient.<sup>112</sup> Small changes in the collection and processing of shed red cells can make large differences in the volume of blood returned to the surgical patient. Mathematical modeling illustrates this point.<sup>113</sup> Assuming a 70-kg patient with a 5-L blood volume and preoperative hemoglobin of 15 gm/dL, and using a transfusion trigger of 7 gm/dL, a theoretical patient can avoid transfusion of allogeneic blood up to a blood loss of 9600 mL if salvages return 60% of lost red cells. However, the tolerable blood loss rises to 13,750 mL if 70% of the red cells are captured and returned. The most important factors in increasing efficiency of these systems are regulating the suction imposed on the red cells and washing bloody surgical sponges.

### Suction

For blood recovery systems to work, it is necessary to deliver shed blood to a collection reservoir where the blood awaits processing. Collection is done through suction from the site of surgery or a salvage system can be connected to a surgical drain. The way this suction pressure is applied affects the shear forces applied to the red cells. In general, turbulence and high negative pressure destroy red cells. Shear force occurs anytime a fluid moves in contact with a solid surface.<sup>114</sup> High suction pressure leads to increased mechanical force, hemolysis, and subsequently fewer salvageable erythrocytes. As such, the lowest tolerable suction pressure should be applied when removing blood from the surgical field.

Suction pressure should be regulated to 80–120 mmHg, which is generally adequate to clear blood from the surgical field.<sup>115,116</sup> If massive blood loss occurs, it is important to increase the suction pressure so that the surgeon can clearly see the surgical field. Following control of the blood loss, the suction pressure can be lowered.

### Sponge rinsing

Fully soaked surgical sponges may contain up to 100 mL of blood.<sup>117</sup> Of this blood, approximately 95% of these erythrocytes can be captured by rinsing the sponge in a basin of normal saline or Ringer's Lactate solution. The bloody rinse solution is then intermittently sucked into the salvage collection reservoir at a point when the rinse solution appears to be grossly bloody. This practice has been reported to increase erythrocyte retrieval rates by 28%.<sup>118</sup>

### Indications

Determining when to salvage erythrocytes depends upon anticipated blood loss. Prediction of anticipated blood loss is difficult. With this lack of predictability, a cell salvage program should be assessed in composite rather than for a single case. Some cases might generate 20 units of blood, whereas other cases will not generate any. If the sum of salvaged units achieves one allogeneic red cell unit equivalent on average, then the program is generally considered successful, although financial success may be dependent upon whether the service is provided in-house or whether an external perfusion service is hired.<sup>119</sup> Major vascular, cardiac, and transplantation surgery tend to be procedures that generate a large amount of blood loss.<sup>112</sup> Blood loss can also be surgeon dependent. Surgeons will have widely varying blood loss performing the same procedure. So, the type of procedure and who is performing it are primary criteria for determining need.

Given the lack of predictability of blood loss, an important feature of washed salvage is recognizing that the cost of the disposables can be staged through the use of a "standby" system. A standby system simply involves the collection of shed blood. The standby system utilizes a collection reservoir, a suction line, and anticoagulant. This represents approximately half of the cost of the disposables of a salvage system. If processing is indicated, then a processing bowl and tubing system are utilized that double the cost. In this way, half of the cost is not expended if an inadequate volume of blood is captured.

### Contraindications

Absolute contraindications to cell salvage involve contamination of the blood with anything that will lyse the erythrocytes. This would include hypotonic solutions such as sterile water, hydrogen peroxide, and alcohol. Topical collagen hemostatic agents when incorporated into a salvaged blood product can also be hazardous if the topical agent is infused. Heavy metals (chromium and cobalt) can be found in blood salvaged from metal on metal hip prostheses.<sup>120</sup> Accumulation of metal debris in the surrounding joint tissue can be suctioned into blood during replacement. Neuropathy and cardiomyopathy can result from high heavy metal blood levels.

Traditionally, cell salvage has been avoided in obstetrics where the blood might be contaminated with amniotic fluid, malignant surgery where cancer cells might be entrained into the blood, and "dirty" surgery where blood might be contaminated with bacteria. All of these areas are recommended to be contraindicated by the machine manufacturers; however, a striking lack of evidence is available to support these contraindicated areas. Theoretical concerns regarding risk of amniotic fluid embolism when using salvaged blood in obstetrical hemorrhage have not been substantiated. National and international bodies including the American College of Obstetricians and Gynecologists (ACOG)<sup>121–123</sup> have promoted the use of cell salvage in obstetrics; limitations of cell salvage in the obstetrical setting have been primarily related to the availability of appropriate staff and equipment.<sup>124</sup>

The fear of generating a diffuse metastasis when salvaging blood around a tumor site has not been borne out. In 2008, the National Institute for Health and Care Excellence (formerly National Institute for Health and Clinical Excellence) in the United Kingdom<sup>125</sup> approved the use of salvage during urological malignancies. Systematic reviews have also been performed evaluating salvage use during malignant surgery<sup>126</sup> as well as surgery involving tumors of the spine.<sup>127</sup> In neither of these reviews was there support for avoiding the salvage in these surgeries for malignancy. Lastly, blood that might be contaminated with bacteria has been a further contraindication. Surprisingly, bacterial contamination of recovered blood appears to be common. Bland *et al.*<sup>128</sup> reported that bacterial contamination of recovered blood in cardiac surgery approaches 30% of the units processed. Kang *et al.*<sup>129</sup> reported that 9% of the blood returned to liver transplant patients contained bacterial contaminants, usually of skin origin. In these circumstances of bacterial contamination, no clinical effects were seen. Although it would be prudent to avoid use of blood that has been grossly contaminated with stool, blood salvage during support of abdominal trauma would appear to be safe. In these contraindicated circumstances, the use of leukocyte depletion filters has been advocated.<sup>130</sup> Leukocyte depletion filters have been demonstrated to remove many contaminants, including cancer cells, cellular contaminants associated with amniotic fluid, and bacteria. Although these filters have not been demonstrated to produce better outcomes, theoretically additional safety may be provided by their use.

### Acute normovolemic hemodilution (ANH)

Acute normovolemic hemodilution (ANH) is a technique intended to minimize or decrease the need for allogeneic transfusion. With ANH, blood is phlebotomized from a surgical patient at the start of surgery, generally shortly after the induction of anesthesia. The amount of blood removed is that projected to leave an end of phlebotomy hematocrit of approximately 30%. The blood that is taken off is replaced with a colloid or crystalloid volume expander in order to maintain isovolemia. At the end of surgery, the phlebotomized blood is given back to the patient. The central tenet of ANH is that the patient will bleed blood that is less concentrated in terms of its erythrocytes. Although this theoretical savings sounds substantial, the savings appear to be small clinically.<sup>131</sup>

Given that the phlebotomized blood is whole blood, the effectiveness in transfusion avoidance applies to both erythrocytes and coagulation products. The real value of ANH is in the preservation of platelets and plasma. If sufficient whole blood is collected prior to surgery, a dilutional coagulopathy can be reversed.<sup>132,133</sup> Pairing of ANH and cell salvage provides a comprehensive hematologic approach to avoiding allogeneic transfusion. Cell salvage provides erythrocytes for treating anemia, whereas the ANH provides the coagulation product avoidance. In addition, the anemia created by hemodilution exposes fewer red cells to the mechanical trauma of salvage, thus providing a higher rate of erythrocyte return.<sup>134</sup>

A number of mechanisms allow the patient to tolerate aggressive phlebotomy. Increased cardiac output resulting from increases in heart rate and cardiac contractility, and a reduction in whole blood viscosity, lead to maintenance of oxygen delivery.<sup>135,136</sup> In addition, tissue oxygen needs are reduced during hemodilution from anesthesia and mechanical ventilation.

The practice of ANH is relatively limited due to a lack of understanding of how it is performed. In general, multiple units of blood are withdrawn into a standard donor bag containing 63 mL

of citrate anticoagulant. The goal is to remove 450–500 mL of whole blood into each donor bag. The 63 mL of citrate is adequate to anticoagulate this volume of blood. Typically, the blood is removed through an arterial or venous catheter. Optimally, the shortest catheter should be used in order to minimize resistance to flow and to minimize activation of platelets. Double- or triple-lumen catheters with their long catheter lengths are likely to fail because flow rates are slow. As a result of the slow flow rate, blood clotting may result. Blood flow should be greater than 30 mL/min in order to prevent clotting in the collection bag. Periodic agitation of the collected blood should take place in order to optimally mix the citrate anticoagulant with the blood.<sup>137</sup> Once the blood is collected, it should be maintained at room temperature in the operating room close to the patient. Once the blood has been mixed with the anticoagulant, there is no need to continuously agitate it.<sup>138</sup> Units should be reinfused in the reverse order of collection, i.e., first out → first in.

A systematic review and meta-analysis of randomized trials on the use of ANH in cardiac surgery, which included 29 RCTs with a total of 2439 patients (1252 patients in the ANH group and 1187 in the control group), demonstrated a reduction in the rate of allogeneic RBC transfusion (42.1% in the ANH group vs. 56.1% in the control group; risk ratio = 0.74;  $p < 0.0001$ ) and a reduction in post-operative blood loss (388 mL in the ANH group vs. 450 mL in the control group;  $p < 0.0001$ ).<sup>139</sup>

## Point-of-care testing

Point-of-care or near-patient testing involves the placement of laboratory equipment near or at the patient bedside. A number of point-of-care devices are available for the measurement of the hemoglobin concentration, prothrombin time (PT)/INR and activated partial thromboplastin time (APTT), glucose, blood gas chemistry and electrolyte concentrations, platelet function, and whole blood clotting function.

The advantage of using point-of-care devices instead of centralized laboratory testing relates to the speed of getting data for management decisions. In the acute care setting, such as the operating room or the intensive care unit where critically ill, dynamically changing patients are being cared for, the tendency is to make empiric care decisions based on clinical judgement regarding the patient condition. When laboratory information is obtained at the patient bedside, more informed patient care decisions can be made.

Another advantage of point-of-care testing involves the use of microsampling. Generally, these devices require blood samples in the microliter volume range, whereas traditional laboratory-based testing requires milliliter volume samples. It is well recognized that repeated, large-volume samples can quickly result in an iatrogenic anemia, most prominently in the critical care setting.<sup>140</sup> It has been estimated that the average ICU patient will have a fall in hemoglobin concentration of 0.5 gm/dL/day with 80% of the fall related to blood draws.<sup>141</sup>

One of the drawbacks to point-of-care testing is that the methodology for measurement is frequently different from that of laboratory-based testing, which will sometimes produce results that are not directly comparable to conventional laboratory assays. In many of these circumstances, there is no gold standard by which to say one methodology is superior to another. As such, it is important to recognize the biases of each device and react accordingly. It is also important to understand the approved label indication or intended use population for the device and/or assay before applying it to routine patient care. Robust quality management systems,

end-user trainings frequently differencing and competency evaluations, and input from laboratory medicine, where available, are critical to the proper implementation of a point-of-care testing program.

For PBM programs, whole blood viscoelastic assays using thromboelastography (TEG, Haemonetics, Braintree, MA, USA) or rotational thromboelastometry (ROTEM, TEM Systems Inc., Durham, NC, USA) have become increasingly popular in managing perioperative coagulopathic bleeding and blood product therapy. In addition to the advantage of rapid results and point-of-care availability, these assays have the theoretical advantage of providing assessment of the interactions among the various components of hemostasis. Traditional laboratory measures of hemostasis such as APTT, PT, fibrinogen, and platelet count provide a limited assessment of only that aspect of hemostasis and not their interaction. The use of TEG- and ROTEM-based algorithms for assessing hemostasis and managing blood component therapy have been shown to reduce transfusions and bleeding in the settings of massive trauma, liver transplantation, and cardiac surgery,<sup>142–155</sup> and this is discussed extensively in this volume.

## Use of hemostatic agents

The hemostatic management of patients has been advanced through better understanding of the mechanisms of coagulopathy, availability of point-of-care testing, and a growing array of hemostatic agents. The clinical use and description of these agents have been reviewed<sup>156,157</sup> and are briefly described here.

### Solvent/detergent plasma

Physicians are familiar with using plasma from a single donation of whole blood or apheresis collection to treat a coagulopathy. A pooled solvent detergent (S/D)-treated plasma called Octaplas LG (Octapharma AG, Vienna, Austria) is now approved in the United States.<sup>158</sup> This product is manufactured from plasma pools of 630–1520 donors, which are ultrafiltered (1 μm pore size) and then subjected to solvent (1% tri(*n*-butyl)phosphate [TNBP]) and detergent (1% Octoxynol-9) treatment for 1–1.5 hours.<sup>158</sup> This processing inactivates lipid membrane-bound viruses. The product is further processed through an affinity column to remove prions. Protein-coated nonenveloped viruses such as HAV or parvovirus B19 are resistant to S/D treatment. Transmission is prevented by screening for low virus loads in the starting plasma units, dilution through pooling, and the presence of neutralization antibodies introduced by pooling. The risk of transfusion-related lung injury appears to be dramatically reduced, if not eliminated, which is likely due to pooling and screening for HLA antibodies.<sup>159</sup> Octaplas LG is provided as a standard 200 mL bag of type-specific S/D plasma. It is maintained frozen at 18 °C and thawed when requested. Once thawed, Octaplas LG is stored for up to 12 hours at 2–4 °C.<sup>158</sup> The content of Octaplas LG is similar to that of plasma with the exception of lower levels of protein S activity (0.61 IU/mL; normal range, 0.56–1.68) and α2-antiplasmin activity (0.48 IU/mL; normal range, 0.72–1.32).<sup>160</sup> Prior S/D plasma formulations approved in the United States had even lower levels of protein S and α2-antiplasmin activity, and were associated with reports of enhanced fibrinolysis and thrombosis during liver transplant.<sup>161</sup> This does not appear to be the case with current Octaplas LG formulations.<sup>159</sup> Octaplas LG can be used clinically interchangeably with plasma,<sup>159</sup> including for TTP as ADAMTS13 levels are adequate.<sup>162</sup> Octaplas also appears to be safe in pediatric patients. A recently published open-label, multicenter, postmarketing study of 50 pediatric patients undergoing cardiac or

liver surgery or with liver dysfunction, who were administered Octaplas LG for the replacement of multiple coagulation factors, reported no adverse drug reactions and no serious adverse events attributable to the Octaplas LG administration.<sup>163</sup>

### **Prothrombin complex concentrates (PCC)**

Three-factor nonactivated PCC (3-PCC) containing lyophilized factors II, IX, and X but low levels of factor VII (Profilnine-Grifols, Bebulin VHBaxter) and an activated 3-PCC called FEIBA (factor VIII inhibitory bypass activity; Baxter) have been available in the United States for years. These have been used primarily for the treatment of hemophilia. In April 2013, the FDA approved the first nonactivated four-factor PCC (4-PCC) called K-Centra (CSL Behring GmbH, Marburg, Germany).<sup>164</sup> K-Centra contains hemostatic levels of factors II, VII, IX, and X. It is indicated for the urgent reversal of acquired coagulation factor deficiency induced by vitamin K antagonist (VKA; e.g., warfarin) therapy in adult patients with acute major bleeding. Dosing is based on weight and baseline INR values. The dose calculation uses the factor IX content, which is approximately 500 IU/vial. For an INR of 2–4, 25 IU/kg is used, not to exceed 2500 IU; for an INR of 4–6, 35 IU/kg is used, not to exceed 3500 IU; and, for an INR>6, 50 IU/kg is used, not to exceed 5000 IU. Patients should receive vitamin K concomitantly with K-Centra. Repeated dosing is not recommended. The primary US study upon which the US Food and Drug Administration (FDA) approval was based was an open-label RCT comparing K-Centra to plasma for urgent VKA reversal in 202 patients with major bleeding.<sup>165</sup> The study demonstrated that K-Centra was equivalent to plasma in achieving the hemostatic endpoint and did so more rapidly (17 minutes vs. 148 minutes). There was no difference in thromboembolic rates (7.8% PCC vs 6.4% FFP) or serious adverse events, although the mortality rate at 45 days was 9.7% in the PCC group versus 4.6% in the FFP group. Of note, K-Centra contains trace amounts of heparin and thus should not be used in patients with heparin-induced thrombocytopenia. The use of 3-PCC for warfarin reversal is controversial, although nonactivated 3-PCC has been used in combination with recombinant factor VIIa when there have been shortages of 4-PCC.<sup>166</sup>

There are limited studies on the use of 4-PCC for treatment of coagulopathy in other settings. A pilot randomized controlled trial (PROPHESY trial) comparing the impact of 4-PCC versus FFP on hemostasis (1 and 24 hour postintervention) in patients undergoing heart surgery showed a significant increase in factor II and factor X activity in the 4-PCC arm one-hour postadministration and no increase in thromboembolic complications.<sup>167</sup> A nationwide propensity score-matched analysis of the American College of Surgeons-Trauma Quality Improvement Program database of adult trauma patients who received 4-PCC plus FFP versus FFP alone demonstrated a lower mortality rate (17.5% vs. 27.7%,  $p = 0.01$ ), lower rates of acute respiratory distress syndrome (1.3% vs. 4.7%,  $p = 0.04$ ) and acute kidney injury (2.1% vs. 7.3%,  $p = 0.01$ ), and a decreased requirement for pRBCs (6 units vs. 10 units;  $p = 0.02$ ) in the combined 4-PCC + FFP group compared with the control group (FFP only).<sup>168</sup> Clinical trials of four-factor PCCs with regard to their efficacy, safety (thrombotic risk), and cost-effectiveness in patients not on VKAs are needed.

While 4-PCC were once used as reversal agents for direct factor Xa inhibitors, such as rivaroxaban and apixaban,<sup>169,170</sup> their use in this setting is declining due to the recent FDA approval of andexanet-alfa, a specific antidote for these anticoagulant drugs.<sup>171</sup>

### **Antifibrinolytics**

The fibrinolytic system contributes to the balance between bleeding and thrombosis by controlling clot formation, extension and remodeling, and dissolving unnecessary clots. In patients with excessive bleeding, inhibiting fibrinolysis can improve hemostasis by delaying clot dissolution. The two most commonly used antifibrinolytic agents,  $\epsilon$ -aminocaproic acid (EACA) and tranexamic acid (TXA), are lysine analogs that bind to lysine receptor sites on plasminogen, thereby slowing the rate of conversion to its active form, plasmin.<sup>157</sup> With the removal of aprotinin from the US market in 2007, these agents have been shown to be efficacious in reducing bleeding in cardiac surgery.<sup>172</sup> TXA interest was greatly promoted by the trauma study, Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH-2).<sup>173</sup> This was an RCT involving 20,211 adult trauma patients assigned to receive TXA versus placebo within eight hours of injury. The primary end point, all-cause mortality, was reduced in the TXA arm (14.5% vs. 16.0%) as was death due to bleeding (4.9% vs. 5.7%). A follow-up analysis showed that the benefit was strongest when TXA was given within one hour of injury; it was still apparent at 1–3 hours after injury, but TXA actually increased mortality if given 3–8 hours after injury.<sup>174</sup> There was no difference in bleeding or transfusions. The subsequent CRASH-3 RCT demonstrated that tranexamic acid was safe in patients with traumatic brain injury (TBI) and that treatment within three hours of injury reduced head-injury-related death.<sup>175</sup> The WOMAN trial, a large international randomized, double-blind trial of TXA versus placebo in nearly 20,000 women with postpartum hemorrhage, also showed a reduction in death due to bleeding, especially in women given TXA within three hours of giving birth (1.2% in the TXA group vs. 1.7% in the placebo group; relative risk: 0.69;  $p = 0.008$ ).<sup>176</sup> A recent review and meta-analysis of RCTs of TXA versus no TXA in surgical patients found 129 trials involving more than 10,000 patients who underwent cardiac, orthopedic, hepatic, urologic, gynecologic, cranial, or vascular surgery published between 1972 and 2011 and showed that the need for transfusion was consistently reduced by approximately one-third.<sup>177</sup> In the nonsurgical setting, TXA was not found to be effective in preventing bleeding in severely thrombocytopenic patients with hematologic malignancy.<sup>178</sup>

Antifibrinolytic use is not without risk. An RCT of TXA in cardiac surgery reported an increased risk of seizures when TXA was used at high doses (100 mg/kg of body weight).<sup>179</sup> There is also some concern that TXA may increase the risk of fibrinolysis shutdown in severely injured trauma patients, and there have been calls to limit its use to patients with evidence of hyperfibrinolysis in this setting.<sup>180,181</sup> While fibrinolysis shutdown is also amplified by TXA in surgical settings, such as oral and maxillofacial surgery,<sup>182</sup> there are no data to suggest that its use in these settings results in an increase in adverse events or poor outcomes.

### **Desmopressin**

Desmopressin (DDAVP) is a synthetic analog of vasopressin that is primarily used for the treatment of patients with von Willebrand disease (VWD), hemophilia A, some platelet disorders, and uremic bleeding. DDAVP is known to increase the plasma levels of von Willebrand factor (VWF), factor VIII, and tissue plasminogen activator. The hemostatic effect of DDAVP is well understood.<sup>183</sup> DDAVP has been used to enhance hemostasis in patients undergoing surgery with expected high blood loss. A meta-analysis of 38 trials involving 2488 patients undergoing mostly cardiac surgery but also orthopedic, vascular, and plastic surgery found a statistically

significant reduction in bleeding (80 mL) and transfusion (0.3 units), but the clinical relevance of these findings is questionable.<sup>184</sup> Due to its limited efficacy, DDAVP is not routinely used in surgical patients.

### Fibrinogen concentrates

There are two human plasma-derived, sterile, purified, virus-inactivated, and nanofiltered lyophilized fibrinogen concentrates available in the United States: RiaSTAP (CSL Behring GmbH, Marburg, Germany) and FIBRYGA (Octapharma AG, Vienna, Austria).<sup>185,186</sup> The labeled indication for both concentrates is for the treatment of acute bleeding episodes in patients with congenital fibrinogen deficiency, including afibrinogenemia and hypofibrinogenemia; neither product has a labeled indication for dysfibrinogenemia or acquired hypo-fibrinogenemia. Each bottle of RiaSTAP contains approximately 900–1300 mg of fibrinogen and each bottle of FIBRYGA contains approximately 1000 mg of fibrinogen, equivalent to 4–5 units of cryoprecipitate. Fibrinogen concentrates have been widely used in Europe for patients with perioperative bleeding and acquired hypofibrinogenemia.<sup>187</sup> The fibrinogen level at which replacement is recommended in the perioperative setting has evolved from 100 mg/dL<sup>188</sup> to more recently 150–200 mg/dL in the European trauma guidelines.<sup>189</sup> In the perioperative setting, the recommended dose is 2–4 g (25–50 mg/kg) of fibrinogen concentrate with an expected increment of 25–28 mg/dL per gram of fibrinogen concentrate.<sup>156</sup> The reported side effects include allergic reactions (chills, fever, nausea, vomiting, and thrombosis).

A recent meta-analysis of eight RCTs evaluating fibrinogen concentrate use in cardiovascular surgery patients at high risk or with evidence of bleeding found a significant reduction in transfusions but not mortality.<sup>190</sup> A later RCT of 735 patients who underwent cardiac surgery compared fibrinogen concentrates to cryoprecipitate in bleeding patients with hypofibrinogenemia, and found fibrinogen concentrates to be equivalent in blood product use and risk of thrombosis.<sup>191</sup>

### Recombinant activated factor VII (rFVIIa)

Recombinant activated factor VII (rFVIIa, NovoSeven, Novo Nordisk A/S, Bagsvaerd, Denmark) is structurally similar to plasma-derived factor VIIa and is intended to promote hemostasis through the activation of the extrinsic pathway of the coagulation cascade.<sup>192</sup> rFVIIa binds to tissue factor, which then converts factor X to factor Xa, as well as coagulation factor IX to factor IXa. The factor VII gene was cloned and expressed in Chinese hamster kidney cells where the expressed protein is autoactivated during chromatographic purification.<sup>193</sup> The labeled indication for rFVIIa is to treat or prevent bleeding in hemophilia A or B patients with inhibitors or patients with congenital factor VII deficiency.<sup>192</sup> Dosing in hemophilia patients with bleeding is 90 µg/kg every two hours until hemostasis is achieved ( $t_{1/2}$  is 2.3 hours). It is available as a lyophilized powder requiring reconstitution in 1, 2, or 5 mg vials.

There has been extensive interest in using rFVIIa off-label to promote hemostasis in trauma, surgery, intracranial bleeding, and other patient populations.<sup>194</sup> Early enthusiasm based on largely observational data or small RCTs<sup>195,196</sup> was not confirmed by RCTs in penetrating trauma,<sup>195</sup> pediatric cardiac surgery,<sup>197</sup> intracranial bleeding,<sup>198</sup> liver resection,<sup>199</sup> or variceal bleeding.<sup>200</sup> rFVIIa has also been suggested as a potential therapy for the reversal of anti-coagulants, such as warfarin, direct factor Xa inhibitors, and direct thrombin inhibitors. With the availability of four-factor

PCC, rFVIIa should not be used for warfarin reversal. Data on its use to reverse dabigatran or rivaroxaban are mixed.<sup>201–204</sup> Given the uncertainty regarding clinical effectiveness in off-label settings, safety issues must be carefully considered. A systematic review of 35 clinical trials involving 4468 patients who received rFVIIa for an off-label indication reported significantly higher risk of arterial (but not venous) thromboembolic events (CI 1.68 [1.20–2.36]).<sup>205</sup> A recent meta-analysis of six clinical trials involving 470 cardiac surgery patients reported a higher risk of stroke (OR 3.69 [1.1–12.38],  $p = 0.03$ ) in those treated with rFVIIa.<sup>206</sup> Taken together the literature suggests that the use of rFVIIa in an off-label setting has unproven efficacy, should be entertained with caution, and, if used, should be limited to patients with life-threatening bleeding.<sup>207</sup>

### Limiting phlebotomy blood loss for laboratory testing

Although it might seem like a trivial amount of blood loss, repetitive phlebotomy for laboratory testing can result in a significant decrease in the patient's hemoglobin concentration and can result in anemia. A computerized model of blood loss predicted that it would take a healthy adult of average weight and blood volume about 40–70 days of 53 mL daily blood draws to reach a hemoglobin concentration of 7 g/dL, whereas a sick patient in the ICU would require only 9–14 days to reach the same level.<sup>208</sup> The volume of phlebotomy has been correlated with the decrease in the recipient's hemoglobin or RBC transfusion requirements,<sup>209–212</sup> and one Canadian study found that for every 100 mL of blood lost by phlebotomy, the recipient's hematocrit decreased by nearly 2%.<sup>209</sup> Several studies have demonstrated that the amount of blood that is collected for diagnostic purposes is far in excess of that which is actually necessary to complete the testing,<sup>212,213</sup> suggesting that measures to reduce the volume of blood collected for laboratory testing should be implemented. To this end, the AABB has suggested several steps that can be implemented.<sup>13</sup> Some of these suggestions involve educating the providers about the potential problems caused by reduced hemoglobin and anemia that can arise from excessive phlebotomies, and changing their practices when ordering laboratory testing; limiting the number of phlebotomies to the absolute minimum number required for patient care should reduce the amount of blood lost to testing, as will eliminating standing orders for certain laboratory tests, that is, laboratory tests should only be ordered when there is a change in the patient's condition or when a diagnostic or therapeutic intervention based on their results is being considered. Other recommendations involve making changes in the way that laboratory tests are ordered, such as by electronically limiting the number of times that a test can be ordered during a defined time period<sup>214</sup> and redesigning the electronic or paper forms on which laboratory tests are ordered to discourage ordering unnecessary testing. If a laboratory test is indeed required, then the smallest volume possible should be phlebotomized. This means that special small-volume tubes must be easily accessible on the ward and that the laboratory's diagnostic equipment must be able to process these kinds of tubes, which might have different dimensions than standard tubes. Furthermore, point-of-care testing should be performed when available (and when validated) as the volume of blood required to perform the testing is usually much smaller than that required by the instruments in the main laboratory.

## Summary

PBM has become a major clinical and research focus for not only the field of transfusion medicine but also any discipline in which patients are transfused. It is designed to be patient care focused and requires a multidisciplinary approach. A PBM program requires resources, effort, and institutional support but can be implemented gradually by initially capitalizing on the obvious opportunities. IT has provided unprecedented opportunity to systematically influence ordering and monitoring of physician practices. A PBM program is one of the most powerful ways to optimize patient care in a cost-effective manner.

## Acknowledgments

## CHAPTER 28

# Clinical and technical aspects of blood administration

Edward S. Lee, Debra L. Mraz, & Edward L. Snyder

Department of Laboratory Medicine, Yale School of Medicine; and Blood Bank, Yale-New Haven Hospital, New Haven, CT, USA

## Introduction

Errors in pretransfusion specimen collection, omission of appropriate transfusion filters, or coadministration of incompatible fluids with blood products could transform blood transfusions from a lifesaving measure into a life-threatening event. This chapter summarizes key aspects of safe blood component administration and emphasizes processes and technologic advances that aim to improve the quality of patient care and patient safety. This chapter provides general guidance based on current guidelines and regulations. In addition to this information, the reader is directed to the latest version of the AABB Standards for Blood Banks and Transfusion Services, the College of American Pathologists (CAP) Transfusion Medicine Checklist, local standards of practice, and institutional requirements.<sup>1,2</sup>

## Pretransfusion considerations

Prior to transfusion, several steps should be taken to ensure safe administration of blood products for patients. First, it is essential to obtain informed consent for blood transfusion except in the setting of emergent requests for blood products. Per the AABB Standards for Blood Banks and Transfusion Services (Standard 5.28.1.1), informed consent at minimum requires the inclusion of the following: (1) a description of the risks, benefits, possible side effects, and alternatives (including nontreatment); (2) the opportunity to ask questions; and (3) the right to accept or refuse transfusion.<sup>1</sup> In some parts of the United States, there is also a legal requirement (e.g., the Paul Gann Blood Safety Act in California) to discuss alternatives to transfusion. The informed consent discussion between the health-care provider and patient should be properly documented in the patient's medical record.<sup>3,4</sup>

Second, a transfusion history should be obtained from the patient.<sup>5</sup> The history should include information about previous transfusions such as the timing and the types of blood products that were transfused and if the patient had previous transfusion reactions. If the patient has a history of transfusion reactions, the clinical team should consider whether the patient should receive prophylactic medication (see more details in Chapter 48) and if the blood component requires specific pretransfusion processing, such

as the pretransfusion modifications described later in the section "Component modification and preparation." The transfusion history should also include documentation of alloantibodies to red blood cell antigens identified in the patient to supplement the compatibility testing described below.

Third, pretransfusion compatibility testing should be performed prior to component issue unless the indication for transfusion is emergent. Determining the ABO and RhD blood type of the transfusion recipient and identifying any unexpected antibodies in the plasma of the recipient can prevent hemolytic transfusion reactions and conserve limited resources.<sup>6</sup> To begin the pretransfusion compatibility testing process, the clinical staff must obtain a blood sample from a correctly identified patient. The pretransfusion sample should be labeled legibly in the presence of the patient with a minimum of two patient identifiers (e.g., name, medical record number, and date of birth), the date and time of the blood draw, and the identification of the person who collected the sample. The blood bank must reject samples that do not strictly meet these requirements or if there are any discrepancies in labeling.<sup>1</sup> Other reasons that pretransfusion samples should be rejected include if the requisition form is missing key identifying information or if the sample was drawn in an incorrect tube.<sup>1,5</sup>

Studies have consistently shown that human errors throughout the pretransfusion process occur at substantial rates, can lead to wrong blood in tube (WBIT), and result in fatal incompatible transfusions.<sup>7–10</sup> As a consequence, both the AABB Standards for Blood Banks and Transfusion Services and CAP Transfusion Medicine Checklist require that transfusion medicine services have a policy and systems in place to reduce the risk of misidentification of pretransfusion samples and the risk of transfusion of red cells to the wrong patient.<sup>1,2</sup> Examples of processes that can reduce these risks include verifying the ABO typing of a patient with a second sample collected at a separate blood draw, using an electronic identification system that verifies at the time of transfusion that the patient about to receive a blood product is the same patient from whom that pretransfusion sample was drawn, or utilizing a mechanical barrier system that uses a code on the patient wristband to open the correctly issued blood component.<sup>2,11</sup> These protocols are necessary because the consequences of WBIT can be fatal.

## Venipuncture for intravenous (IV) access

Blood components are most often transfused intravenously through peripheral veins, but central venous access can also be used in critically ill patients.<sup>12</sup> IV line sizes typically range from 25- to 14-gauge; 20–18-gauge IV lines are usually suitable for adults, and 25–24-gauge IV lines can be used in infants and toddlers as long as an infusion device maintains constant flow.<sup>13,14</sup> Slower transfusion rates should be used with smaller gauge needles to prevent hemolysis, and special care is needed in administering red blood cells with handheld syringes through smaller needles (e.g., 23-gauge or smaller).<sup>15</sup> A previously established IV line can be used for blood transfusion. However, prior to use, the line should always be examined for patency and signs of infection. Ideally, the line should be flushed with normal saline to ensure that any incompatible fluid is removed prior to blood component infusion.

## Component issue, release, storage, and transport

### Component issue and release

Blood banks must have a formal process when issuing blood components to verify that the correct blood product is being given to the correct recipient. The verification process must check the following<sup>1</sup>:

- 1 The type of blood component
- 2 The recipient's two independent identifiers, ABO group, and Rh type
- 3 The donation identification number, donor ABO group, and if required, Rh type
- 4 The interpretation of crossmatch results, if performed
- 5 Completion of any special transfusion requirements (e.g., irradiation or washing)
- 6 The expiration date (and time, if applicable)
- 7 A check for any visual abnormalities of the unit

After this checklist is completed, the date and time of issue should be noted. Once at the bedside, the transfusionist and either another individual or an electronic identification system must identify and match the patient and the intended recipient of the issued blood product with two independent identifiers, all in the presence of the patient.<sup>1</sup>

### Component storage

Blood components must be stored within strict temperature requirements to maintain their quality and safety. All storage devices should be equipped with an emergency power supply and a continuous alarm monitoring system. In the absence of such a system, the temperature must be monitored and documented every four hours.<sup>16</sup> Alarms should continue to function even in the event of a power failure. Scheduled alarm checks should occur at least quarterly as required by the CAP Transfusion Medicine Checklist.<sup>2,17</sup>

### Red blood cells

RBCs must be stored within refrigerators in the blood bank, in refrigerators at other satellite sites, or in validated coolers monitored by the blood bank. The refrigerators must continuously maintain temperatures at 1–6 °C to limit RBC metabolic activity while ensuring cell viability.<sup>18,19</sup> During the transport process, RBCs must maintain temperatures of 1–10 °C.<sup>1</sup> Options for maintaining these temperatures for transport include bagged wet ice, commercial cooling packs, and specially designed coolers (see the section

"Component transport").<sup>5</sup> If RBCs are not maintained in these temperatures, they must be discarded and should not be transfused nor returned back to inventory.

The expiration time of RBCs is dependent on what anticoagulant is used during collection.<sup>5</sup> RBCs derived from whole blood collected in acid–citrate–dextrose (ACD), citrate–phosphate–dextrose (CPD), or citrate–phosphate–double–dextrose (CP2D) expire 21 days from collection. RBC units collected in citrate–phosphate–dextrose–adenine (CPDA-1) expire 35 days from collection. RBC units that are processed to include additive solution (AS-1) expire 42 days from collection. As discussed later, a leukoreduced RBC unit has the same expiration times as the original unit, and an irradiated RBC has an expiration of 28 days from the time of irradiation or the original expiration date, whichever is sooner.

### Platelets

Indications for platelet transfusion include prophylaxis for hypoproliferative thrombocytopenia, prophylaxis for invasive procedures in patients with thrombocytopenia or platelet dysfunction, and the treatment of active bleeding in thrombocytopenic patients. Platelets should be stored at room temperature (20–24 °C) with continuous gentle agitation.<sup>1,5</sup> During transport, platelets should also be kept at 20–24 °C but do not need to be agitated. Room temperature storage is favored because platelets stored at 20–24 °C have good post-transfusion in vivo recovery; exposure to cold temperatures results in platelet inactivation and rapid in vivo clearance.<sup>20</sup> Despite these properties, cold-stored and cryopreserved platelets are actively being investigated and are discussed in Chapter 17. Platelets are sensitive to pH changes and have storage requirements to maintain an optimal pH range. Platelets are stored in containers made of plastic that are permeable to gas, and continuous adequate agitation promotes gas exchange and helps to effectively maintain pH.<sup>21,22</sup> Platelet agitation devices have been extensively studied, and results of these studies show that horizontal agitation (circular or flatbed agitators moving side to side) maintain platelet functionality more effectively than vigorous, vertical (end over end) methods of agitation.<sup>20,23,24</sup> Studies have also demonstrated that deleterious effects on platelet components can begin to take place after one day or longer of interrupted agitation.<sup>25–27</sup> Accordingly, AABB Standards for Blood Banks and Transfusion Services permit a maximum 30-hour period during product transport when platelets are not required to be agitated.<sup>1</sup>

Room temperature storage puts platelets at increased risk of bacterial contamination, and guidelines set by the FDA and new pathogen reduction technologies address this challenge. In the FDA guidance released in September 2019 and updated in the autumn of 2021, platelets are recommended to undergo procedures that mitigate the risks of bacterial contamination. Compliant approaches include primary culture, large volume delayed sampling (LVDS), pathogen reduction, and rapid bacterial testing (see details in Chapters 17, 42, and 46).<sup>28</sup> The first two methods use standard bacterial culture methods available in microbiology laboratories but differ on sample timing and sample volume taken for culture. FDA-approved pathogen reduction technology reduces the transmission of infectious agents in platelet components by using UV-A light with a psoralen photoactive agent to crosslink DNA and/or RNA (see Chapter 42). A second technology using riboflavin and UV light is available in some countries outside the US. Finally, rapid bacterial testing utilizes either an immunoassay or colorimetric assay to detect Gram-positive and Gram-negative bacteria.<sup>29,30</sup>

## Plasma

Transfusions with plasma products are indicated for bleeding patients with coagulation factor deficiencies and patients with specific plasma-protein deficiencies. Plasma transfusions are often given to patients before invasive procedures to correct abnormalities in coagulation tests despite the lack of evidence that this practice provides real clinical benefit.<sup>31–33</sup> There are several different preparations of plasma that are differentiated based on the manner and timing of the plasma separation and freezing processes. Fresh-frozen plasma (FFP) is separated from whole blood and placed in a freezer within eight hours of collection. Generally, if plasma is frozen within 8–24 hours of collection, it can be labeled either as plasma frozen within 24 hours (PF24) or plasma frozen within 24 hours after phlebotomy held at room temperature up to 24 hours after phlebotomy (PF24RT24). FFP, PF24, and PF24RT24 can generally be maintained in a freezer at  $\leq -18^{\circ}\text{C}$  for 12 months after collection; FDA variances can be obtained to store plasma frozen for longer periods of time. Plasma that is separated from whole blood and is never frozen can be labeled as *liquid plasma*, which expires five days after the expiration date of the whole blood from which it was derived. These variations in labeling are due to concern that plasma that is not separated and frozen within eight hours could have diminished levels of coagulation factors.<sup>34,35</sup>

After thawing, FFP should subsequently be stored at 1–6 °C. Temperatures up to 10 °C are acceptable during transport. If the component is not transfused within 24 hours, it can be relabeled as *thawed plasma* and stored in a refrigerator for an additional four days.<sup>35</sup> Outside of the United States, there is limited availability of freeze-dried plasma.<sup>36</sup>

## Cryoprecipitate

Cryoprecipitate transfusions are used for fibrinogen replacement in patients with low fibrinogen as can be seen in the setting of liver failure and postpartum hemorrhage. Cryoprecipitate is derived from FFP thawed slowly in an ice bath or in a refrigerator at 1–6 °C. Cryoprecipitate must contain at least 150 mg of fibrinogen and a factor VIII activity level of 80 IU.<sup>1</sup> This component also contains other plasma proteins, including fibronectin, factor XIII, and von Willebrand factor. Cryoprecipitate, once collected from thawed FFP, must be frozen within one hour and can be maintained at  $\leq -18^{\circ}\text{C}$  for up to 12 months. When the product is requested for clinical use, it should be thawed at 30–37 °C and then stored and transported at room temperature to prevent reprecipitation of the component. A pooled component expires within four hours unless the pooling occurred with the use of a sterile connection device. In the case of single units and sterile pools, the product shelf life is extended to six hours.<sup>1,37</sup>

## Granulocytes

Granulocytes have been transfused in septic patients with severe neutropenia despite controversy over the clinical benefit of these transfusions.<sup>38</sup> From a blood component administration perspective, patients must receive the infusion of granulocytes within 24 hours of collection, and granulocytes must be irradiated because recipients are significantly immunocompromised and the product contains a substantial number of lymphocytes.<sup>1</sup> Because the RBC content of a granulocyte collection usually exceeds 2% (typically approximately 6%), granulocyte products must also be ABO and crossmatch compatible with the recipient.<sup>1</sup> Granulocytes should be maintained at room temperature without agitation and must never be leukoreduced.<sup>1,37</sup>

## Hematopoietic progenitor cells and cell-based immunotherapies

Hematopoietic progenitor cells (HPCs) can be collected from the bone marrow, from peripheral blood with stem cell mobilization, or from cord blood. These products are stored in liquid nitrogen.<sup>5</sup> Shipping and transport of HPCs are highly regulated by the FDA, AABB, FACT, and other organizations.<sup>39</sup> Hematopoietic progenitor cells that are infused must never be irradiated. To minimize hematopoietic progenitor cell loss, many transplant centers infuse hematopoietic stem cells into the recipient without the use of a standard infusion set and never with a leukoreduction filter. However, a standard infusion set can be used when debris is noted in the HPC product. After infusion, sterile saline may be injected into the empty stem cell container to rinse the bag to maximize stem cell recovery.

Cell-based immunotherapies such as CAR T cells have been FDA-approved for the treatment of a number of hematologic malignancies.<sup>40</sup> These immunotherapy products must be stored, transported, and administered according to manufacturers' instructions and product labeling and, like HPC products, they must never be leukoreduced. Before thawing, identification information on the product's label must match the patient's identity, and the infusion bag and contents should be visually inspected. Tubing should be primed with saline before infusion, and after all the contents are infused, sterile saline should be used to rinse the bag and tubing to maximize the number of cells infused into the patient.

Specific standards for cellular therapy products are established and maintained by the US Food and Drug Administration (FDA; [www.fda.gov](http://www.fda.gov)), AABB ([www.aabb.org](http://www.aabb.org)), CAP ([www.cap.org](http://www.cap.org)), and the Foundation for the Accreditation of Cellular Therapy (FACT; [www.factwebsite.org](http://www.factwebsite.org)).

## Prothrombin complex concentrates and recombinant clotting factors

Some transfusion services are responsible for dispensing prothrombin complex concentrates (PCCs)—which are used to reverse vitamin K antagonists such as warfarin—and recombinant clotting factors, which are increasingly utilized in patients with uncontrolled bleeding.<sup>41–43</sup> PCCs are also used to reverse the effects of direct oral anticoagulants in place of specific reversal medications (e.g., andexanet alfa for direct factor Xa inhibitors and idarucizumab for dabigatran) as a cost-effective alternative or when these agents are not available.<sup>44–46</sup> These products are often lyophilized and must be reconstituted with sterile water or another diluent prior to infusion. In general, recombinant factors can be administered by a slow intravenous push whereas multifactor pooled plasma products (e.g., factor VIII inhibitor bypassing agent [FEIBA] and the four-factor PCC) must be administered much more slowly. Details of preparation and administration of PCCs and recombinant clotting factors differ as some formulations include specific syringe and filter sets; in all cases, manufacturer instructions and details in product labeling must be followed. For hospitals that regularly infuse FEIBA or four-factor PCC, the use of a syringe pump or infusion pump can help to ensure that the product is administered safely and at the recommended rate.

## Storage equipment

Automated equipment for blood component storage includes refrigerators, freezers, cell washers, platelet agitators, and plasma thawing devices. Automatic refrigerators have been engineered to act as “vending machines” that store and dispense RBCs remotely.

These devices maintain appropriate temperatures for the blood components, and the computer system interfaces with that of the hospital's blood bank to perform electronic crossmatches to issue compatible blood to patients.<sup>47</sup> If a particular patient cannot receive an electronically crossmatched unit, the system also allows for the emergency release of uncrossmatched blood. These devices have been implemented to allow for quick release of blood products in settings such as the emergency room or intensive care units. Their utility is still under evaluation.<sup>48</sup>

### **Component transport**

Considerations for component transportation are critical to maintaining the integrity of the component to be transfused. Many medical centers rely on coolers with different types of cooler packs to transport blood products as long as they have been validated by the blood bank to maintain RBC and plasma temperatures between 1 and 10 °C. These coolers have been reported to be validated for up to 24 hours to maintain appropriate temperatures; however, these coolers should be used with the expectation that the transfusion should occur quickly and before substantial temperature shifts have taken place.<sup>1</sup> Temperature-sensitive adhesive labels that attach directly to the component or the containers can also be used to monitor transport temperatures. These labels have indicators that change color when the temperature limit is exceeded.<sup>49</sup> Therefore, when a blood component is not transfused, the label can be checked for a color change and/or the temperature of the unit can be taken to determine whether it can be safely returned to the blood bank inventory.<sup>2,17</sup>

### **Novel transport and storage devices**

Portable refrigerator units have been developed that are capable of maintaining a refrigerated temperature of 1–6 °C and are battery-powered, lasting up to 48 hours after leaving the blood bank according to the manufacturer. In addition, at least one model has been designed that maintains refrigerated temperatures of 1–10 °C for the transport of blood components. Although these mobile refrigerators have not been extensively studied, preliminary investigations have shown decreased wastage of blood components by allowing unused issued blood components to be returned to inventory.<sup>50,51</sup> Some models incorporate tracking devices so that the location of the cooler can be tracked by the blood bank at all times. In addition, some coolers maintain a temperature log during use or have real-time wireless temperature monitoring. One study has suggested that unmanned aerial vehicles, or drones, can be used to transport blood products from one location to another, potentially addressing challenges of transporting products in regions with geographical barriers.<sup>52</sup>

### **Return of blood components**

The blood bank must have a validated written procedure for returning blood components back into inventory after they have been issued, which should include steps to "verify the integrity and appearance of blood/blood components and maintenance at appropriate temperature."<sup>22</sup> Issued blood components may be put back into inventory if the following conditions are met<sup>1</sup>:

- 1 The container has not been opened or disturbed
- 2 The component has been maintained within the appropriate temperature range
- 3 For RBCs, at least one sealed segment remains attached to the container
- 4 Documentation that the component has been inspected and is acceptable for reissue

### **Component modification and preparation**

When ordering blood components, physicians should stipulate any specific product modification requirements. As these component modifications often influence the expiration date of the component, the time of outdate must be noted as well.

### **Leukoreduction**

Prestorage leukoreduction, the process of removing leukocytes from blood components prior to storage, is utilized to prevent transfusion-mediated transmission of cytomegalovirus (CMV),<sup>53</sup> human leukocyte antigen (HLA) alloimmunization,<sup>54</sup> platelet refractoriness,<sup>55</sup> and febrile nonhemolytic transfusion reactions.<sup>56</sup> Importantly, certain blood components, such as granulocytes and hematopoietic progenitor cells, must never be processed through a leukoreduction filter (Table 28.1).<sup>37</sup> Leukoreduction filters work by interception and adhesion of white blood cells to filter fiber media and remove >99.99% of leukocytes in RBCs.<sup>57,58</sup> These filters should not be confused with standard component filters, such as the 170–260-µm screen filters incorporated into standard blood administration tubing sets that are used for all blood component infusions and work by clot or debris interception (see Table 28.1). Additionally, 40-µm microaggregate filters are used in cell salvage devices and also work by interception.

In the United States, 95% of sampled leukoreduced components should have less than  $5.0 \times 10^6$  residual leukocytes per RBC unit or apheresis-derived platelet unit and less than  $8.3 \times 10^5$  residual leukocytes per unit of whole-blood derived platelets.<sup>1,58</sup> Notably, this requirement is less stringent than current European requirements, which stipulate that less than  $1 \times 10^6$  leukocytes should remain.<sup>5,59</sup> Many developed countries have mandated universal prestorage leukocyte reduction. Although the United States has not adopted universal leukocyte reduction, the FDA has recommended its implementation. According to 2017 National Blood Collection and Utilization Survey, 95.8% of RBCs (either apheresis or whole-blood-derived) and 99.2% of apheresis platelets transfused in the United States were leukoreduced.<sup>60</sup> Despite these high rates of leukoreduction, leukoreduction policies differ by blood bank and blood supplier, and health-care providers must be aware of their hospital-based practices.

### **Irradiation**

Irradiation of cellular blood components (i.e., granulocytes, non-pathogen-reduced platelets, and RBCs) must be performed when transfusing patients who are at high risk for transfusion-associated graft-versus-host disease (TA-GVHD). Patients at risk for TA-GVHD are usually immunocompromised due to hematologic malignancies, congenital immunodeficiency disorders, immunosuppression from myeloablative drugs, and immature immunity in neonates and fetuses.<sup>61,62</sup> Irradiation of donor units is also performed when the blood donor is known to be a blood relative or an HLA match with the recipient.<sup>1,12</sup> Ensuring proper irradiation is especially critical because TA-GVHD is generally fatal with no known effective treatment.<sup>61,63</sup> In the United States, an irradiated blood component must receive a radiation dose of 25 Gy (2500 cGy) directed at the central portion of the blood canister with no less than 15 Gy to any part of the canister and no more than 50 Gy to any part of the canister.<sup>1,61</sup> This dose of irradiation damages the DNA of T cells contained within the cellular blood component, prevents T-cell replication and engraftment, and thus eliminates the risk of TA-GVHD. Noncellular blood components—such as plasma and cryoprecipitate—and pathogen-reduced platelets do not require irradiation.<sup>35</sup>

**Table 28.1** Considerations in the Preparation and Administration of Various Blood Components

Component	Transfuse through Standard Transfusion Set and Filter	Need for Leukoreduction	Indications for Irradiation
Red blood cells	Always	Recommended—to reduce risk of CMV transmission, febrile nonhemolytic transfusion reactions, platelet refractoriness, and HLA alloimmunization	Prevention of TA-GVHD in vulnerable populations
Platelets	Always	Recommended—to reduce risk of CMV transmission, febrile nonhemolytic transfusion reactions, platelet refractoriness, and HLA alloimmunization	Prevention of TA-GVHD in vulnerable populations Not necessary for pathogen-reduced platelets
Plasma	Always	Not applicable	None
Cryoprecipitate	Always	Not applicable	None
Granulocytes	Always	Never	Always for prevention of TA-GVHD
Hematopoietic precursor cells	No	Never	Never

Sources of radiation used by blood banks are either gamma rays from cesium-137 or cobalt-60 sources or X rays from either a linear accelerator or stand-alone generators. Irradiators that utilize cesium-137 or cobalt-60 contain the isotope within chambers made of lead to prevent escape of gamma rays from the irradiator device. Linear accelerator irradiators generate a beam of X rays, allowing blood components to be irradiated.<sup>64</sup> X ray tube generating devices can also be used.

All types of irradiators require periodic maintenance and quality assurance programs to ensure that the blood container is receiving an appropriate dose of radiation. Irradiators using cesium-137 or cobalt-60 must periodically have the exposure time recalculated to account for the gradual radioactive decay of the radioactive isotopes. The FDA requires the verification of delivered doses annually for cesium-137 sources and semiannually for cobalt-60 sources.<sup>64</sup> Dose verification and adjustments for X ray irradiators should be performed per manufacturer's protocols.<sup>1</sup> In 2019, the US government set a goal to eliminate blood irradiation devices relying on cesium by the end of 2027 by working with hospitals to replace cesium irradiators with X ray devices.<sup>65</sup>

Regardless of the source of irradiation, the expiration date of irradiated RBC units is either 28 days from the date of irradiation or the original expiration date, whichever is sooner.<sup>5,66</sup> Irradiation can increase the levels of hemolysis and potassium in RBCs and so transfusions with irradiated RBCs require special consideration in vulnerable populations (e.g., the increased potassium may cause cardiac complications in small children).<sup>5,67</sup> Irradiation, however, does not alter the expiration date or the function of platelets, and as a result, some hospitals with large oncology wards irradiate platelets at the time that they are placed in hospital inventory. It should be noted that platelets processed with pathogen reduction technology do not need to be irradiated because the process crosslinks nucleic acids and effectively inactivates lymphocytes to prevent TA-GVHD.

### Washing

Cellular blood products usually contain some volume of plasma, and washing can be performed to remove plasma proteins. Washing RBCs or platelets is indicated for patients who have a history of severe allergic reactions to products containing plasma; patients with antibodies against IgA who are receiving products that are not IgA-deficient; removal of complement in products given to patients with post-transfusion purpura; and patients who cannot tolerate the potassium and preservatives in the blood component. The washing process for RBCs or platelets is usually performed with

isotonic saline in an automated, centrifuge-based machine housed in the blood bank or blood center. Once the RBCs or platelets are centrifuged into a "packed" state, isotonic saline flows through the packed cellular mass, washing out the plasma and preservative solution and taking their place. Washing can result in the loss of up to 20% of the RBCs and 33% of platelets and thus should be performed only if there is a clear indication. Furthermore, cells are generally washed in an open system, and as a result, RBCs expire 24 hours after washing, and platelets expire 4 hours after washing, regardless of the original product expiration dates.<sup>5</sup> Some washing devices may induce more RBC destruction during the washing process than others, resulting in higher supernatant potassium levels.<sup>68</sup> For these reasons, washing RBCs and platelets immediately prior to use is preferred.

### Volume reduction via aliquoting

In an effort to mitigate risk for transfusion-associated circulatory overload (TACO) in at-risk patients, RBC, platelet, and plasma units can be split into smaller aliquots using transfer bags and a sterile connecting device. Splitting units can also be utilized in times of inventory shortage in the right clinical context and under medical director guidance. Sterile connecting devices work by connecting sterile tubing segments with copper wafers heated to more than 260–300 °C, melting the plastic tubing and juxtaposing the severed ends together. The heating process prevents bacterial contamination. If the system remains closed throughout the process, the shelf life of the transfer bag will remain the same as the shelf life of the primary unit. Similar technology is employed by heat sealers, which melt plastic tubing and generate a seal that can be detached without opening the blood component.

For neonates requiring very small transfusion volumes (sometimes as little as 10–30 mL), aliquoting of cellular components with the use of connecting devices into a syringe can help to maintain an aseptic (although open system) environment and can preserve the remainder of the blood component, which can be stored properly in the blood bank for future transfusions.<sup>69</sup> Shortening of expiration dates of aliquots should be based on regulatory, institutional, and local policies.<sup>5</sup> Alternatively, RBC aliquots can be made by blood centers by using a multiple-pack system, which diverts a collection of whole blood into a primary bag with three attached smaller bags.<sup>70</sup> When this "quad pack" is centrifuged, the plasma can be separated into one bag, and RBCs are separated into the other three bags. Quad packs provide transfusion services with three RBC aliquots derived from one single RBC unit without having to use sterile connection devices.<sup>16</sup>

### **Thawing plasma**

Frozen plasma can be thawed either in a 30–37 °C water bath or in FDA-approved microwave devices. FFP and PF24 are stored at -18 °C or below and can take 20–30 minutes to thaw in a 37 °C water bath. Water baths have the potential to introduce bacterial contamination into the component if the component is not properly sealed and protected in a waterproof bag.<sup>71</sup> As such, water baths should be regularly cleaned according to the manufacturer's procedures. Water-based warmers—which circulate warm water through a plastic attachment inserted next to the plasma bag rather than requiring the plasma bag to be submerged in the water bath—may also protect against this risk.

Microwave ovens are more expensive than water baths but may be more suitable for urgent plasma requests. Specially designed microwave ovens have been shown to thaw components more quickly, in approximately 5–10 minutes.<sup>72</sup> Microwave ovens also do not carry the same risk of introducing bacterial contamination into the unit. However, microwave ovens have been reported to damage the component plasma proteins in the event of malfunction or the development of “hot spots.”<sup>73</sup> Indeed, some experiments with early microwave ovens identified areas of overheating within the plasma bag, such as at the junction where the tubing segment connects to the bag.<sup>71</sup> More recent studies with newer microwave thawing machines have not identified overheating during normal function,<sup>74</sup> and no significant effects on coagulation factor levels were observed when thawing solvent-treated plasma with modern thawing microwaves.<sup>75</sup> Radiofrequency-based thawing systems have been developed that use longer wavelengths to achieve a more uniform distribution of energy, thus minimizing temperature gradients within the plasma during rapid warming; at least one study has shown FFP thawed with these systems contains adequate coagulation factor levels.<sup>76,77</sup>

## **At the bedside: transfusion administration**

### **Pretransfusion**

Once a blood product reaches the patient's bedside, the transfusionist and either a second person or an electronic verification system must verify several pertinent pieces of information before the transfusion is initiated.<sup>1,5</sup> Transfusionists must check for a valid order for transfusion and confirm the presence of an appropriately signed consent form. They must positively identify the recipient in their presence using two unique identifiers and confirm the recipient's ABO group and Rh type. Transfusionists must confirm the following documentation on the blood bag label: donation identification number, ABO group and Rh type of the blood unit, crossmatch interpretation, documentation of special transfusion requirements and processing (e.g., irradiation), and the unit expiration to confirm it is in-date. All identification attached to the blood container must remain attached until the transfusion is terminated.<sup>1</sup> After the above steps have been completed, but before the transfusion begins, pretransfusion vital signs should be documented (e.g., temperature, pulse, blood pressure, and oxygen saturation). If the patient experiences any clinical changes during the transfusion, these initial vital signs will serve as baseline values.

### **Blood administration sets and filters**

Once blood components leave the blood bank, transfusion should be initiated as quickly as possible to avoid the risk of bacterial overgrowth.<sup>78</sup> All blood component transfusions should be completed

within four hours of the beginning of the transfusion. Institution-specific criteria should be followed, but standard blood administration infusion sets are required for the infusion of all blood products (except for hematopoietic progenitor cells). These sets consist of three main parts: inline filters, drip chambers, and tubing that can be attached directly to a previously established IV line.

Macroaggregate (standard) inline filters are typically included in the administration sets and usually have a 170–260-μm pore size to remove large fibrin clots and cellular debris from all blood components immediately before they enter the patient.<sup>1,12,79,80</sup> The filters should be used and replaced according to manufacturer recommendations. In addition, microaggregates of cellular debris and fibrin strands were historically found to potentially develop within stored blood and were thought to play a role in the development of acute respiratory distress syndrome (ARDS) despite the lack of an established causal link.<sup>80</sup> Microaggregate filters were used in the past to remove this debris but are no longer routinely used at the bedside. Instead, the majority of blood components undergo leukocyte reduction filtration at the blood center, which more efficiently filters out debris.<sup>81</sup>

The drip chamber is a standard component of the infusion set that allows the transfusionist to control the rate of infusion and importantly serves to avoid infusion of air. Prior to use, the infusion set and tubing can be rinsed or primed with either 0.9% sodium chloride or the component to be transfused.<sup>5</sup>

As previously discussed in this chapter, aliquoting for small-volume infusions in neonates utilizes a special syringe administration set, which typically includes an inline screen filter that filters the component during aliquoting.<sup>5</sup>

### **Coadministration of fluids and blood components**

In general, no IV solutions other than 0.9% normal saline should be coadministered with blood components through the same IV line. According to the AABB Standards for Blood Banks and Transfusion Services, the only compatible fluid is 0.9% normal saline, but allowances are made for drugs or solutions that have been approved by the FDA to be used with blood administration or if there is documentation that shows that coadministration is safe and does not affect the blood or component.<sup>1</sup> Hypertonic (e.g., hypertonic saline) or hypotonic solutions (e.g., dextrose 5% in water) should not be coadministered as they can cause osmotic hemolysis of the transfused blood component. Lactated Ringer's solution and other solutions that contain high calcium concentrations should be avoided as well because they can cause clotting of the blood component by overwhelming the ability of the citrate to effectively anticoagulate the product.<sup>5</sup>

### **Coadministration of medications**

Although this practice has not been extensively studied, in general, medications should not be administered simultaneously through the same IV line as the blood component.<sup>5</sup> The main reason is it would be difficult to differentiate a reaction to the medication from a reaction to the blood component in the setting of simultaneous administration of a blood component and a medication. In addition, if a transfusion needed to be stopped, then the patient may not receive the intended dose of the coadministered medication. Furthermore, some medications may not be compatible with the blood components and may cause hemolysis or clotting. For these reasons, medications should be administered with a second IV line. In the event that additional IV access has not been established, then the IV line used for the blood component should be clamped and

flushed with 0.9% saline before infusing any medications.<sup>12</sup> When blood components must be administered concomitantly, as in the setting of trauma or surgery, this can be accomplished with the use of separate IV lines. Multiple blood components can be sequentially transfused through the same tubing and IV line.<sup>5</sup>

### Patient monitoring

After the transfusion has begun, the patient's vital signs should be evaluated and documented 15 minutes after the start of the transfusion. A slow transfusion rate (e.g., 2 mL per minute) should be used because severe reactions often occur within the first 15 minutes and can be caused by volumes as small as 10 mL.<sup>5</sup> If the patient has any suspected adverse reactions, then the transfusion should be stopped until the patient can be clinically evaluated. Depending on the scenario, the transfusion may need to be discontinued altogether. If a patient has a mild allergic reaction (i.e., hives) without signs of vasomotor instability, laryngeal edema, or tongue or lip swelling, the transfusion usually can be restarted if the symptoms resolve with antihistamine therapy. However, a transfusion should not be restarted if the recipient has a change in blood pressure, fever, chills, an anaphylactoid reaction such as just described, or an increase in temperature (even if there was a preexisting fever). These symptoms should trigger a transfusion reaction workup by the physician responsible for the transfusion, the blood bank, and the blood bank consulting physician.

### Infusion flow rates

Beyond the first 15 minutes of a transfusion, optimal infusion rates vary with the component being transfused, the clinical situation, and the patient's ability to tolerate increased intravascular volume. Components should generally be infused slowly at first, and then the rate can be increased as tolerated by the patient. Patients at risk for volume overload, such as those with poor cardiac status, should receive a slow infusion rate with close monitoring, if feasible. In general, RBCs and plasma have volumes ranging from 200 to 400 mL and are typically infused over 1–2 hours. Platelets range in volume from 200 to 300 mL and are also generally infused over 1–2 hours.<sup>5,37</sup> Cryoprecipitate can be given as rapidly as tolerated and should be infused as soon after the thawing procedure as is clinically acceptable.<sup>5</sup> Transfusions for all blood components should be completed within four hours of the start of transfusion.<sup>35</sup>

There is a paucity of evidence to make specific recommendations regarding blood component flow rates in neonatal and pediatric patients. Although concern exists that increased rates can cause intraventricular hemorrhage or electrolyte imbalances in neonates, there is limited high-quality evidence to support this theory. Therefore, in this patient population, for routine blood component administration, transfusions are usually administered over 2–4 hours.<sup>5</sup> Some authors recommend infusion rates of 5 mL/kg/hour for RBCs and 10–20 mL/kg/hour for platelets, but local and institutional policies should be consulted regarding infusion rates.<sup>82</sup>

In certain clinical scenarios, there can be a need to transfuse RBCs, plasma, or platelets at a slower rate than would allow for the completion of transfusion in a four-hour period. As mentioned in the "Volume reduction via aliquoting" section, one strategy to accomplish this relies on the blood bank's ability to use a sterile tubing welder to split and aliquot units in a sterile manner. These aliquots can be issued to the patient, and the remaining sterile unit can be properly stored in the blood bank. In the case of split units, the transfusionist can administer the split unit over a four-hour period and then contact the blood bank to request the other half of

the unit. This practice allows for a unit of RBCs, plasma, or platelets to be divided and effectively infused over eight hours.

### RBC salvage devices

RBC salvage refers to techniques for reclaiming and processing blood lost in the surgical field for intraoperative autologous transfusion. The blood salvage device takes suctioned blood and separates, concentrates, and washes RBCs to provide a red blood cell suspension that can be reinfused into the patient.<sup>83</sup> Blood is suctioned from the surgical field and mixed with either heparin or citrate to prevent coagulation. The mixture is fed into a storage chamber until sufficient volume is collected for processing, and then it is centrifuged to separate the RBCs and remove all other components. The RBCs are washed to remove free hemoglobin, cellular debris, and anticoagulants, and then passed through a 40- $\mu\text{m}$  filter when they are infused back into the patient. In settings of rapid blood loss, the salvaged blood can be reinfused into the patient without the centrifugation and washing steps. However, the risks of infusing unwashed blood stem from the added anticoagulant, thrombogenic substances, free hemoglobin, and other debris, and thus salvaged RBCs should be washed except for severe emergencies.<sup>84</sup> Salvage devices have been shown by some studies to reduce allogeneic RBC transfusions for both adult and pediatric patients undergoing cardiac surgery.<sup>85,86</sup> Due to the relatively large volume needed to prime and effectively run RBC salvage, these devices are not useful in children under six months of age.<sup>87</sup>

### Rapid infusion practices

Blood products are occasionally requested on an urgent basis when a patient is deemed to have a life-threatening condition that does not allow for sufficient time for a full crossmatch prior to blood component issue. Conspicuously labeled uncrossmatched units can be stored in blood-bank-monitored refrigerators in critical areas throughout the hospital such as the emergency department, operating rooms, labor and delivery suites, and intensive care units. When uncrossmatched units are issued, there must be record of a signed statement from the ordering physician indicating a sufficient clinical requirement for the release of blood components before the completion of compatibility testing.<sup>1</sup> Although specific protocols can vary with institutional and local policies, the following should be followed when uncrossmatched units are released<sup>5</sup>:

- 1 Uncrossmatched type O RBC units should be issued, with preference to giving RhD-negative units to women of childbearing potential, infants, and individuals with a history of anti-D antibodies. Other groups may receive RhD-positive units, particularly if there are inventory limitations.
- 2 ABO- and RhD-compatible units should be issued if results of patient blood typing are available.
- 3 The unit should be labeled conspicuously on the tag or label that compatibility testing was not completed at the time of issue.
- 4 Compatibility testing should be performed and completed as soon as possible. If the uncrossmatched units are found to be incompatible, both the transfusion medical director and the patient's physicians should be alerted immediately.

In the setting of massive transfusion, transfusion services are encouraged to develop standardized protocols that rapidly deliver blood components in a balanced ratio of RBCs to plasma to platelets (discussed in more detail in Chapter 40). Before ABO typing is completed, group O RBCs should be issued. Consideration should be given to using group AB or A plasma. Transfusing group A plasma to patients with an unknown ABO type in trauma settings

has been demonstrated to be safe.<sup>88</sup> When RhD-negative trauma patients receive RhD-positive blood components, they are at risk of alloimmunization to the D antigen, and so policies should be developed to identify when RhD-positive RBCs can be issued (e.g., to all adult males and females with no childbearing potential).<sup>5,89</sup> However, if the patient's ABO and Rh type are known, then the patient should reasonably receive type-specific products rather than defaulting to universally compatible products.

In urgent circumstances, blood components often need to be transfused as quickly as possible, and large-bore intravenous catheters can be used for this purpose. When blood losses are substantial, blood infusers can be utilized for rapid transfusion. Rapid infusers can deliver warmed blood components at rates as fast as 500–1500 mL per minute through a pump, which is far faster than the rate that a standard infusion can be delivered.<sup>90</sup> Given this rapid rate of infusion, it is essential that blood components are warmed in order to prevent hypothermia-induced coagulopathy.<sup>91</sup> Rapid infusers are frequently credited with providing lifesaving delivery of blood, but care should be taken to avoid air emboli.<sup>92</sup> Some models of infusion pumps have improved safety features that automatically stop transfusion when air emboli are detected.<sup>93</sup>

### Blood warming and bedside blood pumps

Stand-alone blood warmers may be utilized when large volumes of blood components are transfused (without a rapid infuser) or when patients have cold agglutinins detected during compatibility testing. Only validated, FDA-approved blood warmers should be used for this purpose to ensure patient safety. The AABB Standards for Blood Banks and Transfusion Services require that warmers have a temperature-sensing device and a system that will warn about malfunctions and will prevent hemolysis to the blood component.<sup>1</sup> Blood warmers often consist of tubing coiled around a central heating core that is temperature-monitored. Blood must never be warmed by holding the unit in a hot water stream under a faucet or by heating it in a standard microwave oven because these methods can cause clinically significant hemolysis. Monitored blood

warmers are frequently used during lengthy apheresis procedures to promote patient comfort. Importantly, nonwarmed blood has been historically shown to lower the core temperature of transfusion recipients, possibly contributing to cardiac arrest and hypothermia.<sup>94</sup> Blood warmers must be maintained regularly to prevent malfunction and possible hemolysis. Blood can also be administered through medication infusion pumps if they have been shown not to cause shear-stress-induced hemolysis. These devices are often used for neonatal or pediatric transfusions when precise infusion volumes are needed. Not all pumps are compatible with red cell infusions, so each device model should be evaluated to ensure red cell compatibility.

### Post-transfusion

At the completion of the transfusion, the patient should be checked again for any signs of an adverse reaction to the blood component, and a final set of vital signs should be taken. Because transfusion reactions can occur several hours after the completion of the transfusion, inpatients should be monitored for at least 4–6 hours after the infusion is completed. If a patient will be discharged from an ambulatory care setting after receiving a transfusion, then written documentation of signs and symptoms of transfusion reactions and a telephone number of a responsible practitioner should be provided to the patient prior to leaving the clinic.<sup>5</sup>

## Introduction

Red cell transfusion is an extremely common medical intervention. In the United States in 2019, 11,590,000 RBC units were collected and 10,852,000 RBC units were transfused, a 2.5% increase from 2017.<sup>1</sup> Worldwide, 118.5 million units of blood are collected per year.<sup>2</sup> In Northern England, about 50% of units are given to medical patients and 40% to surgical patients; hip replacement and coronary artery bypass graft (CABG) procedures were the most common surgical indications.<sup>3</sup> RBC units are also frequently administered to critically ill patients, as a supportive therapy to patients receiving chemotherapy and marrow transplants, and to patients with blood loss from medical conditions such as gastrointestinal bleeding.<sup>4</sup> Approximately 25% of all red cells transfused are given to patients with a primary diagnosis of cardiac disease,<sup>5</sup> and 8% of all cardiology admissions are transfused RBCs.<sup>6</sup> In recent years, blood use has declined as clinicians adopt a more restrictive approach to transfusion.<sup>7</sup> Estimates of the cost of an RBC unit in different health systems range from \$522 to \$1183 (mean: \$761 ± \$294).<sup>8</sup>

This chapter reviews the current knowledge about red cell transfusion, their risks and benefits, as well as the risk posed by anemia, all in the hopes of providing the reader an evidence-informed approach to understanding at what hemoglobin concentration a transfusion will mitigate the effects of anemia and result in improved outcomes. In order to provide a more comprehensive overview, sections on physiological effects of transfusion and anemia give readers an indication of changes related to anemia and its treatment. This overview also summarizes observational studies. Clinical recommendations in this chapter are largely based on randomized clinical trials identified and synthesized in systematic reviews. Clinical guidelines on transfusion practices also guided some recommendations. We do our best throughout the chapter to point out where evidence or guidelines are strong. Importantly, we also emphasize where data are much weaker leading to recommendations primarily based on our experience.

## Adaptive mechanisms in anemia

In anemia, oxygen-carrying capacity decreases, but tissue oxygenation is preserved at hemoglobin levels well below 10 g/dL. After the development of anemia, adaptive changes include a shift in the

oxyhemoglobin dissociation curve, hemodynamic alterations, and microcirculatory alterations (Table 29.1). The shift to the right of the oxyhemoglobin dissociation curve in anemia is primarily the result of increased synthesis of 2,3-diphosphoglycerate (2,3-DPG) in red cells.<sup>9–11</sup> This rightward shift enables more oxygen to be released to the tissues at a given PO<sub>2</sub>, offsetting the effect of reduced oxygen-carrying capacity of the blood. *in vitro* studies have shown rightward shifts in the oxyhemoglobin dissociation curve with increases in temperature and decreases in pH.<sup>12</sup> Although clinically important shifts have been documented in a number of studies, hemoglobin oxygen saturation generally is measured in arterial specimens processed at standard temperature and pH. Therefore, current measurement techniques do not reflect oxygen-binding affinity or unloading conditions in the patient's microcirculatory environment, which may be affected by temperature, pH, and a number of disease processes. The shift in the oxyhemoglobin dissociation curve caused by decreases in pH (increase in hydrogen ion concentration) is termed the Bohr effect.<sup>13</sup> Because changes in pH rapidly affect the ability of hemoglobin to bind oxygen, this mechanism has been postulated to be an important early adaptive response to anemia.<sup>14</sup> However, the equations describing the physical process indicate that a very large change in pH is needed to modify the partial pressure of oxygen at which hemoglobin is 50% saturated with oxygen ( $P_{50}$ ) by a clinically important amount (~10 mmHg). As a result, the Bohr effect is unlikely to have significant clinical consequences.<sup>12</sup>

Several hemodynamic alterations occur after the development of anemia. The most important determinant of cardiovascular response is the patient's volume status or more specifically left ventricular preload. The combined effect of hypovolemia and anemia often occurs because of acute blood loss. Acute anemia can cause tissue hypoxia or anoxia through both diminished cardiac output (stagnant hypoxia) and decreased oxygen-carrying capacity (anemic hypoxia).<sup>15</sup> The body primarily attempts to preserve oxygen delivery to vital organs by compensatory increases in myocardial contractility and heart rate as well as increased arterial and venous vascular tone mediated through increased sympathetic discharge. In addition, a variety of mechanisms redistribute organ blood flow. The adrenergic system plays an important role in redistributing blood flow between and within specific organs; increased sympathetic tone diverts an

**Table 29.1** Physiologic Changes Associated with Normovolemic Anemia**Oxyhemoglobin Dissociation Curve**

- Oxyhemoglobin curve shifted to the right because of increased 2,3-diphosphoglycerate levels.
- Rightward shift in the oxyhemoglobin curve is not a result of the Bohr effect in patients.
- The shift in the oxyhemoglobin curve has been clearly established in many forms of anemia (excluding hemoglobinopathies).
- Shift in the oxyhemoglobin curve has been clearly established in a number of human diseases.

**Hemodynamic Alteration**

- Changes in blood viscosity result in many of the hemodynamic changes.
- Increased sympathetic activity resulting in increased heart rate and contractility.
- Increased stroke volume more than vascular resistance
- Redistribution of cardiac output toward the heart and brain and away from the splanchnic circulation.
- Systemic oxygen delivery is optimized at hemoglobin values of 10–11 g/dL.
- Global oxygen delivery declines above and below hemoglobin values of 10–16 g/dL.
- Microvascular hematocrit and regulation of RBC distribution is loosely correlated with systemic hematocrit over wide range of values

**Cardiac Output**

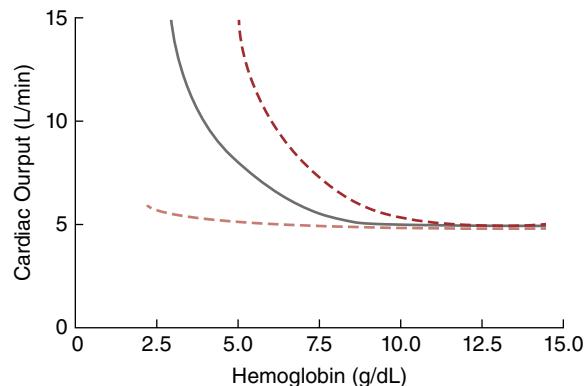

- Cardiac output increases with increasing degrees of anemia.
- Increased cardiac output is a result of increased stroke volume.
- The contribution of increased heart rate to the increase in cardiac output is variable.

**Coronary and Cerebral Blood Flow**

- Coronary and cerebral blood flow is increased.
- Coronary artery disease in the presence of moderate degrees of anemia (hemoglobin values below 9 g/dL) results in impaired left ventricular contractility or ischemia.
- Moderate anemia does not aggravate cerebral ischemia in patients with cerebrovascular disease.

ever-decreasing global blood flow (cardiac output) away from the splanchnic, skeletal, and cutaneous circulation toward the coronary and cerebral circulation. The renin–angiotensin–aldosterone system is stimulated to retain both water and sodium. Losses ranging from 5% to 15% in blood volume result in variable increases in resting heart rate and diastolic blood pressure. Orthostatic hypotension often is a sensitive indicator of relatively small losses in blood volume not sufficient to cause a marked decrease in blood pressure.<sup>16</sup> Larger losses result in progressive increases in heart rate and decreases in arterial blood pressure accompanied by evidence of organ hypoperfusion. Once vital organ systems such as the kidneys, the central nervous system, and the heart are affected, the patient is considered in hypovolemic shock. Although the American College of Surgeons Committee on Trauma<sup>17</sup> has categorized the cardiovascular and systemic response to acute blood loss according to degree of blood loss, many of these responses are modified by the rapidity of blood loss and patient characteristics, such as age, coexisting illnesses, preexisting volume status, hemoglobin value, and the use of medications having cardiac effects ( $\beta$ -blockers) or peripheral vascular effects (antihypertensives).

The compensatory changes in cardiac output most thoroughly studied are the cardiovascular consequence of normovolemic anemia. When intravascular volume is stable or high after the development of anemia (as opposed to hypovolemic anemia and shock), increases in cardiac output have been consistently reported. Indeed, an inverse relationship between hemoglobin level (or hematocrit) and cardiac output has been clearly established in well-controlled laboratory studies (Figure 29.1).<sup>18–20</sup> Similar clinical observations have been made in the perioperative setting<sup>21</sup> and for chronic anemia.<sup>18</sup> Unfortunately, the strength of inferences from clinical studies is limited by confounding factors arising from major coexisting illnesses such as cardiac disease, a lack of appropriate control patients,

**Figure 29.1** The theoretic effect of hemoglobin concentration on cardiac output. The curves illustrate how cardiac output increases as hemoglobin concentration decreases. The solid curve is meant to describe the increase in a healthy adult. The dashed line on the top shows how the cardiac output response can be accentuated in a young athlete, and the lower dashed line might correspond to someone with poor cardiovascular function.

and significant weaknesses in study design. Researchers have attempted to determine the level of anemia at which cardiac output begins to rise. Reported thresholds for this phenomenon identified in primary clinical and laboratory studies have ranged from 7 to 12 g/dL of hemoglobin.<sup>18</sup> Two major mechanisms are thought to be responsible for the physiologic processes underlying increased cardiac output during normovolemic anemia:<sup>1</sup> reduced blood viscosity and<sup>2</sup> increased sympathetic stimulation of cardiac effectors.<sup>22</sup> Blood viscosity inversely affects both preload and afterload, two major determinants of cardiac output,<sup>22–24</sup> whereas sympathetic stimulation primarily increases the two other determinants, heart rate and contractility. Unlike the situation for hypovolemic anemia, in this setting the effects of blood viscosity appear to predominate.<sup>23,24</sup>

Complex interactions exist among blood flow, blood viscosity, and cardiac output. In vessels, blood flow alters whole blood viscosity, and blood viscosity modulates cardiac output. Under experimental conditions in a rigid hollow cylinder, blood flow is directly related to the fourth power of the diameter and to driving pressure. It is inversely related to the length of the vessel and to blood viscosity (Poiseuille–Hagen law).<sup>22,25</sup> If cardiac function is normal, the increase in venous return or left ventricular preload is the most important determinant of increased cardiac output during normovolemic anemia. The conclusion is based on experiments in which viscosity was maintained during anemia by means of high-viscosity colloidal solutions. In such studies, the cardiovascular effects of hemodilution were attenuated<sup>23</sup> compared with similar levels of hemodilution accompanied by reduced whole blood viscosity. Decreased left ventricular afterload, another cardiac consequence of decreased blood viscosity, may also be an important mechanism for the increase in cardiac output as anemia worsens.<sup>23</sup>

Sympathetic stimulation can result in increased cardiac output through enhanced myocardial contractility<sup>26</sup> and increased venomotor tone.<sup>27,28</sup> The effects of anemia on left ventricular contractility in isolation have not been clearly determined, given the complex changes in preload, afterload, and heart rate. Only one before and after hemodilution study was performed with load-independent measures to document increased left ventricular contractility.<sup>26</sup> Chaper and Cain<sup>28</sup> summarized several well-controlled animal studies indicating that venomotor tone increases as a result of stimulation of the aortic chemoreceptors. If sympathetic stimulation is

significant in the specific clinical setting, contractility is increased from the stimulation of the  $\beta$ -adrenergic receptors.<sup>22,29</sup>

Fick's law states that global oxygen delivery is related to the product of cardiac output and blood oxygen content (overwhelmingly determined by hemoglobin). Yet, the inverse relationship between cardiac output and hemoglobin level (via changes in blood viscosity) has led investigators to attempt to determine the hemoglobin level that maximizes oxygen transport within the systemic circulation. Richardson and Guyton<sup>30</sup> evaluated the effects of hematocrit on cardiac performance in a canine model. They established that the hematocrit range that optimized cardiac efficiency and global oxygen transport was 40–60%. Others determined maximum oxygen delivery to be in the lower end of the range, at a hematocrit of 40–45% (hemoglobin 13–15 g/dL).<sup>31,32</sup> However, in one of the most widely quoted studies addressing this topic,<sup>33</sup> investigators found that peak oxygen transport as determined by the Fick equation occurs at a hematocrit of 30% (hemoglobin concentration, 10 g/dL). Unfortunately, global indices of oxygen delivery mask any differences in blood flow between specific organs<sup>34,35</sup> and do not reflect the net impact on microvascular oxygen delivery (see below). In addition, these studies attempted to identify a single optimal hemoglobin concentration that maximizes oxygen delivery in the equivalent of young healthy patients with anemia, an approach that neglects the large number of factors interfering with adaptive mechanisms during the management of patients with disease.

Will the transfusion of allogeneic RBCs reverse any adaptive response to acute or chronic normovolemic anemia? Assuming that oxygen-carrying capacity is not impaired during storage and that hematocrit is restored after a transfusion, the cardiovascular consequences should be reversed. However, the storage process alters the properties of red cells. These alterations may impair flow and oxygen release from hemoglobin.<sup>9</sup>

## **Microcirculatory effects of anemia and red cell transfusion**

In the systemic circulation, blood is considered a homogenous medium operating under the classical laws of fluid dynamics. By contrast, blood flow in the microcirculation—defined as arterioles, capillaries, and venules with diameter less than 300  $\mu\text{m}$ <sup>36</sup>—is governed by unique biophysical properties that impact oxygen delivery.<sup>37</sup> The reason for these discrepancies is the *two-phase nature* of blood in the microcirculation, whereby RBC and plasma flow are treated as distinct components. In microvessels, RBCs migrate away from the vessel wall, causing differential flow velocities and unequal partition of RBC and plasma at microvascular bifurcations.<sup>38</sup>

Most strikingly, these properties synergize within large microvascular networks to result in a marked reduction in hematocrit within microvessels of decreasing diameter. These phenomena partly explain why a significant proportion of microvascular hematocrits are less than 20% under normal conditions and can even be as low as 5% within capillary networks.<sup>39,40</sup> This reduced hematocrit, in combination with cell–cell interactions, also causes significant reduction in microvascular blood viscosity—well below the systemic circulation—that counteracts the impact of reduced flow velocities in the microcirculation.<sup>37</sup>

Furthermore, if the ultimate goal of RBC transfusion is to increase tissue oxygen delivery, attention then logically turns to the physiology of RBC distribution in capillary networks as the terminal site of oxygen exchange. As mentioned above, capillaries have the lowest hematocrits in the microcirculation, but also the most functional

variability in hematocrits, RBC velocity, and RBC supply rate.<sup>41</sup> While Krogh<sup>42</sup> originally proposed that capillary recruitment (i.e., the number of flowing capillaries) increases to support oxygen delivery, it has now been recognized that the overwhelming majority of capillaries are perfused at rest.<sup>43</sup> Increased oxygen demand is therefore supported by increasing RBC flux through capillaries that are already flowing, as well as increasing oxygen extraction.

The degree of anemia, the specific tissue bed, and a variety of disease processes affect microcirculatory blood flow and oxygen supply.<sup>25,44</sup> Animal studies of acute normovolemic hemodilution illustrate the ability of the microcirculation to dynamically adapt to changes in systemic hematocrit. In the cerebral circulation, capillary hematocrit was maintained even when the systemic hematocrit was diluted to 15%, and RBC velocity and supply rate increased.<sup>45</sup> In the mesentery<sup>46</sup> and skeletal muscle,<sup>47</sup> hemodilution resulted in minor reductions in capillary hematocrit (much less than the systemic drop), and these were offset by increases to RBC supply rate to maintain oxygen delivery. Moreover, the ratio of microvascular hematocrit to systemic hematocrit increased, suggesting that upstream arterioles adjusted their tone throughout the vascular network to accommodate the drop in systemic hematocrit. Taken together, these studies highlight two important physiological concepts to consider: (a) the relationship between systemic and microvascular hematocrit is nonlinear and (b) microvascular hematocrit is actively regulated to ensure adequate oxygen delivery. In the setting of microvascular injury (e.g., sepsis, diabetes), the ability to regulate hematocrit may be disrupted, which further weakens the ability of systemic transfusion to influence tissue oxygen delivery. These concepts may partly explain why the modulation of systemic hematocrit via RBC transfusion has not consistently improved clinical outcomes (see the below sections).

Stored red cells have properties that differ from those of their *in vivo* counterparts; many are related to the duration of storage (see Chapter 14). Characteristically, older RBC units have lower levels of 2,3-DPG. The result is a leftward shift in the oxyhemoglobin dissociation curve, which can impede delivery of oxygen to the tissues.<sup>14</sup> In addition, the storage of red cells decreases the deformability of their membrane.<sup>48</sup> As a consequence, stored red cells may become so rigid as to impede flow in the microcirculation<sup>49</sup> and may have limited ability to release oxygen to tissues. However, these storage lesions are reversible within 24–48 hours after transfusion.<sup>50</sup> There are also reports<sup>51</sup> suggesting that disease processes such as sepsis impair red cell deformability. In conjunction with significant systemic microcirculatory dysfunction, the decrease in red cell deformability may dramatically affect tissue oxygen delivery in sepsis and septic shock.<sup>51,52</sup> However, despite potential laboratory concerns, clinical trials have not demonstrated increased harms related to the use of standard issue red cells, averaging 20 days of storage.<sup>53</sup> Similarly, a large randomized controlled trial transfusing the shortest storage red cells did not show any benefit for clinical outcomes.<sup>54</sup> However, there are no clinical trials comparing red cells stored more than 35 days to standard issue red cells to better understand the consequences of red cells stored for prolonged intervals.

Bedside tools to assess microvascular oxygenation have been evaluated in the setting of RBC transfusion. The two most common modalities being used are near-infrared spectroscopy (NIRS) of the brain and skeletal muscle, and handheld vital microscopy (HVM) of the sublingual microcirculation. Generally, studies confirm the theory of dissociation between the microcirculation and systemic hemoglobin levels. In a small study of traumatic brain injury patients, NIRS was unable to detect a difference in cerebral oxygen

saturation despite an appropriate increase in systemic hemoglobin post-transfusion.<sup>55</sup> In other studies, when critically ill patients receiving RBC transfusion were monitored with both HVM and NIRS,<sup>56,57</sup> the change in systemic hemoglobin could not reliably predict microvascular response to transfusion. A systematic review<sup>58</sup> also found a lack of microvascular response to RBC transfusion but suggested that patients with poor microvascular indices at baseline may derive more benefit; these findings should be interpreted with caution given the heterogeneity and methodology of studies. Overall, more research is required to determine whether microvascular monitoring can guide RBC transfusions in select patient populations.

### Interaction between pathophysiologic processes and anemia

Several disease processes affecting either the entire body or specific organs potentially limit adaptive responses and make patients more vulnerable to the effects of anemia. Specifically, heart, lung, and cerebrovascular diseases have been proposed to increase the risk of adverse consequences of anemia. Age, severity of illness, and therapeutic interventions may also affect adaptive mechanisms.

The heart, specifically the left ventricle, is particularly prone to adverse consequences of anemia. This is because the myocardium consumes 60–75% (extraction ratio) of all oxygen delivered by the coronary circulation.<sup>31,34,59</sup> Such a high extraction ratio is unique to the coronary circulation. As a result, oxygen delivery to the myocardium can increase substantially only with an increase in blood flow.<sup>60</sup> In addition, most left ventricular perfusion is restricted to the diastolic period because pressures inside the left ventricle are too high to allow adequate coronary blood flow during systole. Thus, any shortening of its duration (e.g., tachycardia) decreases blood flow. Laboratory studies have been performed to investigate the effects of normovolemic anemia on the coronary circulation.<sup>32,59,61</sup> There appear to be minimal consequences of anemia with hemoglobin levels in the range of 7 g/dL if the coronary circulation is normal.<sup>19,26</sup> However, myocardial dysfunction and ischemia either occur earlier or are greater in anemic animal models with moderate- to high-grade coronary stenosis compared with controls with normal hemoglobin values.<sup>62</sup>

Unfortunately, data from studies with human participants are inconsistent on these points. Several clinical studies involving patients with coronary artery disease undergoing normovolemic hemodilution have not shown any increase in cardiac complications or silent ischemia during electrocardiographic monitoring.<sup>63</sup> In addition, a retrospective analysis involving 224 patients undergoing CABG surgery did not show a significant association between the hemoglobin level and coronary sinus lactate level (an indicator of myocardial ischemia).<sup>64</sup> However, in two recent cohort studies, moderate anemia was poorly tolerated by perioperative<sup>65</sup> and critically ill patients<sup>66</sup> with cardiovascular disease. Thus, retrospective studies seem to support preclinical reports. It is also plausible that anemia results in considerable increases in morbidity and mortality among patients with other cardiac diseases, including heart failure and valvular heart disease, presumably because of the greater burden of the adaptive increase in cardiac output.

During normovolemic anemia, cerebral blood flow increases as hemoglobin values decrease. Investigators have observed increases ranging from 50% to 500% of baseline value in laboratory studies<sup>67</sup> and in one study with human subjects.<sup>68</sup> Cerebral blood flow increases because of overall increases in cardiac output, which is

preferentially diverted to the cerebral circulation. As oxygen delivery begins to decrease, cerebral tissues can increase the amount of oxygen extracted from blood. A number of factors, including degree of hemodilution, type of fluid used for volume expansion, volume status (preload), and extent of cerebrovascular disease, are capable of potentially modifying global or regional cerebral blood flow during anemia.<sup>69</sup> The increase in global cerebral blood flow combined with the potential for improved flow characteristics across areas of vascular stenosis (improved rheologic properties of blood because of decreased viscosity) prompted a number of laboratory and clinical<sup>69–72</sup> studies to investigate the use of hemodilution as therapy for acute ischemic stroke.<sup>70–72</sup>

The results of laboratory studies suggest that moderate degrees of anemia alone should rarely result in or worsen cerebral ischemia. However, none of the randomized clinical trials demonstrated that hemodilution in acute ischemic stroke improved clinical outcomes in patients.<sup>73</sup> Because of the variety of variables that affect clinical outcomes, the negative findings may not fully rule out the possibility that hemodilution offers therapeutic benefit. Thus, the currently available evidence indicates that cerebrovascular disease does not appear to predispose patients to serious morbidity from anemia.

Changes in oxygen delivery to the brain during normovolemic anemia (either increases or decreases in blood flow) do not uniformly affect various cerebral pathologic conditions. For example, patients with high intracranial pressure from traumatic brain injury may be adversely affected by increased cerebral blood flow. On the other hand, after subarachnoid hemorrhage, mild degrees of normovolemic or hypervolemic anemia may improve overall oxygen delivery, possibly by overcoming the effects of cerebral vasospasm and thereby improving cerebral blood flow through decreased viscosity.<sup>74</sup> However, the effects of moderate to severe anemia in subarachnoid hemorrhage have not been assessed in laboratory or clinical studies.

One of the major consequences of redistributing some of the available cardiac output toward the coronary and cerebral circulation during normovolemic anemia is the shunting of flow away from other organs, including the kidneys and intestines. Critically ill patients may be adversely affected by this redistribution,<sup>75</sup> which could result in increased intestinal ischemia, bacterial translocation, and multiple-system organ failure.<sup>76</sup> Critical illness can also tax many of the body's adaptive responses. Specifically, cardiac performance may be impaired<sup>77</sup> or may already be at maximal capacity in response to increased metabolic demands. Pathologic processes affecting the microcirculation, particularly prevalent among critically ill patients, may also affect the patient's response to anemia and transfusions.

### Clinical outcomes of anemia and red cell transfusion

The decision to administer RBC units must weigh the risks of blood transfusion (see Chapters 43–51 for risks of transfusion), the ongoing risk of uncorrected anemia, and the level of anemia at which blood transfusion is expected to result in clinical benefits that outweigh the risks of associated adverse outcomes.

#### Risk of anemia

##### Preclinical laboratory studies

The critical hemoglobin threshold is similar in different animals.<sup>78</sup> Results of studies suggest that healthy animals can tolerate hemoglobin levels as low as 3–5 g/dL after normovolemic hemodilution.

Electrocardiographic changes consistent with ischemia occur at hemoglobin levels less than 5 g/dL, whereas lactate production, depressed ventricular function, and death have occurred at hemoglobin levels of 3 g/dL or less. While some animals survive with hemoglobin levels as low as 1–2 g/dL,<sup>79</sup> studies suggest a decreased ability to tolerate anemia in the presence of cardiac disease. In dogs with experimentally induced coronary stenosis varying from 50% to 80%, ST-segment changes or locally depressed cardiac function occurred at hemoglobin levels in the range of 7–10 g/dL.<sup>80,81</sup>

### Human studies

Studies involving patients who refuse blood transfusion for religious reasons provide critical insight into the effect of anemia on humans. The largest study was performed with 1958 adult surgical patients who refused transfusion for religious reasons.<sup>65</sup> The mortality was greatest among patients with the lowest preoperative hemoglobin concentrations. Among patients with underlying cardiovascular disease, the risk of death was markedly greater than for patients without cardiovascular disease, especially in those patients with a hemoglobin concentration less than 10 g/dL. Among patients without underlying cardiovascular disease, the difference in mortality at hemoglobin levels greater than or less than 10 g/dL was not as great (Figure 29.2). These results, as well as data on animals and physiologic data, suggest that anemia is not tolerated as well in the presence of cardiovascular disease.

Two studies in patients who declined blood transfusion for religious reasons evaluated the mortality and morbidity associated with nadir postoperative hemoglobin concentrations less than 8 g/dL (Table 29.2).<sup>82,83</sup> Mortality was very low (0.9%) in patients with hemoglobin concentrations between 7 and 8 g/dL but steadily rose with lower hemoglobin levels. The risk of death increased sharply below a hemoglobin concentration of 5 g/dL.

In a series of studies, the effect of anemia was evaluated among healthy volunteers who underwent isovolemic reduction of hemoglobin level to 5 g/dL. Transient and asymptomatic electrocardiographic changes were found in 5 of the 87 volunteers included in two studies.<sup>86,87</sup> These changes occurred when the hemoglobin level was between 5 and 7 g/dL and in patients with faster heart rates.<sup>87</sup> Changes in critical oxygen delivery were not measured. Subtle but reversible changes in cognition were identified in nine volunteers

younger than 35 years at a hemoglobin level between 5 and 7 g/dL.<sup>88</sup> Self-rated fatigue was found in eight volunteers when the hemoglobin level decreased to 7 g/dL. Fatigue increased as hemoglobin levels decreased to 5 g/dL.<sup>89</sup> The results of these studies suggest that important clinical effects can be detected in young, healthy humans with hemoglobin levels between 5 and 7 g/dL.

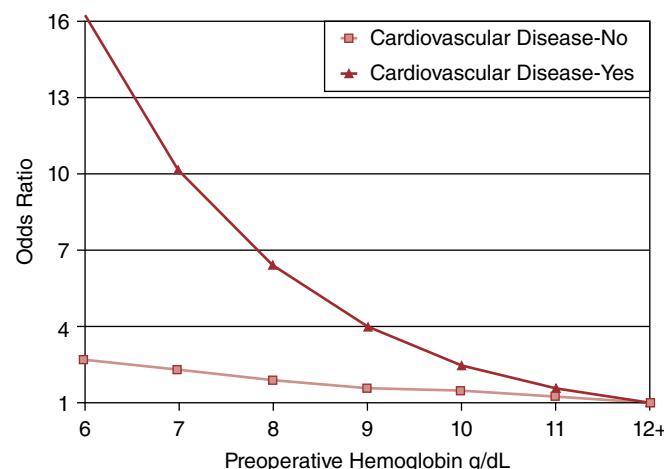

It is uncertain how these results apply to older patients with comorbid factors who are also under stress from surgery or acute illness. An analysis of 31,000 patients 65 years of age or older undergoing major noncardiac surgery examined the association between preoperative hematocrit and mortality or cardiac morbidity (cardiac arrest or Q-wave myocardial infarction).<sup>90</sup> Mortality rose when the hematocrit was less than 36%, and cardiac events were more frequent when the hematocrit was less than 39%. These results, in contrast to experimental data, suggest that mild anemia is associated with increased mortality and morbidity. However, anemia may be only a marker of underlying disease, and studies are needed to demonstrate improved outcome if anemia is corrected by transfusion.

### Clinical trials establishing overall risks and benefits of various transfusion strategies

In this section, we describe the many clinical trials that compare two transfusion strategies where one group received red cells at a higher hemoglobin concentration while another group was transfused at a lower hemoglobin concentration. In doing so, we can determine how best to administer red cells because such studies allow for an unbiased comparison of all clinically important risks of anemia, risks of transfusion, and the benefits of transfusion. We first review overall estimates of treatment effects by aggregating evidence from all trials and then examine clinically important subgroups to better understand if effects are consistent even when the benefits and consequences may vary.

### Meta-analyses

Through January 2021, there have been 48 published randomized clinical trials enrolling 21,433 patients that have contrasted the effects of different transfusion thresholds.<sup>91–137</sup> The clinical settings varied, although each trial randomly assigned patients to transfusion based on a restrictive (less transfusion) or a liberal strategy (more transfusion). In general, the restrictive triggers (specified hemoglobin

**Figure 29.2** Association between the preoperative hemoglobin level and mortality among patients with and without cardiovascular disease.<sup>47</sup> In a population of patients who refused blood transfusion, the risk of death was higher among patients with cardiovascular disease (top line) than among patients without cardiovascular disease (bottom line) for each preoperative hemoglobin level. (Source: Modified from Carson *et al.* (1996).<sup>47</sup>)

**Table 29.2** Unadjusted Rate of Death by 1 g/dL Decrement of the Nadir Postoperative Hb Level in the Two Series of Bloodless Surgery Patients<sup>83,84</sup>

Postoperative Hemoglobin	Carson et al. (2002) <sup>84</sup> N = 300		Shander et al. (2014) <sup>85</sup> N = 293		Totals N = 593	
	N	Mortality N (%)	N	Mortality N (%)	N	Mortality N (%)
1.1–2.0	7	7 (100%)	0	—	7	7 (100%)
2.1–3.0	24	13 (54.2%)	6	3 (50%)	30	16 (53.3%)
3.1–4.0	28	7 (25.0%)	16	3 (18.8%)	44	10 (22.7%)
4.1–5.0	32	11 (34.4%)	25	6 (19.4%)	57	17 (29.8%)
5.1–6.0	54	5 (9.3%)	49	7 (14.3%)	103	12 (11.7%)
6.1–7.0	56	5 (8.9%)	58	3 (5.2%)	114	8 (7.0%)
7.1–8.0	99	0 (0%)	133	2 (1.5%)	232	2 (0.9%)

concentrations that had to be attained) ranged from 7 to 9 g/dL, and liberal transfusion triggers ranged from 9 to 10 g/dL. Additionally, other transfusion strategies were used as well, and there was overlap between the liberal and restrictive transfusion groups in these trials. Overall, compared with liberal transfusion, patients in the restrictive transfusion group received 41% less transfusions, 1.21 fewer units of blood, and had a lower mean hemoglobin concentration of 1.28 g/dL.<sup>138</sup>

Importantly, the results of the meta-analysis found no clinical benefits or harm attributed to either a restrictive or liberal transfusion strategy. The primary outcome was designated as 30-day mortality as it is a clinically important end point and was adopted in the largest and highest quality trials. In the 30 trials that evaluated 30-day mortality in 16,729 participants, there was no difference between the restrictive versus liberal transfusion groups; relative risk = 0.99; 95% confidence interval [CI] 0.86–1.15 (Figure 29.3).

Other important clinical outcomes were assessed and reported in the meta-analysis.<sup>138</sup> None of the morbidity outcomes found significant differences between liberal and restrictive transfusion strategies (Table 29.3).

### Clinical settings of special interest

Transfusion thresholds could have differential effects in alternative clinical settings. As a consequence, clinicians often consider individualizing transfusion decisions in selected patients. Specific populations where risk–benefit ratios may not be the same as other patient populations have included cardiovascular diseases such as myocardial infarction and cardiac surgery. Other studies have been undertaken in orthopedic surgery and vascular surgery patient populations. A few studies have examined transfusion strategies following acute blood loss including from gastrointestinal (GI) bleeding. There have also been additional studies in subpopulations of critically ill patients including septic shock and various forms of brain injury.

### Critical care

The Transfusion Requirements in Critical Care (TRICC) trial was the first well-powered trial to evaluate clinically important outcomes associated with selected transfusion triggers.<sup>94,98</sup> In the main study, the investigators randomly assigned 838 volume-resuscitated ICU patients to a restrictive strategy in which patients received allogeneic RBC transfusions at hemoglobin levels of 7 g/dL (and were maintained between 7 and 9 g/dL) or to a liberal strategy of receiving RBCs at 10 g/dL (and were maintained between 10 and 12 g/dL). Average hemoglobin levels (8.5 g/dL vs. 10.7 g/dL) and RBC units transfused (2.6 units vs. 5.6 units) were significantly lower in the restrictive as opposed to the liberal group, respectively. The 30-day mortality was slightly lower in the restrictive transfusion group

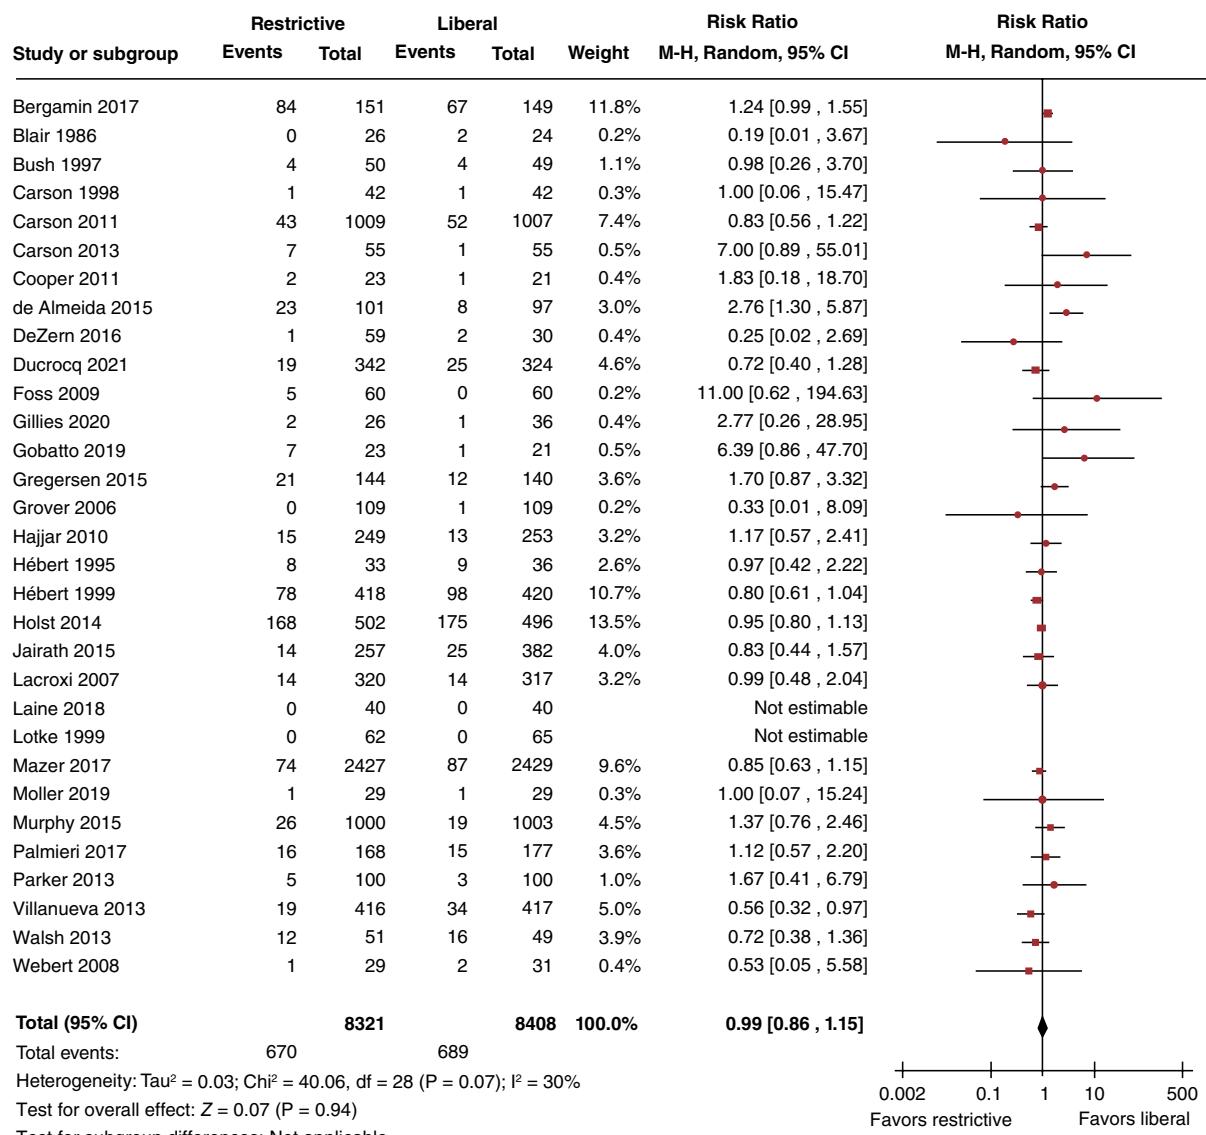

(18.7% vs. 23.3%), although the finding was not statistically significant ( $p = 0.11$ ). Mortality was lower in the restrictive transfusion group in patients less than 55 years of age ( $p < 0.02$ ) and less ill patients defined by APACHE II scores less than 20 ( $p < 0.02$ ). Furthermore, the restrictive transfusion group had fewer patients with myocardial infarction (0.07% vs. 2.9%;  $p = 0.02$ ) and congestive heart failure (5.3% vs. 10.7%;  $p < 0.01$ ).

Following the TRICC trial, there were ongoing concerns in the critical care community regarding the safety of a restrictive strategy in patients with septic shock. This is because disease processes such as overwhelming infections activate inflammatory processes that cause severe microcirculatory abnormalities, resulting in end-organ damage and ongoing oxygen debts as evidenced by high serum lactate concentrations. To address this issue, 1005 patients with septic shock and a hemoglobin level less than 9 g/dL were enrolled in a trial comparing a higher transfusion threshold (9 g/dL) to lower transfusion threshold (7 g/dL).<sup>139</sup> The median number of units transfused in the lower threshold group was 1, and in the higher transfusion group it was 4. Ninety-day mortality occurred in 43% of the lower transfusion group and 45.0% of the higher threshold group (relative risk, 0.94; 95% CI 0.78–1.09;  $p = 0.44$ ). There were no significant differences in secondary outcomes. Overall, ischemic events including myocardial infarctions and stroke, as well as circulatory overload, were not different between the study arms. Similarly, secondary outcomes related to end organ failure and organ support such as mechanical ventilation and renal replacement therapy were no different between groups.

Seven other studies contributed a total of 3529 patients included in trials conducted in critical care settings.<sup>101,113,121,124,127,130</sup> The overall relative risk comparing a restrictive to liberal transfusion strategy was 1.06, 95% CI 0.85–1.32.

### Cardiac surgery

Five transfusion trigger trials have been conducted involving 7869 cardiac surgical patients. This is a patient population where anemia and transfusions are very common, with unique clinical features that may affect the risk–benefit ratio of transfusions. Specifically, as described in the section on physiology, the cardiac muscle is supply dependent, that is, more than 70% of the oxygen delivered is consumed as compared to 30–40% in other tissues. Thus, factors that reduce blood flow (severe coronary artery disease) or oxygen delivery (transfusion restrictions) may adversely affect heart muscle. The largest trial evaluating transfusion thresholds in cardiac surgery enrolled 5243 patients who were randomly allocated to transfusion for a hemoglobin of <7.5 g/dL or <8.5 g/dL if on the non-ICU ward or <9.5 g/dL if in the operating room or ICU.<sup>126</sup> The primary outcome was a composite of death, nonfatal myocardial infarction, stroke, or renal failure with dialysis. This

**Figure 29.3** Effect of restrictive transfusion triggers on 30-day all-cause mortality. Summary of data from randomized clinical trials comparing effect of restrictive versus liberal transfusion strategies on mortality in adults (expressed as risk ratio). (Cochrane Database of Systematic Reviews 2021).

**Table 29.3** Morbidity Outcomes in Cochrane Meta-Analysis 2021

Outcome	Number of Studies	Number of Participants	Risk Ratio [95% Confidence Interval]
Myocardial infarction	23	14,370	1.04 [0.87 – 1.24]
Congestive heart failure	16	7247	0.83 [0.53 – 1.29]
Cerebral vascular accident	19	13,985	0.84 [0.64 – 1.09]
Rebleeding	8	3412	0.80 [0.59 – 1.09]
Infections	25	17,104	0.97 [0.88 – 1.07]
Thromboembolism	13	4201	1.11 [0.65 – 1.88]
Renal failure	15	12,531	1.03 [0.92 – 1.16]
Mental confusion	9	6442	1.11 [0.88 – 1.40]

composite outcome occurred in 12.3% of participants in the restrictive arm and 12.9% in the liberal arm (odds ratio 0.95; 95% CI -2.38 to -1.27). Mortality at 30 days was similar at 3.0% versus 3.6%. At six months, the primary composite outcome, mortality, and other secondary outcomes were also similar between the two arms of the trial.

A second influential trial, The Transfusion Indication Threshold Reduction (TITRe2) trial, enrolled 2007 patients undergoing cardiac surgery with hemoglobin concentration less than 9 g/dL. Participants were randomly allocated to a liberal transfusion threshold of 9 g/dL or a restrictive transfusion threshold of 7.5 g/dL.<sup>120</sup> The primary outcome was a composite of serious infection and ischemic events

(stroke, myocardial infarction, gut infarction, or acute kidney injury) within three months of enrollment in the trial. The primary outcome occurred in a similar number of patients in both groups. However, there were more deaths at 90 days in the restrictive group (4.2%) than the liberal group (2.6%) (hazard ratio = 1.64; 95% CI 1.00–2.67;  $p = 0.045$ ). At 30 days, the differences in mortality was small and nonsignificant (2.6% for the restrictive group vs. 1.9% for the liberal group). There were no differences in infectious events, sepsis, or wound infections.

Three other trials in cardiac patients found no differences in outcomes between groups. In a study of 428 patients undergoing CABG who were randomized to postoperative transfusion at a hemoglobin <8 g/dL versus <9 g/dL, there was no difference in morbidity, mortality, or self-assessment for fatigue or anemia between the two groups.<sup>125</sup> In a second trial of 502 cardiac surgery patients comparing patients transfused at hematocrit at 30% or 24%, there was no difference in composite end point of 30-day all-cause mortality, cardiogenic shock, acute respiratory distress syndrome, or acute renal injury requiring dialysis or hemofiltration.<sup>104</sup> Finally, a trial of 722 cardiac surgery patients found no differences in a composite end point of postoperative in-hospital morbidity and mortality between transfusion thresholds.<sup>97</sup>

From the four cardiac surgery trials involving 7441 participants, the 30-day mortality relative risk ratio was 0.99 (95% CI 0.74–1.33).<sup>138</sup>

### Orthopedic surgery

There have been eight trials that enrolled 3111 participants undergoing orthopedic surgery. Most of the trials enrolled patients undergoing repair of hip fracture; these patients have frequent comorbidity and are elderly. Transfusion Trigger Trial for Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair (FOCUS) enrolled 2016 patients undergoing surgical repair of hip fracture.<sup>105</sup> Patients had a history of cardiovascular disease (myocardial infarction, stroke or transient ischemic attack, congestive heart failure, or peripheral vascular disease) or cardiovascular risk factors (diabetes mellitus, hypertension, renal insufficiency, smoking, and hypercholesterolemia) and hemoglobin concentration less than 10 g/dL. The patients were randomly allocated to a liberal transfusion trigger where blood was administered to maintain the hemoglobin above 10 g/dL, or restrictive transfusions in which blood was administered when the hemoglobin concentration was less than 8 g/dL or for symptoms. The symptoms of anemia included chest pain thought to be cardiac in origin, congestive heart failure, or unexplained tachycardia or hypotension unresponsive to intravenous fluids. The primary outcome was inability to walk across the room without human assistance or death 60 days after randomization, which occurred in 35.2% in the liberal transfusion trigger and 34.7% in the restrictive transfusion trigger (odds ratio in the liberal transfusion trigger, 1.01; 95% CI 0.84–1.22). In-hospital acute coronary syndrome or death occurred in 4.3% in the liberal transfusion group and 5.2% in the restrictive transfusion group, respectively (absolute risk difference, 0.9%; 99% CI 3.3–1.6). Mortality was similar between the groups at 30 days, 60 days, and a median of 3.1 years. The causes of death were also similar. The frequencies of other complications, including delirium,<sup>140</sup> were similar in the two groups.

The other seven trials included another 1000 patients of the total 3111 participants.<sup>96,99,100,103,109,118,132</sup> The results of those trials were mostly consistent with the FOCUS trial. When the 30-day mortality results were combined in meta-analysis, the relative risk was 1.16,

95% CI 0.75–1.79. None of the trials found differences in activities of daily living or function.

### Upper gastrointestinal bleeding

This patient population often becomes anemic because of active bleeding from several potential causes. Bleeding may have resolved, may be ongoing, and may even become massive. We should also note that red cells transfusions may be accompanied by approaches to correct a coagulation disturbance and the use of blood conservation treatments such as tranexamic acid.

In terms of transfusion strategies, a total of 921 patients with severe upper gastrointestinal bleeding were enrolled in a trial comparing a liberal transfusion strategy (defined as a transfusion threshold of 9 g/dL) versus a restrictive transfusion threshold of 7 g/dL.<sup>112</sup> Patients were excluded if they had massive exsanguinating bleeding, acute coronary syndrome, symptomatic peripheral vascular disease, stroke or transient ischemic attack, high risk of further bleeding, recent history of trauma or surgery, and other less common reasons. All patients at the time of enrollment were transfused one unit of red blood cells. Survival at six weeks was higher in the restrictive transfusion group (95%) compared to the liberal transfusion group (91%; 0.55; 95% CI 0.33–0.92;  $p = 0.02$ ). Recurrent bleeding occurred more frequently in the liberal transfusion group (16%) than the restrictive transfusion group (10%) ( $p = 0.01$ ). In a subgroup of patients, portal pressures were higher in the liberal transfusion group than the restrictive transfusion group.

A multicenter cluster trial randomly allocated 936 patients with acute upper gastrointestinal bleeding to a restrictive or liberal threshold (8 g/dL vs. 10 g/dL) in six university hospitals.<sup>119</sup> Mean difference in hemoglobin levels was only 0.2 g/dL but fewer patients received transfusion in restrictive group (33%) compared to liberal group (46%). There were no differences in clinical outcomes; 28-day mortality occurred in 5% in restrictive threshold and 7% in liberal threshold, and rebleeding occurred in 5% in restrictive and 9% in liberal transfusion strategy. The other trial only included 50 patients.<sup>92</sup>

An important finding, which has not been found in other clinical settings, was that the 30-day mortality was significantly lower using the restrictive strategy compared with the liberal strategy (RR = 0.65; 95% CI 0.43–0.97) in the 1522 participants in GI bleeding trials.<sup>138</sup>

### Acute myocardial infarction

Much like patients undergoing coronary artery bypass grafting, patients who have an acute coronary syndrome may either require a higher transfusion threshold to overcome the acute ischemia caused by occluded coronary arteries or may be more susceptible to volume overload from red cells. Three trials enrolled patients with acute myocardial infarction. The REALITY trial randomly allocated 668 patients with acute MI and hemoglobin less than 10 g/dL to a restrictive transfusion trigger of <8 g/dL or liberal transfusions at ≤10 g/dL.<sup>137</sup> The primary clinical outcome of MACE (consisting of death, stroke, recurrent MI, or emergency revascularization) at 30 days occurred in 11.1% of participants in the restrictive group and 14.2% in the liberal group; relative risk 0.78; 95% CI 0.00–1.17. At one year, MACE occurred in 32.4% in restrictive threshold and 28.1% in liberal threshold (hazard ratio = 1.16; 95% CI 0.88–1.53).

In addition to REALITY, two smaller trials have been published in patients with acute MI and anemia. A pilot trial of 110 patients found that compared with transfusion for a hemoglobin <8 g/dL (restrictive strategy), transfusion to raise the hemoglobin ≥10 (liberal strategy) was associated with greater survival at 30 days (98% vs.

87%).<sup>42,108</sup> Another trial of 44 patients reported one death in the liberal transfusion group and two deaths in the restrictive strategy group.<sup>106</sup>

In aggregate, the 30-day mortality risk was higher in the restrictive strategy group than in the liberal strategy group (RR 1.61; 95% CI 0.38–6.88) although the confidence intervals are wide.<sup>138</sup> A 3500-patient trial called MINT is ongoing which will provide much needed data in this important group of patients.

### Oncology patients

There are several clinical settings in which oncology patients are frequently transfused with red cells. These include patients undergoing chemotherapy, stem cell transplantation, chronic anemia in patients with cancer, and surgery for cancer. One trial has been published in which cancer patients who underwent surgery were randomized to liberal versus restrictive transfusion triggers.<sup>124</sup> Three hundred patients undergoing abdominal surgery at a cancer hospital with septic shock and admitted to intensive care unit were randomly allocated to a 9 g/dL threshold (liberal) or a 7 g/dL threshold (restrictive). The primary outcome was 28-day all-cause mortality. Unexpectedly, the liberal transfusion group had superior outcomes to the restrictive transfusion group (liberal, 45%; restrictive, 56%;  $p = 0.08$ ). At 90 days' post-randomization, mortality was also lower in the liberal (59%) versus restrictive group (70%) (hazard ratio = 0.72; 95% CI 0.53–0.97).

Several trials have compared restrictive versus liberal transfusion thresholds in patients with hematological disorders. One trial enrolled patients undergoing autologous or allogeneic hematopoietic cell transplantation for any hematological malignancy.<sup>136</sup> There were no differences in the primary outcome of health-related quality of life. Three small trials evaluated transfusion in patients with leukemia and myelodysplasia but were not powered to examine clinical outcomes.<sup>102,122,135</sup>

### Children

Children have unique age-dependent adaptations to anemia. Similarly, very young children and those undergoing procedures such as cardiac surgery may also have different risk–benefit ratios for transfusion at different thresholds. As a consequence, investigators undertook several studies in this patient population. Of note, blood is frequently transfused in critically ill infants and children. In a recent survey, 14% of patients in pediatric ICUs received blood transfusion.<sup>141</sup> There have been five clinical trials evaluating liberal versus restrictive transfusion thresholds in this population. In one study, 100 hospitalized preterm infants with birthweights between 500 and 1300 g were randomly assigned to two transfusion levels.<sup>142</sup> The transfusion protocol adjusted the hematocrit level for transfusion based on the respiratory status of the infant. A primary outcome was not designated among the 15 clinical events evaluated. Infants in the restrictive group received a median of two units less than the liberal group during the study, and the mean difference in hemoglobin concentration was ~2 g/dL. There were no differences between the liberal and restrictive transfusion groups for most outcomes, including survival, patent ductus arteriosus, retinopathy, or bronchopulmonary dysplasia. Infants assigned to the restrictive group had more apneic events and more neurologic events (combined parenchymal brain hemorrhage or periventricular leukomalacia). These differences in outcomes should be interpreted as hypothesis-generating because the composite neurologic outcomes were not designated a priori,<sup>143</sup> apnea was assessed by an unblinded

nurse<sup>143</sup> and the differences were small, and the large number of outcomes increase the risk of false-positive results.

In the second study, 451 infants weighing less than 1000 g, whose gestational age was less than 31 weeks and who were less than 48 hours old, were randomly assigned to receive transfusion at either a low or high transfusion threshold.<sup>144</sup> The thresholds used varied by respiratory support using a prespecified transfusion algorithm. The primary composite outcome was in-hospital death, severe retinopathy, bronchopulmonary dysplasia, or brain injury on cranial ultrasound. The mean hemoglobin concentration was ~1 g/dL different between groups, and the number of RBC transfusions was not significantly different. There was no difference in the composite outcomes (low threshold [74.0%] vs. high threshold [69.7%]). This trial did not confirm the hypothesis that restrictive transfusion is associated with brain injury in preterm infants.

The largest study involved 637 children admitted to pediatric ICUs.<sup>101</sup> When a 7 g/dL threshold was compared to a 9.5 g/dL threshold, the mean hemoglobin concentration was ~2 g/dL lower in the restrictive group. RBC units were transfused to 46% of patients in the restrictive group and 98% in the liberal group. The frequency of new or progressive multiorgan dysfunction (primary outcome) was 12% in both groups, and there were no significant differences in any of the secondary outcomes including death, which occurred in 4% of both groups.

The fourth trial enrolled 107 children from six weeks to six years of age with noncyanotic congenital defects undergoing corrective cardiac surgery.<sup>145</sup> The patients were randomly allocated to either a liberal transfusion group with a hemoglobin threshold of less than 10.8 g/dL or restrictive transfusions for hemoglobin levels less than 8 g/dL. The length of stay was statistically significantly although only slightly shorter in the restrictive group (median = 8 [IQR 7–11] days) versus liberal group (median = 9 [IQR 7–14] days;  $p = 0.047$ ). There were no differences in other outcomes.

A fifth trial randomized children from sub-Saharan Africa with hemoglobin less than 6 g/dL and severity symptoms including respiratory distress or reduced consciousness to receive immediate transfusion of 20 or 30 mL/kg.<sup>146,147</sup> A total of 3196 children with median age of 37 months were enrolled. Malaria was the most common cause of anemia in 64.1% of participants. The primary outcome was 28-day mortality. Overall, there was no difference in the primary outcome of 28-day mortality between the low and higher doses of RBC transfusion (hazard ratio = 0.76; 95% CI 0.54–1.08). However, in a prespecified subgroup of febrile children with temperature greater than 37.5 °C, there was significant heterogeneity ( $p = 0.001$ ). In the children without fever, mortality was lower in the higher dose transfusion group (hazard ratio = 0.43; 95% CI 0.27–0.69). In the group with fever, mortality was elevated in those that received a higher transfusion dose (hazard ratio = 1.91; 95% CI 1.04–3.49).

### Transfusion guidelines

Since the National Institutes of Health Consensus Conference developed landmark guidelines for the transfusion of blood components in 1988,<sup>148</sup> many organizations have issued guidelines with the intent of aiding clinical decisions. The administration of RBCs is based on the balance of benefits, risks, and costs. Physicians making transfusion decisions are sometimes faced with massive amounts of conflicting information. Since 1983, concerns about the transmission of human immunodeficiency virus and other viruses through blood components have significantly modified both real and perceived risks and benefits. Many organizations responded by issuing clinical

practice guidelines advocating a more restrictive approach to the use of allogeneic RBC units and other components. In recent years, there have been additional guidelines that benefit from accumulating clinical trial evidence.

Although some of the specific recommendations varied among the guidelines, most of the recommendations were similar.<sup>149–159</sup> Based on results of the multiple trials and other evidence, all the guidelines published in the past few years recommended a 7 g/dL threshold in intensive care unit patients and often in other patient populations. Many guidelines suggested 8 g/dL threshold in patients with preexisting cardiac disease. Most of the guidelines also recommended that transfusion be guided by clinical judgment rather than hemoglobin level.

The AABB guideline recommendations (chaired by Dr. Carson) emphasized that the results of clinical trials should serve as the basis of all recommendations.<sup>160</sup> Further, the guidelines began with a good practice statement: “When deciding to transfuse an individual patient, it is good practice to consider not only the hemoglobin level, but the overall clinical context and alternative therapies to transfusion. Variables to take into consideration include the rate of decline in hemoglobin level, intravascular volume status, shortness of breath, exercise tolerance, light-headedness, chest pain thought to be cardiac in origin, hypotension or tachycardia unresponsive to fluid challenge, and patient preferences. This practice guideline is not intended as an absolute standard and will not apply to all individual transfusion decisions.” The recommendations were: (1) restrictive transfusion is not indicated until the hemoglobin level is 7 g/dL for hospitalized adult patients who are hemodynamically stable, including critically ill patients. (2) A restrictive RBC transfusion threshold of 8 g/dL is recommended for patients undergoing orthopedic surgery, cardiac surgery, and those with preexisting cardiovascular disease. (3) A restrictive transfusion threshold of 7 g/dL is likely comparable with 8 g/dL, but RCT evidence is not available for all patient categories. These recommendations do not apply to patients with acute coronary syndrome, severe thrombocytopenia (patients treated for hematological or oncological reasons who are at risk of bleeding), and chronic-transfusion-dependent anemia due to insufficient evidence.

Additional authoritative evidence-based recommendations for RBC transfusion were provided by the 2018 Frankfurt Consensus Conference,<sup>161</sup> including the use of the following hemoglobin thresholds: (1) <7 g/dL in critically ill but clinically stable intensive care patients, (2) <7.5 g/dL in patients undergoing cardiac surgery, (3) <8 g/dL in patients with hip fracture and cardiovascular disease or other risk factors, and (4) 7–8 g/dL in hemodynamically stable patients with acute gastrointestinal bleeding.

Clinical Practice Guidelines on Patient Blood Management in Cardiac surgery was published by the joint effort of STS/SCA/AmSECT/SABM.<sup>162</sup> These guidelines advise using a restrictive perioperative transfusion strategy to reduce the transfusion rate and units of allogeneic RBCs administered without adversely impacting mortality or morbidity.

## **Decision-making in red cell transfusion**

### **An approach to evaluating a bleeding patient**

In the care of a bleeding patient, the physician first must determine the degree of blood loss and the rate of bleeding. As part of the initial assessment, the healthcare team must rapidly address the patient's ABCs (airway, breathing, and circulation). Although blood loss usually leads to circulatory compromise, the severe

form, termed *hemorrhagic shock*, often leads to airway and breathing concerns as well due to altered mental status, metabolic (acid-base) derangement, and physiological stress. Once airway and breathing have been assessed and cleared, the assessment of the heart rate and blood pressure—in addition to a rapid scan of the scene and the patient—will reveal obvious threats such as dramatic blood loss. During the initial assessment, patients must be completely uncovered and rapidly examined to rule out rapidly bleeding wounds, obvious signs of massive bleeding such as a rapidly expanding abdomen in patients with a ruptured abdominal aortic aneurysm, or severe hematochezia in patients with severe lower gastrointestinal bleeding. In the trauma patient, significant blood loss can occur in the hemithorax, pelvis, retroperitoneum, or long bones.<sup>163</sup> The focus is on possible causes of bleeding and important comorbid conditions, such as cardiovascular disease that could exacerbate any injury. An emergency complete blood cell count, type and crossmatch, prothrombin time, and partial thromboplastin time should be obtained. From these data and the clinical examination, the source and rate of bleeding are estimated; note that in the exsanguinating patient, point measurement of the hemoglobin level may be falsely normal. A decision can be made about the rate of RBC unit transfusion as well as any curative and supportive measures. For patients with gastrointestinal bleeding, consultations may be requested from the gastroenterology and possibly surgery departments. In the care of patients with postoperative bleeding, measures such as angiography or exploratory surgery should be considered.

In patients with active bleeding, the hemodynamic status and need for emergency intervention must be determined. Crystalloid is administered to maintain intravascular volume only if RBC transfusion is unavailable or bleeding is relatively mild; otherwise, red cell transfusions are administered rapidly to maintain adequate oxygen-carrying capacity, sometimes in an emergent fashion with uncross-matched O-negative blood. Clinical judgment is needed to estimate how much more bleeding may occur and how much lower the hemoglobin level will likely decrease, and then to perform expectant transfusion. Vital signs are examined for a decrease in blood pressure and tachycardia. The patient is asked about symptoms that can result from anemia, including cardiac ischemia (chest pain), congestive heart failure (dyspnea, paroxysmal nocturnal dyspnea, and edema), fatigue, dizziness, weakness, and orthostatic hypotension unresponsive to intravenous fluids. The hemoglobin level is measured at regular intervals.

It is important to determine the presence of coronary artery disease because results of studies with animals and with human subjects suggest that patients with coronary artery disease may be less tolerant of anemia. Review of the medical history for angina, myocardial infarction, and CABG surgery is essential. The electrocardiogram is examined for evidence of old myocardial infarction or ischemic changes. The chest radiograph is examined for cardiomegaly and other changes consistent with congestive heart failure. Patients with a history of peripheral or cerebral vascular disease are more likely also to have asymptomatic coronary artery disease.

In the care of patients with moderate to severe blood loss that has abated, there is more time for complete assessment of the source of bleeding, development of a course of management, and thorough evaluation of the patient. After bleeding has stopped and equilibration has occurred, the hemoglobin level stabilizes and the nadir hemoglobin level can be determined. Then, transfusion decisions can be made accordingly.

## Surgical patient

Patients undergoing major surgical intervention often experience hemodynamic instability and frequently require RBC unit transfusion as a consequence of considerable blood loss. Various aspects of transfusion management for surgical patients are discussed in Chapters 39 and 40.

## Chronic anemia

In chronic anemia, there is time for compensation to develop and for careful observation of the patient. Anemia is associated with an increase in blood flow resulting from decreased viscosity, greater release of oxygen caused by higher levels of 2,3-DPG, and an increase in cardiac output. There is time to determine whether these physiologic events are clinically important in the individual patient and carefully determine whether the patient has symptoms. Besides cardiac symptoms (angina and dyspnea), anemia can lead to nonspecific symptoms, such as fatigue, weakness, dizziness, reduced exercise tolerance, and impaired performance of activities of daily living. Two small pilot trials in patients with myelodysplastic syndrome were focused on function.<sup>133,135</sup> There also may be time to implement alternative treatments to correct anemia, depending on the cause. Iron, vitamin B<sub>12</sub>, and folate can be replaced. Erythropoietin can be administered. It is important to correct preoperative anemia because the hemoglobin level strongly correlates with the probability of transfusion.<sup>164</sup>

## Transfusion threshold

Recent clinical trials have assessed the optimal threshold for transfusion, and there are reliable data for many clinical settings. A 7 g/dL threshold should be used in critical care patients because multiple trials have confirmed that it is safe to withhold blood until the hemoglobin level decreases to less than this level (see the critical care summary above). A 7 g/dL threshold should also be used in patients with acute gastrointestinal bleeding because trials found a lower mortality than patients transfused at 9 g/dL.<sup>112</sup> However, it can be difficult to anticipate how low the hemoglobin level might fall in rapidly bleeding patients. Thus, blood pressure and pulse along with clinical judgment must be strongly considered in an actively bleeding patient. In postoperative cardiac surgical patients, a 7.5 g/dL threshold should be used<sup>126</sup> (see the cardiac surgery summary), while an 8 g/dL threshold is appropriate in orthopedic surgery<sup>105</sup> (see the orthopedic surgery summary) as it has been proven to be as safe as a 10 g/dL threshold. The weight of the evidence suggests asymptomatic patients with preexisting cardiovascular disease safely tolerate an 8 g/dL threshold. However, it is unclear what transfusion threshold is appropriate for patients with acute coronary syndrome as the trials have not excluded a clinically significant benefit with liberal transfusion to 10 g/dL (see the summary of acute MI above). At this time, we have no specific recommendation in this group of patients, and it is necessary to rely on clinical judgment. Patients with symptoms of anemia should be transfused as needed. No set of guidelines applies to every patient. In the end, careful clinical assessment of each patient with thoughtful consideration of risks and benefits should guide the transfusion decision.

## Dose and administration

In patients who experience acute blood loss, the rate of administration of RBCs is guided by the rate of bleeding and hemodynamic compromise. In the treatment of rapidly bleeding patients, RBCs should be given at the rate necessary to maintain oxygen transport while definitive therapy is instituted. Rates may range from 5 to 10 units over 10–15 minutes in patients who are exsanguinating to rates

in the range of one unit every 2–4 hours (1 mL/kg/hour) in patients with severe left ventricular dysfunction. When blood loss is predictable and not massive, RBC units should generally be administered one at a time. In the care of patients with chronic anemia, enough blood should be given to control symptoms. In most adult patients, 1 RBC unit increases the hemoglobin level approximately 1 g/dL and hematocrit approximately 3%. Ordinarily, 1 RBC unit is given over 1–2 hours. After transfusion of each RBC unit, the measurement of the hemoglobin level is repeated, and the patient reassessed.

## Future

During the next decade, advances and risks may dramatically alter transfusion practice. Research is underway to develop safer red cell components. Further clinical trials should be performed to better describe the clinical effect of different transfusion strategies. Trials are especially needed in patients with acute coronary syndrome, neurological disorders, and acute and chronic hematological disorders. It is possible that within the next one or two decades a cost-effective oxygen carrier will be developed that will reduce the use of allogeneic RBC units.

## Summary

Red cell transfusion is an extremely common intervention in modern medical care. Blood is administered to improve oxygen delivery, but the connection between systemic hematocrit and the microcirculation is not linear. Patients compensate for anemia through increased cardiac output, through redistribution of blood flow to the cardiac and cerebral circulation, and through microvascular regulation of capillary RBC flow. Particular attention must be paid to maintaining adequate oxygen delivery to the heart. The preponderance of evidence suggests that a hemoglobin level of 7–8 g/dL is a safe threshold for red cell transfusion. For patients with acute cardiovascular disease, a higher transfusion threshold should be considered. RBC units should usually be administered one at a time, and the patient and hemoglobin level should be reassessed after each transfusion. Transfusion decisions should also consider the rate of bleeding, the presence of underlying medical problems, the hemodynamic status of the patient, the presence of symptoms, and whether anemia is acute or chronic. Further evidence in the support of a transfusion strategy is required in patients with acute brain injury and coronary ischemia as well as whether transfusion improves subjective symptoms in chronic complex diseases.
